- `-X no_debug_ranges` disables the inclusion of the tables mapping extra location information (end line, start column offset and end column offset) to every instruction in code objects. This is useful when smaller code objects and pyc files are desired as well as suppressing the extra visual location indicators when the interpreter displays tracebacks. See also **PYTHONNODEBUGRANGES**.
- `-X frozen_modules` determines whether or not frozen modules are ignored by the import machinery. A value of "on" means they get imported and "off" means they are ignored. The default is "on" if this is an installed Python (the normal case). If it's under development (running from the source tree) then the default is "off". Note that the "importlib_bootstrap" and "importlib_bootstrap_external" frozen modules are always used, even if this flag is set to "off".

It also allows passing arbitrary values and retrieving them through the **sys._xoptions** dictionary.

Changed in version 3.2: The **-X** option was added.

New in version 3.3: The `-X faulthandler` option.

New in version 3.4: The `-X showrefcount` and `-X tracemalloc` options.

New in version 3.6: The `-X showalloccount` option.

New in version 3.7: The `-X importtime`, `-X dev` and `-X utf8` options.

New in version 3.8: The `-X pycache_prefix` option. The `-X dev` option now logs `close()` exceptions in **`io.IOBase`** destructor.

Changed in version 3.9: Using `-X dev` option, check *encoding* and *errors* arguments on string encoding and decoding operations.

The `-X showalloccount` option has been removed.

New in version 3.10: The `-X warn_default_encoding` option.

Deprecated since version 3.9, removed in version 3.10: The `-X oldparser` option.

New in version 3.11: The `-X no_debug_ranges` option.

New in version 3.11: The `-X frozen_modules` option.

New in version 3.11: The `-X int_max_str_digits` option.

1.1.4. Options you shouldn't use

-J

Reserved for use by Jython [https://www.jython.org/].

1.2. Environment variables

These environment variables influence Python's behavior, they are processed before the command-line switches other than -E or -I. It is customary that command-line switches override environmental variables where there is a conflict.

PYTHONHOME

Change the location of the standard Python libraries. By default, the libraries are searched in *`prefix`*`/lib/`

`python`*`version`* and *`exec_prefix`*`/lib/python`*`version`*, where *`prefix`* and *`exec_prefix`* are installation-dependent directories, both defaulting to `/usr/local`.

When **`PYTHONHOME`** is set to a single directory, its value replaces both *`prefix`* and *`exec_prefix`*. To specify different values for these, set **`PYTHONHOME`** to *`prefix`*`:`*`exec_prefix`*.

PYTHONPATH

Augment the default search path for module files. The format is the same as the shell's **`PATH`**: one or more directory pathnames separated by **`os.pathsep`** (e.g. colons on Unix or semicolons on Windows). Non-existent directories are silently ignored.

In addition to normal directories, individual **`PYTHONPATH`** entries may refer to zipfiles containing pure Python modules (in either source or compiled form). Extension modules cannot be imported from zipfiles.

The default search path is installation dependent, but generally begins with *`prefix`*`/lib/python`*`version`* (see **`PYTHONHOME`** above). It is *always* appended to **`PYTHONPATH`**.

An additional directory will be inserted in the search path in front of **`PYTHONPATH`** as described above under Interface options. The search path can be manipulated from within a Python program as the variable **`sys.path`**.

PYTHONSAFEPATH

If this is set to a non-empty string, don't prepend a potentially unsafe path to **`sys.path`**: see the **`-P`** option for details.

New in version 3.11.

PYTHONPLATLIBDIR

If this is set to a non-empty string, it overrides the **`sys.platlibdir`** value.

New in version 3.9.

PYTHONSTARTUP

If this is the name of a readable file, the Python commands in that file are executed before the first prompt is displayed in interactive mode. The file is executed in the same namespace where interactive commands are executed so that objects defined or imported in it can be used without qualification in the interactive session. You can also change the prompts **sys.ps1** and **sys.ps2** and the hook **sys.__interactivehook__** in this file.

Raises an auditing event `cpython.run_startup` with the filename as the argument when called on startup.

PYTHONOPTIMIZE

If this is set to a non-empty string it is equivalent to specifying the **-O** option. If set to an integer, it is equivalent to specifying **-O** multiple times.

PYTHONBREAKPOINT

If this is set, it names a callable using dotted-path notation. The module containing the callable will be imported and then the callable will be run by the default implementation of **sys.breakpointhook()** which itself is called by built-in **breakpoint()**. If not set, or set to the empty string, it is equivalent to the value “pdb.set_trace”. Setting this to the string “0” causes the default implementation of **sys.breakpointhook()** to do nothing but return immediately.

New in version 3.7.

PYTHONDEBUG

If this is set to a non-empty string it is equivalent to specifying the **-d** option. If set to an integer, it is equivalent to specifying **-d** multiple times.

PYTHONINSPECT

If this is set to a non-empty string it is equivalent to specifying the **-i** option.

This variable can also be modified by Python code using **os.environ** to force inspect mode on program termination.

PYTHONUNBUFFERED

If this is set to a non-empty string it is equivalent to specifying the **-u** option.

PYTHONVERBOSE

If this is set to a non-empty string it is equivalent to specifying the **-v** option. If set to an integer, it is equivalent to specifying **-v** multiple times.

PYTHONCASEOK

If this is set, Python ignores case in **import** statements. This only works on Windows and macOS.

PYTHONDONTWRITEBYTECODE

If this is set to a non-empty string, Python won't try to write `.pyc` files on the import of source modules. This is equivalent to specifying the **-B** option.

PYTHONPYCACHEPREFIX

If this is set, Python will write `.pyc` files in a mirror directory tree at this path, instead of in `__pycache__` directories within the source tree. This is equivalent to specifying the **-X** `pycache_prefix=PATH` option.

New in version 3.8.

PYTHONHASHSEED

If this variable is not set or set to `random`, a random value is used to seed the hashes of str and bytes objects.

If **PYTHONHASHSEED** is set to an integer value, it is used as a

fixed seed for generating the hash() of the types covered by the hash randomization.

Its purpose is to allow repeatable hashing, such as for selftests for the interpreter itself, or to allow a cluster of python processes to share hash values.

The integer must be a decimal number in the range [0,4294967295]. Specifying the value 0 will disable hash randomization.

New in version 3.2.3.

PYTHONINTMAXSTRDIGITS

If this variable is set to an integer, it is used to configure the interpreter's global integer string conversion length limitation.

New in version 3.11.

PYTHONIOENCODING

If this is set before running the interpreter, it overrides the encoding used for stdin/stdout/stderr, in the syntax `encodingname:errorhandler`. Both the `encodingname` and the `:errorhandler` parts are optional and have the same meaning as in **`str.encode()`**.

For stderr, the `:errorhandler` part is ignored; the handler will always be `'backslashreplace'`.

Changed in version 3.4: The `encodingname` part is now optional.

Changed in version 3.6: On Windows, the encoding specified by this variable is ignored for interactive console buffers unless **`PYTHONLEGACYWINDOWSSTDIO`** is also specified. Files and pipes redirected through the standard streams are not affected.

PYTHONNOUSERSITE

If this is set, Python won't add the **user site-packages directory** to **sys.path**.

See also

PEP 370 [https://peps.python.org/pep-0370/] – Per user site-packages directory

PYTHONUSERBASE

Defines the **user base directory**, which is used to compute the path of the **user site-packages directory** and Distutils installation paths for `python setup.py install --user`.

See also

PEP 370 [https://peps.python.org/pep-0370/] – Per user site-packages directory

PYTHONEXECUTABLE

If this environment variable is set, `sys.argv[0]` will be set to its value instead of the value got through the C runtime. Only works on macOS.

PYTHONWARNINGS

This is equivalent to the **-W** option. If set to a comma separated string, it is equivalent to specifying **-W** multiple times, with filters later in the list taking precedence over those earlier in the list.

The simplest settings apply a particular action unconditionally to all warnings emitted by a process (even those that are otherwise ignored by default):

```
PYTHONWARNINGS=default  # Warn once per call locati
PYTHONWARNINGS=error    # Convert to exceptions
PYTHONWARNINGS=always   # Warn every time
```

```
PYTHONWARNINGS=module    # Warn once per calling mod
PYTHONWARNINGS=once      # Warn once per Python proc
PYTHONWARNINGS=ignore    # Never warn
```

See The Warnings Filter and Describing Warning Filters for more details.

PYTHONFAULTHANDLER

If this environment variable is set to a non-empty string, **`faulthandler.enable()`** is called at startup: install a handler for **`SIGSEGV`**, **`SIGFPE`**, **`SIGABRT`**, **`SIGBUS`** and **`SIGILL`** signals to dump the Python traceback. This is equivalent to **`-X`** `faulthandler` option.

New in version 3.3.

PYTHONTRACEMALLOC

If this environment variable is set to a non-empty string, start tracing Python memory allocations using the **`tracemalloc`** module. The value of the variable is the maximum number of frames stored in a traceback of a trace. For example, `PYTHONTRACEMALLOC=1` stores only the most recent frame. See the **`tracemalloc.start()`** for more information.

New in version 3.4.

PYTHONPROFILEIMPORTTIME

If this environment variable is set to a non-empty string, Python will show how long each import takes. This is exactly equivalent to setting `-X importtime` on the command line.

New in version 3.7.

PYTHONASYNCIODEBUG

If this environment variable is set to a non-empty string, enable the debug mode of the **`asyncio`** module.

New in version 3.4.

PYTHONMALLOC

Set the Python memory allocators and/or install debug hooks.

Set the family of memory allocators used by Python:

- `default`: use the default memory allocators.
- `malloc`: use the **`malloc()`** function of the C library for all domains (**`PYMEM_DOMAIN_RAW`**, **`PYMEM_DOMAIN_MEM`**, **`PYMEM_DOMAIN_OBJ`**).
- `pymalloc`: use the pymalloc allocator for **`PYMEM_DOMAIN_MEM`** and **`PYMEM_DOMAIN_OBJ`** domains and use the **`malloc()`** function for the **`PYMEM_DOMAIN_RAW`** domain.

Install debug hooks:

- `debug`: install debug hooks on top of the default memory allocators.
- `malloc_debug`: same as `malloc` but also install debug hooks.
- `pymalloc_debug`: same as `pymalloc` but also install debug hooks.

Changed in version 3.7: Added the `"default"` allocator.

New in version 3.6.

PYTHONMALLOCSTATS

If set to a non-empty string, Python will print statistics of the pymalloc memory allocator every time a new pymalloc object arena is created, and on shutdown.

This variable is ignored if the **`PYTHONMALLOC`** environment variable is used to force the **`malloc()`** allocator of the C library, or if Python is configured without `pymalloc` support.

Changed in version 3.6: This variable can now also be used on Python compiled in release mode. It now has no effect if set to an empty string.

PYTHONLEGACYWINDOWSFSENCODING

If set to a non-empty string, the default filesystem encoding and error handler mode will revert to their pre-3.6 values of 'mbcs' and 'replace', respectively. Otherwise, the new defaults 'utf-8' and 'surrogatepass' are used.

This may also be enabled at runtime with **sys._enablelegacywindowsfsencoding()**.

Availability: Windows.

New in version 3.6: See **PEP 529** [https://peps.python.org/pep-0529/] for more details.

PYTHONLEGACYWINDOWSSTDIO

If set to a non-empty string, does not use the new console reader and writer. This means that Unicode characters will be encoded according to the active console code page, rather than using utf-8.

This variable is ignored if the standard streams are redirected (to files or pipes) rather than referring to console buffers.

Availability: Windows.

New in version 3.6.

PYTHONCOERCECLOCALE

If set to the value `0`, causes the main Python command line application to skip coercing the legacy ASCII-based C and POSIX locales to a more capable UTF-8 based alternative.

If this variable is *not* set (or is set to a value other than `0`), the `LC_ALL` locale override environment variable is also not set, and the current locale reported for the `LC_CTYPE` category is either the default `C` locale, or else the explicitly ASCII-based `POSIX` locale, then the Python CLI will attempt to configure the following locales for the `LC_CTYPE` category in the order listed before loading the interpreter runtime:

- `C.UTF-8`
- `C.utf8`
- `UTF-8`

If setting one of these locale categories succeeds, then the `LC_CTYPE` environment variable will also be set accordingly in the current process environment before the Python runtime is initialized. This ensures that in addition to being seen by both the interpreter itself and other locale-aware components running in the same process (such as the GNU `readline` library), the updated setting is also seen in subprocesses (regardless of whether or not those processes are running a Python interpreter), as well as in operations that query the environment rather than the current C locale (such as Python's own **`locale.getdefaultlocale()`**).

Configuring one of these locales (either explicitly or via the above implicit locale coercion) automatically enables the `surrogateescape` error handler for **`sys.stdin`** and **`sys.stdout`** (**`sys.stderr`** continues to use `backslashreplace` as it does in any other locale). This stream handling behavior can be overridden using **`PYTHONIOENCODING`** as usual.

For debugging purposes, setting `PYTHONCOERCECLOCALE=warn` will cause Python to emit warning messages on `stderr` if either the locale coercion activates, or else if a locale that *would* have triggered coercion is still active when the Python runtime is initialized.

Also note that even when locale coercion is disabled, or when it fails to find a suitable target locale, **`PYTHONUTF8`** will still activate by default in legacy ASCII-based locales. Both features must be disabled in order to force the interpreter to use `ASCII` instead of `UTF-8` for system interfaces.

Availability: Unix.

New in version 3.7: See **PEP 538** [https://peps.python.org/pep-0538/] for more details.

PYTHONDEVMODE

If this environment variable is set to a non-empty string, enable Python Development Mode, introducing additional runtime checks that are too expensive to be enabled by default.

New in version 3.7.

PYTHONUTF8

If set to `1`, enable the Python UTF-8 Mode.

If set to `0`, disable the Python UTF-8 Mode.

Setting any other non-empty string causes an error during interpreter initialisation.

New in version 3.7.

PYTHONWARNDEFAULTENCODING

If this environment variable is set to a non-empty string, issue a **`EncodingWarning`** when the locale-specific default encoding is used.

See Opt-in EncodingWarning for details.

New in version 3.10.

PYTHONNODEBUGRANGES

If this variable is set, it disables the inclusion of the tables mapping extra location information (end line, start column offset and end column offset) to every instruction in code objects. This is useful when smaller code objects and pyc files are desired as well as suppressing the extra visual location indicators when the interpreter displays tracebacks.

New in version 3.11.

1.2.1. Debug-mode variables

PYTHONTHREADDEBUG

If set, Python will print threading debug info into stdout.

Need a debug build of Python.

Deprecated since version 3.10, will be removed in version 3.12.

PYTHONDUMPREFS

If set, Python will dump objects and reference counts still alive after shutting down the interpreter.

Need Python configured with the **--with-trace-refs** build option.

PYTHONDUMPREFSFILE=FILENAME

If set, Python will dump objects and reference counts still alive after shutting down the interpreter into a file called *FILENAME*.

Need Python configured with the **--with-trace-refs** build option.

New in version 3.11.

2. Using Python on Unix platforms

2.1. Getting and installing the latest version of Python

2.1.1. On Linux

Python comes preinstalled on most Linux distributions, and is available as a package on all others. However there are certain features you might want to use that are not available on your distro's package. You can easily compile the latest version of Python from source.

In the event that Python doesn't come preinstalled and isn't in the repositories as well, you can easily make packages for your own distro. Have a look at the following links:

See also

https://www.debian.org/doc/manuals/maint-guide/first.en.html
for Debian users

https://en.opensuse.org/Portal:Packaging
for OpenSuse users

https://docs-old.fedoraproject.org/en-US/Fedora_Draft_Documentation/0.1/html/RPM_Guide/ch-creating-rpms.html
for Fedora users

http://www.slackbook.org/html/package-management-making-packages.html

for Slackware users

2.1.2. On FreeBSD and OpenBSD

- FreeBSD users, to add the package use:

  ```
  pkg install python3
  ```

- OpenBSD users, to add the package use:

  ```
  pkg_add -r python

  pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packa
  ```

  For example i386 users get the 2.5.1 version of Python using:

  ```
  pkg_add ftp://ftp.openbsd.org/pub/OpenBSD/4.2/packa
  ```

2.1.3. On OpenSolaris

You can get Python from OpenCSW [https://www.opencsw.org/]. Various versions of Python are available and can be installed with e.g. `pkgutil -i python27`.

2.2. Building Python

If you want to compile CPython yourself, first thing you should do is get the source [https://www.python.org/downloads/source/]. You can download either the latest release's source or just grab a fresh clone [https://devguide.python.org/setup/#get-the-source-code]. (If you want to contribute patches, you will need a clone.)

The build process consists of the usual commands:

```
./configure
make
make install
```

Configuration options and caveats for specific Unix platforms are extensively documented in the README.rst [https://github.com/python/

cpython/tree/3.11/README.rst] file in the root of the Python source tree.

Warning

`make install` can overwrite or masquerade the `python3` binary. `make altinstall` is therefore recommended instead of `make install` since it only installs *`exec_prefix`*`/bin/python`*`version`*.

2.3. Python-related paths and files

These are subject to difference depending on local installation conventions; **`prefix`** (`${prefix}`) and **`exec_prefix`** (`${exec_prefix}`) are installation-dependent and should be interpreted as for GNU software; they may be the same.

For example, on most Linux systems, the default for both is `/usr`.

Meaning	Value
Recommended location of the interpreter.	*`exec_prefix`*`/bin/python3`
Recommended locations of the directories containing the standard modules.	*`prefix`*`/lib/python`*`3.11`* and *`exec_prefix`*`/lib/python`*`3.11`*
Recommended locations of the directories containing the include files needed for developing Python extensions and embedding the interpreter.	*`prefix`*`/include/python`*`3.11`* and *`exec_prefix`*`/include/python`*`3.11`*

2.4. Miscellaneous

To easily use Python scripts on Unix, you need to make them executable, e.g. with

```
$ chmod +x script
```

and put an appropriate Shebang line at the top of the script. A good choice is usually

```
#!/usr/bin/env python3
```

which searches for the Python interpreter in the whole **`PATH`**.

However, some Unices may not have the **env** command, so you may need to hardcode `/usr/bin/python3` as the interpreter path.

To use shell commands in your Python scripts, look at the **`subprocess`** module.

2.5. Custom OpenSSL

1. To use your vendor's OpenSSL configuration and system trust store, locate the directory with `openssl.cnf` file or symlink in `/etc`. On most distribution the file is either in `/etc/ssl` or `/etc/pki/tls`. The directory should also contain a `cert.pem` file and/or a `certs` directory.

   ```
   $ find /etc/ -name openssl.cnf -printf "%h\n"
   /etc/ssl
   ```

2. Download, build, and install OpenSSL. Make sure you use `install_sw` and not `install`. The `install_sw` target does not override `openssl.cnf`.

   ```
   $ curl -O https://www.openssl.org/source/openssl-VE
   $ tar xzf openssl-VERSION
   $ pushd openssl-VERSION
   $ ./config \
       --prefix=/usr/local/custom-openssl \
       --libdir=lib \
       --openssldir=/etc/ssl
   $ make -j1 depend
   $ make -j8
   $ make install_sw
   $ popd
   ```

3. Build Python with custom OpenSSL (see the configure `--with-openssl` and `--with-openssl-rpath` options)

   ```
   $ pushd python-3.x.x
   $ ./configure -C \
       --with-openssl=/usr/local/custom-openssl \
       --with-openssl-rpath=auto \
   ```

```
    --prefix=/usr/local/python-3.x.x
$ make -j8
$ make altinstall
```

Note

Patch releases of OpenSSL have a backwards compatible ABI. You don't need to recompile Python to update OpenSSL. It's sufficient to replace the custom OpenSSL installation with a newer version.

3. Configure Python

3.1. Configure Options

List all `./configure` script options using:

```
./configure --help
```

See also the `Misc/SpecialBuilds.txt` in the Python source distribution.

3.1.1. General Options

--enable-loadable-sqlite-extensions

Support loadable extensions in the **`_sqlite`** extension module (default is no).

See the **`sqlite3.Connection.enable_load_extension()`** method of the **`sqlite3`** module.

New in version 3.6.

--disable-ipv6

Disable IPv6 support (enabled by default if supported), see the **`socket`** module.

--enable-big-digits=[15|30]

Define the size in bits of Python **`int`** digits: 15 or 30 bits.

By default, the digit size is 30.

Define the `PYLONG_BITS_IN_DIGIT` to `15` or `30`.

See **`sys.int_info.bits_per_digit`**.

--with-cxx-main

--with-cxx-main=COMPILER

Compile the Python `main()` function and link Python executable with C++ compiler: `$CXX`, or *COMPILER* if specified.

--with-suffix=SUFFIX

Set the Python executable suffix to *SUFFIX*.

The default suffix is `.exe` on Windows and macOS (`python.exe` executable), `.js` on Emscripten node, `.html` on Emscripten browser, `.wasm` on WASI, and an empty string on other platforms (`python` executable).

Changed in version 3.11: The default suffix on WASM platform is one of `.js`, `.html` or `.wasm`.

--with-tzpath=<list of absolute paths separated by pathsep>

Select the default time zone search path for **`zoneinfo.TZPATH`**. See the Compile-time configuration of the **`zoneinfo`** module.

Default: `/usr/share/zoneinfo:/usr/lib/zoneinfo:/usr/share/lib/zoneinfo:/etc/zoneinfo`.

See **`os.pathsep`** path separator.

New in version 3.9.

--without-decimal-contextvar

Build the `_decimal` extension module using a thread-local context rather than a coroutine-local context (default), see the **`decimal`** module.

See **`decimal.HAVE_CONTEXTVAR`** and the **`contextvars`** module.

New in version 3.9.

--with-dbmliborder=<list of backend names>

Override order to check db backends for the **dbm** module

A valid value is a colon (`:`) separated string with the backend names:

- `ndbm`;
- `gdbm`;
- `bdb`.

--without-c-locale-coercion

Disable C locale coercion to a UTF-8 based locale (enabled by default).

Don't define the `PY_COERCE_C_LOCALE` macro.

See **PYTHONCOERCECLOCALE** and the **PEP 538** [https://peps.python.org/pep-0538/].

--with-platlibdir=DIRNAME

Python library directory name (default is `lib`).

Fedora and SuSE use `lib64` on 64-bit platforms.

See **sys.platlibdir**.

New in version 3.9.

--with-wheel-pkg-dir=PATH

Directory of wheel packages used by the **ensurepip** module (none by default).

Some Linux distribution packaging policies recommend against bundling dependencies. For example, Fedora installs wheel packages in the `/usr/share/python-wheels/` directory and don't install the **ensurepip._bundled** package.

New in version 3.10.

--with-pkg-config = [check|yes|no]

Whether configure should use **pkg-config** to detect build dependencies.

- `check` (default): **pkg-config** is optional
- `yes`: **pkg-config** is mandatory
- `no`: configure does not use **pkg-config** even when present

New in version 3.11.

--enable-pystats

Turn on internal statistics gathering.

The statistics will be dumped to a arbitrary (probably unique) file in `/tmp/py_stats/`, or `C:\temp\py_stats\` on Windows.

Use `Tools/scripts/summarize_stats.py` to read the stats.

New in version 3.11.

3.1.2. WebAssembly Options

--with-emscripten-target = [browser|node]

Set build flavor for `wasm32-emscripten`.

- `browser` (default): preload minimal stdlib, default MEMFS.
- `node`: NODERAWFS and pthread support.

New in version 3.11.

--enable-wasm-dynamic-linking

Turn on dynamic linking support for WASM.

Dynamic linking enables `dlopen`. File size of the executable increases due to limited dead code elimination and additional features.

New in version 3.11.

--enable-wasm-pthreads

Turn on pthreads support for WASM.

New in version 3.11.

3.1.3. Install Options

--disable-test-modules

Don't build nor install test modules, like the **test** package or the **_testcapi** extension module (built and installed by default).

New in version 3.10.

--with-ensurepip=[upgrade|install|no]

Select the **ensurepip** command run on Python installation:

- `upgrade` (default): run `python -m ensurepip --altinstall --upgrade` command.
- `install`: run `python -m ensurepip --altinstall` command;
- `no`: don't run ensurepip;

New in version 3.6.

3.1.4. Performance options

Configuring Python using `--enable-optimizations --with-lto` (PGO + LTO) is recommended for best performance.

--enable-optimizations

Enable Profile Guided Optimization (PGO) using **PROFILE_TASK** (disabled by default).

The C compiler Clang requires `llvm-profdata` program for PGO. On macOS, GCC also requires it: GCC is just an alias to Clang on macOS.

Disable also semantic interposition in libpython if `--enable-shared` and GCC is used: add `-fno-semantic-interposition` to the compiler and linker flags.

New in version 3.6.

Changed in version 3.10: Use `-fno-semantic-interposition` on GCC.

PROFILE_TASK

Environment variable used in the Makefile: Python command line arguments for the PGO generation task.

Default: `-m test --pgo --timeout=$(TESTTIMEOUT)`.

New in version 3.8.

--with-lto=[full|thin|no|yes]

Enable Link Time Optimization (LTO) in any build (disabled by default).

The C compiler Clang requires `llvm-ar` for LTO (`ar` on macOS), as well as an LTO-aware linker (`ld.gold` or `lld`).

New in version 3.6.

New in version 3.11: To use ThinLTO feature, use `--with-lto=thin` on Clang.

--with-computed-gotos

Enable computed gotos in evaluation loop (enabled by default on supported compilers).

--without-pymalloc

Disable the specialized Python memory allocator pymalloc (enabled by default).

See also **`PYTHONMALLOC`** environment variable.

--without-doc-strings

Disable static documentation strings to reduce the memory footprint (enabled by default). Documentation strings defined in Python are not affected.

Don't define the `WITH_DOC_STRINGS` macro.

See the `PyDoc_STRVAR()` macro.

--enable-profiling

Enable C-level code profiling with `gprof` (disabled by default).

3.1.5. Python Debug Build

A debug build is Python built with the **`--with-pydebug`** configure option.

Effects of a debug build:

- Display all warnings by default: the list of default warning filters is empty in the **`warnings`** module.
- Add `d` to **`sys.abiflags`**.
- Add **`sys.gettotalrefcount()`** function.
- Add **`-X showrefcount`** command line option.
- Add **`PYTHONTHREADDEBUG`** environment variable.
- Add support for the `__lltrace__` variable: enable low-level tracing in the bytecode evaluation loop if the variable is defined.
- Install debug hooks on memory allocators to detect buffer overflow and other memory errors.
- Define `Py_DEBUG` and `Py_REF_DEBUG` macros.
- Add runtime checks: code surrounded by `#ifdef Py_DEBUG` and `#endif`. Enable `assert(...)` and `_PyObject_ASSERT(...)` assertions: don't set the `NDEBUG` macro (see also the **`--with-assertions`** configure option). Main runtime checks:
  - Add sanity checks on the function arguments.
  - Unicode and int objects are created with their memory filled with a pattern to detect usage of uninitialized objects.

- Ensure that functions which can clear or replace the current exception are not called with an exception raised.
- Check that deallocator functions don't change the current exception.
- The garbage collector (**`gc.collect()`** function) runs some basic checks on objects consistency.
- The **`Py_SAFE_DOWNCAST()`** macro checks for integer underflow and overflow when downcasting from wide types to narrow types.

See also the Python Development Mode and the **`--with-trace-refs`** configure option.

Changed in version 3.8: Release builds and debug builds are now ABI compatible: defining the `Py_DEBUG` macro no longer implies the `Py_TRACE_REFS` macro (see the **`--with-trace-refs`** option), which introduces the only ABI incompatibility.

3.1.6. Debug options

--with-pydebug

Build Python in debug mode: define the `Py_DEBUG` macro (disabled by default).

--with-trace-refs

Enable tracing references for debugging purpose (disabled by default).

Effects:

- Define the `Py_TRACE_REFS` macro.
- Add **`sys.getobjects()`** function.
- Add **`PYTHONDUMPREFS`** environment variable.

This build is not ABI compatible with release build (default build) or debug build (`Py_DEBUG` and `Py_REF_DEBUG` macros).

New in version 3.8.

--with-assertions

Build with C assertions enabled (default is no): `assert(...);` and `_PyObject_ASSERT(...);`.

If set, the `NDEBUG` macro is not defined in the **`OPT`** compiler variable.

See also the **`--with-pydebug`** option (debug build) which also enables assertions.

New in version 3.6.

--with-valgrind

Enable Valgrind support (default is no).

--with-dtrace

Enable DTrace support (default is no).

See Instrumenting CPython with DTrace and SystemTap.

New in version 3.6.

--with-address-sanitizer

Enable AddressSanitizer memory error detector, `asan` (default is no).

New in version 3.6.

--with-memory-sanitizer

Enable MemorySanitizer allocation error detector, `msan` (default is no).

New in version 3.6.

--with-undefined-behavior-sanitizer

Enable UndefinedBehaviorSanitizer undefined behaviour detector, `ubsan` (default is no).

New in version 3.6.

3.1.7. Linker options

--enable-shared

Enable building a shared Python library: `libpython` (default is no).

--without-static-libpython

Do not build `libpythonMAJOR.MINOR.a` and do not install `python.o` (built and enabled by default).

New in version 3.10.

3.1.8. Libraries options

--with-libs='lib1 ...'

Link against additional libraries (default is no).

--with-system-expat

Build the **`pyexpat`** module using an installed `expat` library (default is no).

--with-system-ffi

Build the **`_ctypes`** extension module using an installed `ffi` library, see the **`ctypes`** module (default is system-dependent).

--with-system-libmpdec

Build the `_decimal` extension module using an installed `mpdec` library, see the **`decimal`** module (default is no).

New in version 3.3.

--with-readline=editline

Use `editline` library for backend of the **`readline`** module.

Define the `WITH_EDITLINE` macro.

New in version 3.10.

--without-readline
: Don't build the **readline** module (built by default).

  Don't define the HAVE_LIBREADLINE macro.

  New in version 3.10.

--with-libm=STRING
: Override libm math library to *STRING* (default is system-dependent).

--with-libc=STRING
: Override libc C library to *STRING* (default is system-dependent).

--with-openssl=DIR
: Root of the OpenSSL directory.

  New in version 3.7.

--with-openssl-rpath=[no|auto|DIR]
: Set runtime library directory (rpath) for OpenSSL libraries:

  - no (default): don't set rpath;
  - auto: auto-detect rpath from **--with-openssl** and pkg-config;
  - *DIR*: set an explicit rpath.

  New in version 3.10.

3.1.9. Security Options

--with-hash-algorithm=[fnv|siphash13|siphash24]
: Select hash algorithm for use in Python/pyhash.c:

  - siphash13 (default);
  - siphash24;

- `fnv`.

New in version 3.4.

New in version 3.11: `siphash13` is added and it is the new default.

--with-builtin-hashlib-hashes=md5,sha1,sha256,sha512,sha3,blake2

Built-in hash modules:

- `md5`;
- `sha1`;
- `sha256`;
- `sha512`;
- `sha3` (with shake);
- `blake2`.

New in version 3.9.

--with-ssl-default-suites=[python|openssl|STRING]

Override the OpenSSL default cipher suites string:

- `python` (default): use Python's preferred selection;
- `openssl`: leave OpenSSL's defaults untouched;
- *STRING*: use a custom string

See the **`ssl`** module.

New in version 3.7.

Changed in version 3.10: The settings `python` and *STRING* also set TLS 1.2 as minimum protocol version.

3.1.10. macOS Options

See `Mac/README.rst`.

--enable-universalsdk

--enable-universalsdk=SDKDIR

Create a universal binary build. *SDKDIR* specifies which macOS SDK should be used to perform the build (default is no).

--enable-framework

--enable-framework=INSTALLDIR

Create a Python.framework rather than a traditional Unix install. Optional *INSTALLDIR* specifies the installation path (default is no).

--with-universal-archs=ARCH

Specify the kind of universal binary that should be created. This option is only valid when **`--enable-universalsdk`** is set.

Options:

- `universal2`;
- `32-bit`;
- `64-bit`;
- `3-way`;
- `intel`;
- `intel-32`;
- `intel-64`;
- `all`.

--with-framework-name=FRAMEWORK

Specify the name for the python framework on macOS only valid when **`--enable-framework`** is set (default: `Python`).

3.1.11. Cross Compiling Options

Cross compiling, also known as cross building, can be used to build Python for another CPU architecture or platform. Cross compiling requires a Python interpreter for the build platform. The version of the build Python must match the version of the cross compiled host Python.

--build=BUILD

configure for building on BUILD, usually guessed by **config.guess**.

--host=HOST

cross-compile to build programs to run on HOST (target platform)

--with-build-python=path/to/python

path to build `python` binary for cross compiling

New in version 3.11.

CONFIG_SITE=file

An environment variable that points to a file with configure overrides.

Example *config.site* file:

```
# config.site-aarch64
ac_cv_buggy_getaddrinfo=no
ac_cv_file__dev_ptmx=yes
ac_cv_file__dev_ptc=no
```

Cross compiling example:

```
CONFIG_SITE=config.site-aarch64 ../configure \
    --build=x86_64-pc-linux-gnu \
    --host=aarch64-unknown-linux-gnu \
    --with-build-python=../x86_64/python
```

3.2. Python Build System

3.2.1. Main files of the build system

- `configure.ac => configure`;
- `Makefile.pre.in => Makefile` (created by `configure`);

- `pyconfig.h` (created by `configure`);
- `Modules/Setup`: C extensions built by the Makefile using `Module/makesetup` shell script;
- `setup.py`: C extensions built using the **`distutils`** module.

3.2.2. Main build steps

- C files (`.c`) are built as object files (`.o`).
- A static `libpython` library (`.a`) is created from objects files.
- `python.o` and the static `libpython` library are linked into the final `python` program.
- C extensions are built by the Makefile (see `Modules/Setup`) and `python setup.py build`.

3.2.3. Main Makefile targets

- `make`: Build Python with the standard library.
- `make platform:`: build the `python` program, but don't build the standard library extension modules.
- `make profile-opt`: build Python using Profile Guided Optimization (PGO). You can use the configure **`--enable-optimizations`** option to make this the default target of the `make` command (`make all` or just `make`).
- `make buildbottest`: Build Python and run the Python test suite, the same way than buildbots test Python. Set `TESTTIMEOUT` variable (in seconds) to change the test timeout (1200 by default: 20 minutes).
- `make install`: Build and install Python.
- `make regen-all`: Regenerate (almost) all generated files; `make regen-stdlib-module-names` and `autoconf` must be run separately for the remaining generated files.
- `make clean`: Remove built files.
- `make distclean`: Same than `make clean`, but remove also files created by the configure script.

3.2.4. C extensions

Some C extensions are built as built-in modules, like the `sys` module. They are built with the `Py_BUILD_CORE_BUILTIN` macro defined. Built-in modules have no `__file__` attribute:

```
>>> import sys
>>> sys
<module 'sys' (built-in)>
>>> sys.__file__
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
AttributeError: module 'sys' has no attribute '__file__'
```

Other C extensions are built as dynamic libraries, like the `_asyncio` module. They are built with the `Py_BUILD_CORE_MODULE` macro defined. Example on Linux x86-64:

```
>>> import _asyncio
>>> _asyncio
<module '_asyncio' from '/usr/lib64/python3.9/lib-dynloa
>>> _asyncio.__file__
'/usr/lib64/python3.9/lib-dynload/_asyncio.cpython-39-x8
```

`Modules/Setup` is used to generate Makefile targets to build C extensions. At the beginning of the files, C extensions are built as built-in modules. Extensions defined after the `*shared*` marker are built as dynamic libraries.

The `setup.py` script only builds C extensions as shared libraries using the **`distutils`** module.

The **`PyAPI_FUNC()`**, **`PyAPI_API()`** and **`PyMODINIT_FUNC()`** macros of `Include/pyport.h` are defined differently depending if the `Py_BUILD_CORE_MODULE` macro is defined:

- Use `Py_EXPORTED_SYMBOL` if the `Py_BUILD_CORE_MODULE` is defined
- Use `Py_IMPORTED_SYMBOL` otherwise.

If the `Py_BUILD_CORE_BUILTIN` macro is used by mistake on a C extension built as a shared library, its `PyInit_xxx()` function is not exported, causing an **`ImportError`** on import.

3.3. Compiler and linker flags

Options set by the `./configure` script and environment variables and used by `Makefile`.

3.3.1. Preprocessor flags

CONFIGURE_CPPFLAGS

Value of **`CPPFLAGS`** variable passed to the `./configure` script.

New in version 3.6.

CPPFLAGS

(Objective) C/C++ preprocessor flags, e.g. `-I<include dir>` if you have headers in a nonstandard directory `<include dir>`.

Both **`CPPFLAGS`** and **`LDFLAGS`** need to contain the shell's value for setup.py to be able to build extension modules using the directories specified in the environment variables.

BASECPPFLAGS

New in version 3.4.

PY_CPPFLAGS

Extra preprocessor flags added for building the interpreter object files.

Default: `$(BASECPPFLAGS) -I. -I$(srcdir)/Include $(CONFIGURE_CPPFLAGS) $(CPPFLAGS)`.

New in version 3.2.

3.3.2. Compiler flags

CC

C compiler command.

Example: `gcc -pthread`.

MAINCC

C compiler command used to build the `main()` function of programs like `python`.

Variable set by the **`--with-cxx-main`** option of the configure script.

Default: `$(CC)`.

CXX

C++ compiler command.

Used if the **`--with-cxx-main`** option is used.

Example: `g++ -pthread`.

CFLAGS

C compiler flags.

CFLAGS_NODIST

`CFLAGS_NODIST` is used for building the interpreter and stdlib C extensions. Use it when a compiler flag should *not* be part of the distutils **`CFLAGS`** once Python is installed (bpo-21121 [https://bugs.python.org/issue?@action=redirect&bpo=21121]).

In particular, **`CFLAGS`** should not contain:

- the compiler flag `-I` (for setting the search path for include files). The `-I` flags are processed from left to right, and any flags in **`CFLAGS`** would take precedence over user- and package-supplied `-I` flags.
- hardening flags such as `-Werror` because distributions cannot control whether packages installed by users conform to such heightened standards.

New in version 3.5.

EXTRA_CFLAGS

Extra C compiler flags.

CONFIGURE_CFLAGS

Value of **CFLAGS** variable passed to the `./configure` script.

New in version 3.2.

CONFIGURE_CFLAGS_NODIST

Value of **CFLAGS_NODIST** variable passed to the `./configure` script.

New in version 3.5.

BASECFLAGS

Base compiler flags.

OPT

Optimization flags.

CFLAGS_ALIASING

Strict or non-strict aliasing flags used to compile `Python/dtoa.c`.

New in version 3.7.

CCSHARED

Compiler flags used to build a shared library.

For example, `-fPIC` is used on Linux and on BSD.

CFLAGSFORSHARED

Extra C flags added for building the interpreter object files.

Default: `$(CCSHARED)` when **--enable-shared** is used, or an empty string otherwise.

PY_CFLAGS

Default: `$(BASECFLAGS) $(OPT) $(CONFIGURE_CFLAGS) $(CFLAGS) $(EXTRA_CFLAGS)`.

PY_CFLAGS_NODIST

Default: `$(CONFIGURE_CFLAGS_NODIST) $(CFLAGS_NODIST) -I$(srcdir)/Include/internal`.

New in version 3.5.

PY_STDMODULE_CFLAGS

C flags used for building the interpreter object files.

Default: `$(PY_CFLAGS) $(PY_CFLAGS_NODIST) $(PY_CPPFLAGS) $(CFLAGSFORSHARED)`.

New in version 3.7.

PY_CORE_CFLAGS

Default: `$(PY_STDMODULE_CFLAGS) -DPy_BUILD_CORE`.

New in version 3.2.

PY_BUILTIN_MODULE_CFLAGS

Compiler flags to build a standard library extension module as a built-in module, like the **posix** module.

Default: `$(PY_STDMODULE_CFLAGS) -DPy_BUILD_CORE_BUILTIN`.

New in version 3.8.

PURIFY

Purify command. Purify is a memory debugger program.

Default: empty string (not used).

3.3.3. Linker flags

LINKCC

Linker command used to build programs like `python` and `_testembed`.

Default: `$(PURIFY) $(MAINCC)`.

CONFIGURE_LDFLAGS

Value of **LDFLAGS** variable passed to the `./configure` script.

Avoid assigning **CFLAGS**, **LDFLAGS**, etc. so users can use them on the command line to append to these values without stomping the pre-set values.

New in version 3.2.

LDFLAGS_NODIST

LDFLAGS_NODIST is used in the same manner as **CFLAGS_NODIST**. Use it when a linker flag should *not* be part of the distutils **LDFLAGS** once Python is installed (bpo-35257 [https://bugs.python.org/issue?@action=redirect&bpo=35257]).

In particular, **LDFLAGS** should not contain:

- the compiler flag `-L` (for setting the search path for libraries). The `-L` flags are processed from left to right, and any flags in **LDFLAGS** would take precedence over user- and package-supplied `-L` flags.

CONFIGURE_LDFLAGS_NODIST

Value of **LDFLAGS_NODIST** variable passed to the `./configure` script.

New in version 3.8.

LDFLAGS

Linker flags, e.g. `-L<lib dir>` if you have libraries in a nonstandard directory `<lib dir>`.

Both **CPPFLAGS** and **LDFLAGS** need to contain the shell's value for setup.py to be able to build extension modules using the directories specified in the environment variables.

LIBS

Linker flags to pass libraries to the linker when linking the Python executable.

Example: `-lrt`.

LDSHARED

Command to build a shared library.

Default: `@LDSHARED@ $(PY_LDFLAGS)`.

BLDSHARED

Command to build `libpython` shared library.

Default: `@BLDSHARED@ $(PY_CORE_LDFLAGS)`.

PY_LDFLAGS

Default: `$(CONFIGURE_LDFLAGS) $(LDFLAGS)`.

PY_LDFLAGS_NODIST

Default: `$(CONFIGURE_LDFLAGS_NODIST) $(LDFLAGS_NODIST)`.

New in version 3.8.

PY_CORE_LDFLAGS

Linker flags used for building the interpreter object files.

New in version 3.8.

4. Using Python on Windows

This document aims to give an overview of Windows-specific behaviour you should know about when using Python on Microsoft Windows.

Unlike most Unix systems and services, Windows does not include a system supported installation of Python. To make Python available, the CPython team has compiled Windows installers (MSI packages) with every release [https://www.python.org/download/releases/] for many years. These installers are primarily intended to add a per-user installation of Python, with the core interpreter and library being used by a single user. The installer is also able to install for all users of a single machine, and a separate ZIP file is available for application-local distributions.

As specified in **PEP 11** [https://peps.python.org/pep-0011/], a Python release only supports a Windows platform while Microsoft considers the platform under extended support. This means that Python 3.11 supports Windows 8.1 and newer. If you require Windows 7 support, please install Python 3.8.

There are a number of different installers available for Windows, each with certain benefits and downsides.

The full installer contains all components and is the best option for developers using Python for any kind of project.

The Microsoft Store package is a simple installation of Python that is suitable for running scripts and packages, and using IDLE or other development environments. It requires Windows 10 and above, but can be safely installed without corrupting other programs. It also provides many convenient commands for launching Python and its tools.

The nuget.org packages are lightweight installations intended for continuous integration systems. It can be used to build Python packages or run scripts, but is not updateable and has no user interface tools.

The embeddable package is a minimal package of Python suitable for embedding into a larger application.

4.1. The full installer

4.1.1. Installation steps

Four Python 3.11 installers are available for download - two each for the 32-bit and 64-bit versions of the interpreter. The *web installer* is a small initial download, and it will automatically download the required components as necessary. The *offline installer* includes the components necessary for a default installation and only requires an internet connection for optional features. See Installing Without Downloading for other ways to avoid downloading during installation.

After starting the installer, one of two options may be selected:

If you select “Install Now”:

- You will *not* need to be an administrator (unless a system update for the C Runtime Library is required or you install

the Python Launcher for Windows for all users)
- Python will be installed into your user directory
- The Python Launcher for Windows will be installed according to the option at the bottom of the first page
- The standard library, test suite, launcher and pip will be installed
- If selected, the install directory will be added to your **PATH**
- Shortcuts will only be visible for the current user

Selecting "Customize installation" will allow you to select the features to install, the installation location and other options or post-install actions. To install debugging symbols or binaries, you will need to use this option.

To perform an all-users installation, you should select "Customize installation". In this case:

- You may be required to provide administrative credentials or approval
- Python will be installed into the Program Files directory
- The Python Launcher for Windows will be installed into the Windows directory
- Optional features may be selected during installation
- The standard library can be pre-compiled to bytecode
- If selected, the install directory will be added to the system **PATH**
- Shortcuts are available for all users

4.1.2. Removing the MAX_PATH Limitation

Windows historically has limited path lengths to 260 characters. This meant that paths longer than this would not resolve and errors would result.

In the latest versions of Windows, this limitation can be expanded to approximately 32,000 characters. Your administrator will need to activate the "Enable Win32 long paths" group policy, or set `LongPathsEnabled` to `1` in the registry key `HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem`.

This allows the `open()` function, the `os` module and most other path functionality to accept and return paths longer than 260 characters.

After changing the above option, no further configuration is required.

Changed in version 3.6: Support for long paths was enabled in Python.

4.1.3. Installing Without UI

All of the options available in the installer UI can also be specified from the command line, allowing scripted installers to replicate an installation on many machines without user interaction. These options may also be set without suppressing the UI in order to change some of the defaults.

To completely hide the installer UI and install Python silently, pass the `/quiet` option. To skip past the user interaction but still display progress and errors, pass the `/passive` option. The `/uninstall` option may be passed to immediately begin removing Python - no confirmation prompt will be displayed.

All other options are passed as `name=value`, where the value is usually `0` to disable a feature, `1` to enable a feature, or a path. The full list of available options is shown below.

Name	Description	Default
InstallAllUsers	Perform a system-wide installation.	0
TargetDir	The installation directory	Selected based on InstallAllUsers
DefaultAllUsersTargetDir	The default installation directory for all-user installs	`%ProgramFiles%\Python X.Y` or `%ProgramFiles(x86)%\Python X.Y`
DefaultJustForMeTargetDir	The default installation directory for just-for-me installs	`%LocalAppData%\Programs\Python\PythonXY` or `%LocalAppData%\Programs\Python\PythonXY-32` or `%LocalAppData%\Programs\Python\PythonXY-64`
DefaultCustomTargetDir	The default custom install directory displayed in the UI	(empty)
AssociateFiles	Create file associations if the launcher is also installed.	1
CompileAll	Compile all `.py` files to `.pyc`.	0
PrependPath	Prepend install and Scripts directories to **PATH** and add `.PY` to **PATHEXT**	0

AppendPath	Append Path and Scripts directories to **PATH** and add `.PY` to **PATHEXT**
Shortcuts	Create shortcuts for the interpreter, documentation and IDLE if installed.
Include_doc	Install Python manual
Include_debug	Install debug binaries
Include_dev	Install developer headers and libraries. Omitting this may lead to an unusable installation.
Include_exe	Install `python.exe` and related files. Omitting this may lead to an unusable installation.
Include_launcher	Install Python Launcher for Windows.
InstallLauncherAllUsers	Installs the launcher for all users. Also requires `Include_launcher` to be set to 1
Include_lib	Install standard library and extension modules. Omitting this may lead to an unusable installation.
Include_pip	Install bundled pip and setuptools
Include_symbols	Install debugging symbols (`*.pdb`)
Include_tcltk	Install Tcl/Tk support and IDLE
Include_test	Install standard library test suite
Include_tools	Install utility scripts
Include_launcher	Only installs the launcher. This will override most other options.
SimpleInstall	Disable most install UI
SimpleInstallDescription	A custom message to display when the simplified install UI is used.

For example, to silently install a default, system-wide Python installation, you could use the following command (from an elevated command prompt):

```
python-3.9.0.exe /quiet InstallAllUsers=1 PrependPath=1
```

To allow users to easily install a personal copy of Python without the test suite, you could provide a shortcut with the following command. This will display a simplified initial page and disallow customization:

```
python-3.9.0.exe InstallAllUsers=0 Include_launcher=0 In
    SimpleInstall=1 SimpleInstallDescription="Just for m
```

(Note that omitting the launcher also omits file associations, and is only recommended for per-user installs when there is also a system-

wide installation that included the launcher.)

The options listed above can also be provided in a file named `unattend.xml` alongside the executable. This file specifies a list of options and values. When a value is provided as an attribute, it will be converted to a number if possible. Values provided as element text are always left as strings. This example file sets the same options as the previous example:

```
<Options>
    <Option Name="InstallAllUsers" Value="no" />
    <Option Name="Include_launcher" Value="0" />
    <Option Name="Include_test" Value="no" />
    <Option Name="SimpleInstall" Value="yes" />
    <Option Name="SimpleInstallDescription">Just for me,
</Options>
```

4.1.4. Installing Without Downloading

As some features of Python are not included in the initial installer download, selecting those features may require an internet connection. To avoid this need, all possible components may be downloaded on-demand to create a complete *layout* that will no longer require an internet connection regardless of the selected features. Note that this download may be bigger than required, but where a large number of installations are going to be performed it is very useful to have a locally cached copy.

Execute the following command from Command Prompt to download all possible required files. Remember to substitute `python-3.9.0.exe` for the actual name of your installer, and to create layouts in their own directories to avoid collisions between files with the same name.

```
python-3.9.0.exe /layout [optional target directory]
```

You may also specify the `/quiet` option to hide the progress display.

4.1.5. Modifying an install

Once Python has been installed, you can add or remove features through the Programs and Features tool that is part of Windows. Select the Python entry and choose “Uninstall/Change” to open the installer in maintenance mode.

“Modify” allows you to add or remove features by modifying the checkboxes - unchanged checkboxes will not install or remove anything. Some options cannot be changed in this mode, such as the install directory; to modify these, you will need to remove and then reinstall Python completely.

“Repair” will verify all the files that should be installed using the current settings and replace any that have been removed or modified.

“Uninstall” will remove Python entirely, with the exception of the Python Launcher for Windows, which has its own entry in Programs and Features.

4.2. The Microsoft Store package

New in version 3.7.2.

The Microsoft Store package is an easily installable Python interpreter that is intended mainly for interactive use, for example, by students.

To install the package, ensure you have the latest Windows 10 updates and search the Microsoft Store app for “Python 3.11”. Ensure that the app you select is published by the Python Software Foundation, and install it.

Warning

Python will always be available for free on the Microsoft Store. If you are asked to pay for it, you have not selected the correct package.

After installation, Python may be launched by finding it in Start. Alternatively, it will be available from any Command Prompt or

PowerShell session by typing `python`. Further, pip and IDLE may be used by typing `pip` or `idle`. IDLE can also be found in Start.

All three commands are also available with version number suffixes, for example, as `python3.exe` and `python3.x.exe` as well as `python.exe` (where `3.x` is the specific version you want to launch, such as 3.11). Open "Manage App Execution Aliases" through Start to select which version of Python is associated with each command. It is recommended to make sure that `pip` and `idle` are consistent with whichever version of `python` is selected.

Virtual environments can be created with `python -m venv` and activated and used as normal.

If you have installed another version of Python and added it to your `PATH` variable, it will be available as `python.exe` rather than the one from the Microsoft Store. To access the new installation, use `python3.exe` or `python3.x.exe`.

The `py.exe` launcher will detect this Python installation, but will prefer installations from the traditional installer.

To remove Python, open Settings and use Apps and Features, or else find Python in Start and right-click to select Uninstall. Uninstalling will remove all packages you installed directly into this Python installation, but will not remove any virtual environments

4.2.1. Known issues

4.2.1.1. Redirection of local data, registry, and temporary paths

Because of restrictions on Microsoft Store apps, Python scripts may not have full write access to shared locations such as **`TEMP`** and the registry. Instead, it will write to a private copy. If your scripts must modify the shared locations, you will need to install the full installer.

At runtime, Python will use a private copy of well-known Windows folders and the registry. For example, if the environment variable **`%APPDATA%`** is `c:\Users\<user>\AppData\`, then when writing

to `C:\Users\<user>\AppData\Local` will write to `C:\Users\<user>\AppData\Local\Packages\PythonSoftwareFoundation.Python.3.8_qbz5n2kfra8p0\LocalCache\Local\`.

When reading files, Windows will return the file from the private folder, or if that does not exist, the real Windows directory. For example reading `C:\Windows\System32` returns the contents of `C:\Windows\System32` plus the contents of `C:\Program Files\WindowsApps\package_name\VFS\SystemX86`.

You can find the real path of any existing file using **`os.path.realpath()`**:

```
>>> import os
>>> test_file = 'C:\\Users\\example\\AppData\\Local\\tes
>>> os.path.realpath(test_file)
'C:\\Users\\example\\AppData\\Local\\Packages\\PythonSof
```

When writing to the Windows Registry, the following behaviors exist:

- Reading from `HKLM\Software` is allowed and results are merged with the `registry.dat` file in the package.
- Writing to `HKLM\Software` is not allowed if the corresponding key/value exists, i.e. modifying existing keys.
- Writing to `HKLM\Software` is allowed as long as a corresponding key/value does not exist in the package and the user has the correct access permissions.

For more detail on the technical basis for these limitations, please consult Microsoft's documentation on packaged full-trust apps, currently available at docs.microsoft.com/en-us/windows/msix/desktop/desktop-to-uwp-behind-the-scenes [https://docs.microsoft.com/en-us/windows/msix/desktop/desktop-to-uwp-behind-the-scenes]

4.3. The nuget.org packages

New in version 3.5.2.

The nuget.org package is a reduced size Python environment

intended for use on continuous integration and build systems that do not have a system-wide install of Python. While nuget is "the package manager for .NET", it also works perfectly fine for packages containing build-time tools.

Visit nuget.org [https://www.nuget.org/] for the most up-to-date information on using nuget. What follows is a summary that is sufficient for Python developers.

The `nuget.exe` command line tool may be downloaded directly from `https://aka.ms/nugetclidl`, for example, using curl or PowerShell. With the tool, the latest version of Python for 64-bit or 32-bit machines is installed using:

```
nuget.exe install python -ExcludeVersion -OutputDirector
nuget.exe install pythonx86 -ExcludeVersion -OutputDirec
```

To select a particular version, add a `-Version 3.x.y`. The output directory may be changed from `.`, and the package will be installed into a subdirectory. By default, the subdirectory is named the same as the package, and without the `-ExcludeVersion` option this name will include the specific version installed. Inside the subdirectory is a `tools` directory that contains the Python installation:

```
# Without -ExcludeVersion
> .\python.3.5.2\tools\python.exe -V
Python 3.5.2

# With -ExcludeVersion
> .\python\tools\python.exe -V
Python 3.5.2
```

In general, nuget packages are not upgradeable, and newer versions should be installed side-by-side and referenced using the full path. Alternatively, delete the package directory manually and install it again. Many CI systems will do this automatically if they do not preserve files between builds.

Alongside the `tools` directory is a `build\native` directory. This contains a MSBuild properties file `python.props` that can be used

in a C++ project to reference the Python install. Including the settings will automatically use the headers and import libraries in your build.

The package information pages on nuget.org are www.nuget.org/packages/python [https://www.nuget.org/packages/python] for the 64-bit version and www.nuget.org/packages/pythonx86 [https://www.nuget.org/packages/pythonx86] for the 32-bit version.

4.4. The embeddable package

New in version 3.5.

The embedded distribution is a ZIP file containing a minimal Python environment. It is intended for acting as part of another application, rather than being directly accessed by end-users.

When extracted, the embedded distribution is (almost) fully isolated from the user's system, including environment variables, system registry settings, and installed packages. The standard library is included as pre-compiled and optimized `.pyc` files in a ZIP, and `python3.dll`, `python37.dll`, `python.exe` and `pythonw.exe` are all provided. Tcl/tk (including all dependants, such as Idle), pip and the Python documentation are not included.

Note

The embedded distribution does not include the Microsoft C Runtime [https://docs.microsoft.com/en-US/cpp/windows/latest-supported-vc-redist#visual-studio-2015-2017-2019-and-2022] and it is the responsibility of the application installer to provide this. The runtime may have already been installed on a user's system previously or automatically via Windows Update, and can be detected by finding `ucrtbase.dll` in the system directory.

Third-party packages should be installed by the application installer alongside the embedded distribution. Using pip to manage dependencies as for a regular Python installation is not supported with this distribution, though with some care it may be possible to

include and use pip for automatic updates. In general, third-party packages should be treated as part of the application (“vendoring”) so that the developer can ensure compatibility with newer versions before providing updates to users.

The two recommended use cases for this distribution are described below.

4.4.1. Python Application

An application written in Python does not necessarily require users to be aware of that fact. The embedded distribution may be used in this case to include a private version of Python in an install package. Depending on how transparent it should be (or conversely, how professional it should appear), there are two options.

Using a specialized executable as a launcher requires some coding, but provides the most transparent experience for users. With a customized launcher, there are no obvious indications that the program is running on Python: icons can be customized, company and version information can be specified, and file associations behave properly. In most cases, a custom launcher should simply be able to call `Py_Main` with a hard-coded command line.

The simpler approach is to provide a batch file or generated shortcut that directly calls the `python.exe` or `pythonw.exe` with the required command-line arguments. In this case, the application will appear to be Python and not its actual name, and users may have trouble distinguishing it from other running Python processes or file associations.

With the latter approach, packages should be installed as directories alongside the Python executable to ensure they are available on the path. With the specialized launcher, packages can be located in other locations as there is an opportunity to specify the search path before launching the application.

4.4.2. Embedding Python

Applications written in native code often require some form of

scripting language, and the embedded Python distribution can be used for this purpose. In general, the majority of the application is in native code, and some part will either invoke `python.exe` or directly use `python3.dll`. For either case, extracting the embedded distribution to a subdirectory of the application installation is sufficient to provide a loadable Python interpreter.

As with the application use, packages can be installed to any location as there is an opportunity to specify search paths before initializing the interpreter. Otherwise, there is no fundamental differences between using the embedded distribution and a regular installation.

4.5. Alternative bundles

Besides the standard CPython distribution, there are modified packages including additional functionality. The following is a list of popular versions and their key features:

ActivePython [https://www.activestate.com/activepython/]

: Installer with multi-platform compatibility, documentation, PyWin32

Anaconda [https://www.anaconda.com/download/]

: Popular scientific modules (such as numpy, scipy and pandas) and the `conda` package manager.

Enthought Deployment Manager [https://www.enthought.com/edm/]

: "The Next Generation Python Environment and Package Manager".

  Previously Enthought provided Canopy, but it reached end of life in 2016 [https://support.enthought.com/hc/en-us/articles/360038600051-Canopy-GUI-end-of-life-transition-to-the-Enthought-Deployment-Manager-EDM-and-Visual-Studio-Code].

WinPython [https://winpython.github.io/]

: Windows-specific distribution with prebuilt scientific packages and tools for building packages.

Note that these packages may not include the latest versions of Python or other libraries, and are not maintained or supported by the core Python team.

4.6. Configuring Python

To run Python conveniently from a command prompt, you might consider changing some default environment variables in Windows. While the installer provides an option to configure the PATH and PATHEXT variables for you, this is only reliable for a single, system-wide installation. If you regularly use multiple versions of Python, consider using the Python Launcher for Windows.

4.6.1. Excursus: Setting environment variables

Windows allows environment variables to be configured permanently at both the User level and the System level, or temporarily in a command prompt.

To temporarily set environment variables, open Command Prompt and use the **set** command:

```
C:\>set PATH=C:\Program Files\Python 3.9;%PATH%
C:\>set PYTHONPATH=%PYTHONPATH%;C:\My_python_lib
C:\>python
```

These changes will apply to any further commands executed in that console, and will be inherited by any applications started from the console.

Including the variable name within percent signs will expand to the existing value, allowing you to add your new value at either the start or the end. Modifying **`PATH`** by adding the directory containing **python.exe** to the start is a common way to ensure the correct version of Python is launched.

To permanently modify the default environment variables, click Start and search for 'edit environment variables', or open System properties, *Advanced system settings* and click the *Environment Variables* button. In this dialog, you can add or modify User and

System variables. To change System variables, you need non-restricted access to your machine (i.e. Administrator rights).

Note

Windows will concatenate User variables *after* System variables, which may cause unexpected results when modifying **PATH**.

The **PYTHONPATH** variable is used by all versions of Python, so you should not permanently configure it unless the listed paths only include code that is compatible with all of your installed Python versions.

The `set` command, for temporarily modifying environment variables

https://docs.microsoft.com/en-us/windows-server/administration/windows-commands/setx
The `setx` command, for permanently modifying environment variables

4.6.2. Finding the Python executable

Changed in version 3.5.

Besides using the automatically created start menu entry for the Python interpreter, you might want to start Python in the command prompt. The installer has an option to set that up for you.

On the first page of the installer, an option labelled “Add Python to PATH” may be selected to have the installer add the install location

into the **PATH**. The location of the `Scripts\` folder is also added. This allows you to type **python** to run the interpreter, and **pip** for the package installer. Thus, you can also execute your scripts with command line options, see Command line documentation.

If you don't enable this option at install time, you can always re-run the installer, select Modify, and enable it. Alternatively, you can manually modify the **PATH** using the directions in Excursus: Setting environment variables. You need to set your **PATH** environment variable to include the directory of your Python installation, delimited by a semicolon from other entries. An example variable could look like this (assuming the first two entries already existed):

```
C:\WINDOWS\system32;C:\WINDOWS;C:\Program Files\Python 3
```

4.7. UTF-8 mode

New in version 3.7.

Windows still uses legacy encodings for the system encoding (the ANSI Code Page). Python uses it for the default encoding of text files (e.g. **`locale.getencoding()`**).

This may cause issues because UTF-8 is widely used on the internet and most Unix systems, including WSL (Windows Subsystem for Linux).

You can use the Python UTF-8 Mode to change the default text encoding to UTF-8. You can enable the Python UTF-8 Mode via the `-X utf8` command line option, or the `PYTHONUTF8=1` environment variable. See **`PYTHONUTF8`** for enabling UTF-8 mode, and Excursus: Setting environment variables for how to modify environment variables.

When the Python UTF-8 Mode is enabled, you can still use the system encoding (the ANSI Code Page) via the "mbcs" codec.

Note that adding `PYTHONUTF8=1` to the default environment variables will affect all Python 3.7+ applications on your system. If you have any Python 3.7+ applications which rely on the legacy system encoding, it is recommended to set the environment variable

temporarily or use the `-X utf8` command line option.

Note

Even when UTF-8 mode is disabled, Python uses UTF-8 by default on Windows for:

- Console I/O including standard I/O (see **PEP 528** [https://peps.python.org/pep-0528/] for details).
- The filesystem encoding (see **PEP 529** [https://peps.python.org/pep-0529/] for details).

4.8. Python Launcher for Windows

New in version 3.3.

The Python launcher for Windows is a utility which aids in locating and executing of different Python versions. It allows scripts (or the command-line) to indicate a preference for a specific Python version, and will locate and execute that version.

Unlike the **PATH** variable, the launcher will correctly select the most appropriate version of Python. It will prefer per-user installations over system-wide ones, and orders by language version rather than using the most recently installed version.

The launcher was originally specified in **PEP 397** [https://peps.python.org/pep-0397/].

4.8.1. Getting started

4.8.1.1. From the command-line

Changed in version 3.6.

System-wide installations of Python 3.3 and later will put the launcher on your **PATH**. The launcher is compatible with all available versions of Python, so it does not matter which version is installed. To check that the launcher is available, execute the

following command in Command Prompt:

```
py
```

You should find that the latest version of Python you have installed is started - it can be exited as normal, and any additional command-line arguments specified will be sent directly to Python.

If you have multiple versions of Python installed (e.g., 3.7 and 3.11) you will have noticed that Python 3.11 was started - to launch Python 3.7, try the command:

```
py -3.7
```

If you want the latest version of Python 2 you have installed, try the command:

```
py -2
```

You should find the latest version of Python 3.x starts.

If you see the following error, you do not have the launcher installed:

```
'py' is not recognized as an internal or external commar
operable program or batch file.
```

Per-user installations of Python do not add the launcher to **PATH** unless the option was selected on installation.

The command:

```
py --list
```

displays the currently installed version(s) of Python.

4.8.1.2. Virtual environments

New in version 3.5.

If the launcher is run with no explicit Python version specification, and a virtual environment (created with the standard library **venv**

module or the external `virtualenv` tool) active, the launcher will run the virtual environment's interpreter rather than the global one. To run the global interpreter, either deactivate the virtual environment, or explicitly specify the global Python version.

4.8.1.3. From a script

Let's create a test Python script - create a file called `hello.py` with the following contents

```
#! python
import sys
sys.stdout.write("hello from Python %s\n" % (sys.versior
```

From the directory in which hello.py lives, execute the command:

```
py hello.py
```

You should notice the version number of your latest Python 2.x installation is printed. Now try changing the first line to be:

```
#! python3
```

Re-executing the command should now print the latest Python 3.x information. As with the above command-line examples, you can specify a more explicit version qualifier. Assuming you have Python 3.7 installed, try changing the first line to `#! python3.7` and you should find the 3.11 version information printed.

Note that unlike interactive use, a bare "python" will use the latest version of Python 2.x that you have installed. This is for backward compatibility and for compatibility with Unix, where the command `python` typically refers to Python 2.

4.8.1.4. From file associations

The launcher should have been associated with Python files (i.e. `.py`, `.pyw`, `.pyc` files) when it was installed. This means that when you double-click on one of these files from Windows explorer the launcher will be used, and therefore you can use the same

facilities described above to have the script specify the version which should be used.

The key benefit of this is that a single launcher can support multiple Python versions at the same time depending on the contents of the first line.

4.8.2. Shebang Lines

If the first line of a script file starts with `#!`, it is known as a "shebang" line. Linux and other Unix like operating systems have native support for such lines and they are commonly used on such systems to indicate how a script should be executed. This launcher allows the same facilities to be used with Python scripts on Windows and the examples above demonstrate their use.

To allow shebang lines in Python scripts to be portable between Unix and Windows, this launcher supports a number of 'virtual' commands to specify which interpreter to use. The supported virtual commands are:

- `/usr/bin/env python`
- `/usr/bin/python`
- `/usr/local/bin/python`
- `python`

For example, if the first line of your script starts with

```
#! /usr/bin/python
```

The default Python will be located and used. As many Python scripts written to work on Unix will already have this line, you should find these scripts can be used by the launcher without modification. If you are writing a new script on Windows which you hope will be useful on Unix, you should use one of the shebang lines starting with `/usr`.

Any of the above virtual commands can be suffixed with an explicit version (either just the major version, or the major and minor version). Furthermore the 32-bit version can be requested by adding "-32" after the minor version. I.e. `/usr/bin/python3.7-32` will

request usage of the 32-bit python 3.7.

New in version 3.7: Beginning with python launcher 3.7 it is possible to request 64-bit version by the “-64” suffix. Furthermore it is possible to specify a major and architecture without minor (i.e. `/usr/bin/python3-64`).

Changed in version 3.11: The “-64” suffix is deprecated, and now implies “any architecture that is not provably i386/32-bit”. To request a specific environment, use the new `-V:<TAG>` argument with the complete tag.

The `/usr/bin/env` form of shebang line has one further special property. Before looking for installed Python interpreters, this form will search the executable **`PATH`** for a Python executable. This corresponds to the behaviour of the Unix `env` program, which performs a **`PATH`** search. If an executable matching the first argument after the `env` command cannot be found, it will be handled as described below. Additionally, the environment variable **`PYLAUNCHER_NO_SEARCH_PATH`** may be set (to any value) to skip this additional search.

Shebang lines that do not match any of these patterns are treated as **Windows** paths that are absolute or relative to the directory containing the script file. This is a convenience for Windows-only scripts, such as those generated by an installer, since the behavior is not compatible with Unix-style shells. These paths may be quoted, and may include multiple arguments, after which the path to the script and any additional arguments will be appended.

4.8.3. Arguments in shebang lines

The shebang lines can also specify additional options to be passed to the Python interpreter. For example, if you have a shebang line:

```
#! /usr/bin/python -v
```

Then Python will be started with the `-v` option

4.8.4. Customization

4.8.4.1. Customization via INI files

Two .ini files will be searched by the launcher - `py.ini` in the current user's "application data" directory (i.e. the directory returned by calling the Windows function `SHGetFolderPath` with `CSIDL_LOCAL_APPDATA`) and `py.ini` in the same directory as the launcher. The same .ini files are used for both the 'console' version of the launcher (i.e. py.exe) and for the 'windows' version (i.e. pyw.exe).

Customization specified in the "application directory" will have precedence over the one next to the executable, so a user, who may not have write access to the .ini file next to the launcher, can override commands in that global .ini file.

4.8.4.2. Customizing default Python versions

In some cases, a version qualifier can be included in a command to dictate which version of Python will be used by the command. A version qualifier starts with a major version number and can optionally be followed by a period ('.') and a minor version specifier. Furthermore it is possible to specify if a 32 or 64 bit implementation shall be requested by adding "-32" or "-64".

For example, a shebang line of `#!python` has no version qualifier, while `#!python3` has a version qualifier which specifies only a major version.

If no version qualifiers are found in a command, the environment variable **`PY_PYTHON`** can be set to specify the default version qualifier. If it is not set, the default is "3". The variable can specify any value that may be passed on the command line, such as "3", "3.7", "3.7-32" or "3.7-64". (Note that the "-64" option is only available with the launcher included with Python 3.7 or newer.)

If no minor version qualifiers are found, the environment variable `PY_PYTHON{major}` (where `{major}` is the current major version qualifier as determined above) can be set to specify the full version. If no such option is found, the launcher will enumerate the installed Python versions and use the latest minor release found for

the major version, which is likely, although not guaranteed, to be the most recently installed version in that family.

On 64-bit Windows with both 32-bit and 64-bit implementations of the same (major.minor) Python version installed, the 64-bit version will always be preferred. This will be true for both 32-bit and 64-bit implementations of the launcher - a 32-bit launcher will prefer to execute a 64-bit Python installation of the specified version if available. This is so the behavior of the launcher can be predicted knowing only what versions are installed on the PC and without regard to the order in which they were installed (i.e., without knowing whether a 32 or 64-bit version of Python and corresponding launcher was installed last). As noted above, an optional “-32” or “-64” suffix can be used on a version specifier to change this behaviour.

Examples:

- If no relevant options are set, the commands `python` and `python2` will use the latest Python 2.x version installed and the command `python3` will use the latest Python 3.x installed.
- The command `python3.7` will not consult any options at all as the versions are fully specified.
- If `PY_PYTHON=3`, the commands `python` and `python3` will both use the latest installed Python 3 version.
- If `PY_PYTHON=3.7-32`, the command `python` will use the 32-bit implementation of 3.7 whereas the command `python3` will use the latest installed Python (PY_PYTHON was not considered at all as a major version was specified.)
- If `PY_PYTHON=3` and `PY_PYTHON3=3.7`, the commands `python` and `python3` will both use specifically 3.7

In addition to environment variables, the same settings can be configured in the .INI file used by the launcher. The section in the INI file is called `[defaults]` and the key name will be the same as the environment variables without the leading `PY_` prefix (and note that the key names in the INI file are case insensitive.) The contents of an environment variable will override things specified in the INI file.

For example:

- Setting `PY_PYTHON=3.7` is equivalent to the INI file containing:

```
[defaults]
python=3.7
```

- Setting `PY_PYTHON=3` and `PY_PYTHON3=3.7` is equivalent to the INI file containing:

```
[defaults]
python=3
python3=3.7
```

4.8.5. Diagnostics

If an environment variable **`PYLAUNCHER_DEBUG`** is set (to any value), the launcher will print diagnostic information to stderr (i.e. to the console). While this information manages to be simultaneously verbose *and* terse, it should allow you to see what versions of Python were located, why a particular version was chosen and the exact command-line used to execute the target Python. It is primarily intended for testing and debugging.

4.8.6. Dry Run

If an environment variable **`PYLAUNCHER_DRYRUN`** is set (to any value), the launcher will output the command it would have run, but will not actually launch Python. This may be useful for tools that want to use the launcher to detect and then launch Python directly. Note that the command written to standard output is always encoded using UTF-8, and may not render correctly in the console.

4.8.7. Install on demand

If an environment variable **`PYLAUNCHER_ALLOW_INSTALL`** is set (to any value), and the requested Python version is not installed but is available on the Microsoft Store, the launcher will attempt to

install it. This may require user interaction to complete, and you may need to run the command again.

An additional **PYLAUNCHER_ALWAYS_INSTALL** variable causes the launcher to always try to install Python, even if it is detected. This is mainly intended for testing (and should be used with **PYLAUNCHER_DRYRUN**).

4.8.8. Return codes

The following exit codes may be returned by the Python launcher. Unfortunately, there is no way to distinguish these from the exit code of Python itself.

The names of codes are as used in the sources, and are only for reference. There is no way to access or resolve them apart from reading this page. Entries are listed in alphabetical order of names.

Name	Value	Description
RC_BAD_VENV_CFG	107	A `py.cfg` was found but is corrupt.
RC_CREATE_PROCESS	101	Failed to launch Python.
RC_INSTALLING	111	An install was started, but the command will need to be re-run after it completes.
RC_INTERNAL_ERROR	109	Unexpected error. Please report a bug.
RC_NO_COMMANDLINE	108	Unable to obtain command line from the operating system.
RC_NO_PYTHON	103	Unable to locate the requested version.
RC_NO_VENV_CFG	106	A `py.cfg` was required but not found.

4.9. Finding modules

These notes supplement the description at The initialization of the sys.path module search path with detailed Windows notes.

When no `._pth` file is found, this is how **sys.path** is populated on Windows:

- An empty entry is added at the start, which corresponds to the current directory.
- If the environment variable **PYTHONPATH** exists, as described in Environment variables, its entries are added next. Note

that on Windows, paths in this variable must be separated by semicolons, to distinguish them from the colon used in drive identifiers (`C:\` etc.).

- Additional "application paths" can be added in the registry as subkeys of `\SOFTWARE\Python\PythonCore{version}\PythonPath` under both the `HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` hives. Subkeys which have semicolon-delimited path strings as their default value will cause each path to be added to **`sys.path`**. (Note that all known installers only use HKLM, so HKCU is typically empty.)
- If the environment variable **`PYTHONHOME`** is set, it is assumed as "Python Home". Otherwise, the path of the main Python executable is used to locate a "landmark file" (either `Lib\os.py` or `pythonXY.zip`) to deduce the "Python Home". If a Python home is found, the relevant sub-directories added to **`sys.path`** (`Lib`, `plat-win`, etc) are based on that folder. Otherwise, the core Python path is constructed from the PythonPath stored in the registry.
- If the Python Home cannot be located, no **`PYTHONPATH`** is specified in the environment, and no registry entries can be found, a default path with relative entries is used (e.g. `.\Lib;.\plat-win`, etc).

If a `pyvenv.cfg` file is found alongside the main executable or in the directory one level above the executable, the following variations apply:

- If `home` is an absolute path and **`PYTHONHOME`** is not set, this path is used instead of the path to the main executable when deducing the home location.

The end result of all this is:

- When running `python.exe`, or any other .exe in the main Python directory (either an installed version, or directly from the PCbuild directory), the core path is deduced, and the core paths in the registry are ignored. Other "application paths" in the registry are always read.
- When Python is hosted in another .exe (different directory, embedded via COM, etc), the "Python Home" will not be

deduced, so the core path from the registry is used. Other "application paths" in the registry are always read.
- If Python can't find its home and there are no registry value (frozen .exe, some very strange installation setup) you get a path with some default, but relative, paths.

For those who want to bundle Python into their application or distribution, the following advice will prevent conflicts with other installations:

- Include a `._pth` file alongside your executable containing the directories to include. This will ignore paths listed in the registry and environment variables, and also ignore **`site`** unless `import site` is listed.
- If you are loading `python3.dll` or `python37.dll` in your own executable, explicitly call **`Py_SetPath()`** or (at least) **`Py_SetProgramName()`** before **`Py_Initialize()`**.
- Clear and/or overwrite **`PYTHONPATH`** and set **`PYTHONHOME`** before launching `python.exe` from your application.
- If you cannot use the previous suggestions (for example, you are a distribution that allows people to run `python.exe` directly), ensure that the landmark file (`Lib\os.py`) exists in your install directory. (Note that it will not be detected inside a ZIP file, but a correctly named ZIP file will be detected instead.)

These will ensure that the files in a system-wide installation will not take precedence over the copy of the standard library bundled with your application. Otherwise, your users may experience problems using your application. Note that the first suggestion is the best, as the others may still be susceptible to non-standard paths in the registry and user site-packages.

Changed in version 3.6:

- Adds `._pth` file support and removes `applocal` option from `pyvenv.cfg`.
- Adds `pythonXX.zip` as a potential landmark when directly adjacent to the executable.

Deprecated since version 3.6:

> Modules specified in the registry under `Modules` (not `PythonPath`) may be imported by **`importlib.machinery.WindowsRegistryFinder`**. This finder is enabled on Windows in 3.6.0 and earlier, but may need to be explicitly added to **`sys.meta_path`** in the future.

4.10. Additional modules

Even though Python aims to be portable among all platforms, there are features that are unique to Windows. A couple of modules, both in the standard library and external, and snippets exist to use these features.

The Windows-specific standard modules are documented in MS Windows Specific Services.

4.10.1. PyWin32

The PyWin32 [https://pypi.org/project/pywin32] module by Mark Hammond is a collection of modules for advanced Windows-specific support. This includes utilities for:

- Component Object Model [https://docs.microsoft.com/en-us/windows/win32/com/component-object-model--com--portal] (COM)
- Win32 API calls
- Registry
- Event log
- Microsoft Foundation Classes [https://docs.microsoft.com/en-us/cpp/mfc/mfc-desktop-applications] (MFC) user interfaces

PythonWin [https://web.archive.org/web/20060524042422/https://www.python.org/windows/pythonwin/] is a sample MFC application shipped with PyWin32. It is an embeddable IDE with a built-in debugger.

Win32 How Do I...? **[http://timgolden.me.uk/python/win32_how_do_i.html]**
by Tim Golden

Python and COM **[https://www.boddie.org.uk/python/COM.html]**
by David and Paul Boddie

4.10.2. cx_Freeze

cx_Freeze [https://cx-freeze.readthedocs.io/en/latest/] is a `distutils` extension (see Extending Distutils) which wraps Python scripts into executable Windows programs (`*.exe` files). When you have done this, you can distribute your application without requiring your users to install Python.

4.11. Compiling Python on Windows

If you want to compile CPython yourself, first thing you should do is get the source [https://www.python.org/downloads/source/]. You can download either the latest release's source or just grab a fresh checkout [https://devguide.python.org/setup/#get-the-source-code].

The source tree contains a build solution and project files for Microsoft Visual Studio, which is the compiler used to build the official Python releases. These files are in the `PCbuild` directory.

Check `PCbuild/readme.txt` for general information on the build process.

For extension modules, consult Building C and C++ Extensions on Windows.

4.12. Other Platforms

With ongoing development of Python, some platforms that used to be supported earlier are no longer supported (due to the lack of users or developers). Check **PEP 11** [https://peps.python.org/pep-0011/] for details on all unsupported platforms.

- Windows CE [https://pythonce.sourceforge.net/] is no longer supported [https://github.com/python/cpython/issues/71542] since Python 3 (if it ever was).
- The Cygwin [https://cygwin.com/] installer offers to install the Python interpreter [https://cygwin.com/packages/summary/python3.html] as well

See Python for Windows [https://www.python.org/downloads/windows/] for detailed information about platforms with pre-compiled installers.

5. Using Python on a Mac

Author

Bob Savage <bobsavage@mac.com>

Python on a Mac running macOS is in principle very similar to Python on any other Unix platform, but there are a number of additional features such as the IDE and the Package Manager that are worth pointing out.

5.1. Getting and Installing MacPython

macOS used to come with Python 2.7 pre-installed between versions 10.8 and 12.3 [https://developer.apple.com/documentation/macos-release-notes/macos-12_3-release-notes#Python]. You are invited to install the most recent version of Python 3 from the Python website (https://www.python.org). A current "universal binary" build of Python, which runs natively on the Mac's new Intel and legacy PPC CPU's, is available there.

What you get after installing is a number of things:

- A `Python 3.12` folder in your `Applications` folder. In here you find IDLE, the development environment that is a standard part of official Python distributions; and PythonLauncher, which handles double-clicking Python scripts from the Finder.
- A framework `/Library/Frameworks/Python.framework`, which includes the Python executable and libraries. The installer adds this location to your shell path. To uninstall MacPython, you can simply remove these three things. A symlink to the Python executable is placed in /usr/local/bin/.

The Apple-provided build of Python is installed in `/System/Library/Frameworks/Python.framework` and `/usr/bin/`

`python`, respectively. You should never modify or delete these, as they are Apple-controlled and are used by Apple- or third-party software. Remember that if you choose to install a newer Python version from python.org, you will have two different but functional Python installations on your computer, so it will be important that your paths and usages are consistent with what you want to do.

IDLE includes a help menu that allows you to access Python documentation. If you are completely new to Python you should start reading the tutorial introduction in that document.

If you are familiar with Python on other Unix platforms you should read the section on running Python scripts from the Unix shell.

5.1.1. How to run a Python script

Your best way to get started with Python on macOS is through the IDLE integrated development environment, see section The IDE and use the Help menu when the IDE is running.

If you want to run Python scripts from the Terminal window command line or from the Finder you first need an editor to create your script. macOS comes with a number of standard Unix command line editors, **vim** and **emacs** among them. If you want a more Mac-like editor, **BBEdit** or **TextWrangler** from Bare Bones Software (see http://www.barebones.com/products/bbedit/index.html) are good choices, as is **TextMate** (see https://macromates.com/). Other editors include **Gvim** (https://macvim-dev.github.io/macvim/) and **Aquamacs** (http://aquamacs.org/).

To run your script from the Terminal window you must make sure that `/usr/local/bin` is in your shell search path.

To run your script from the Finder you have two options:

- Drag it to **PythonLauncher**
- Select **PythonLauncher** as the default application to open your script (or any .py script) through the finder Info window and double-click it. **PythonLauncher** has various preferences to control how your script is launched. Option-dragging allows you to change these for one invocation, or use its

Preferences menu to change things globally.

5.1.2. Running scripts with a GUI

With older versions of Python, there is one macOS quirk that you need to be aware of: programs that talk to the Aqua window manager (in other words, anything that has a GUI) need to be run in a special way. Use **pythonw** instead of **python** to start such scripts.

With Python 3.9, you can use either **python** or **pythonw**.

5.1.3. Configuration

Python on macOS honors all standard Unix environment variables such as `PYTHONPATH`, but setting these variables for programs started from the Finder is non-standard as the Finder does not read your `.profile` or `.cshrc` at startup. You need to create a file `~/.MacOSX/environment.plist`. See Apple's Technical Document QA1067 for details.

For more information on installation Python packages in MacPython, see section Installing Additional Python Packages.

5.2. The IDE

MacPython ships with the standard IDLE development environment. A good introduction to using IDLE can be found at http://www.hashcollision.org/hkn/python/idle_intro/index.html.

5.3. Installing Additional Python Packages

There are several methods to install additional Python packages:

- Packages can be installed via the standard Python distutils mode (`python setup.py install`).
- Many packages can also be installed via the **setuptools** extension or **pip** wrapper, see https://pip.pypa.io/.

5.4. GUI Programming on the Mac

There are several options for building GUI applications on the Mac with Python.

PyObjC is a Python binding to Apple's Objective-C/Cocoa framework, which is the foundation of most modern Mac development. Information on PyObjC is available from https://pypi.org/project/pyobjc/.

The standard Python GUI toolkit is **`tkinter`**, based on the cross-platform Tk toolkit (https://www.tcl.tk). An Aqua-native version of Tk is bundled with OS X by Apple, and the latest version can be downloaded and installed from https://www.activestate.com; it can also be built from source.

wxPython is another popular cross-platform GUI toolkit that runs natively on macOS. Packages and documentation are available from https://www.wxpython.org.

PyQt is another popular cross-platform GUI toolkit that runs natively on macOS. More information can be found at https://riverbankcomputing.com/software/pyqt/intro.

5.5. Distributing Python Applications on the Mac

The standard tool for deploying standalone Python applications on the Mac is **py2app**. More information on installing and using py2app can be found at https://pypi.org/project/py2app/.

5.6. Other Resources

The MacPython mailing list is an excellent support resource for Python users and developers on the Mac:

https://www.python.org/community/sigs/current/pythonmac-sig/

Another useful resource is the MacPython wiki:

https://wiki.python.org/moin/MacPython

6. Editors and IDEs

There are a number of IDEs that support Python programming language. Many editors and IDEs provide syntax highlighting, debugging tools, and **PEP 8** [https://peps.python.org/pep-0008/] checks.

Please go to Python Editors [https://wiki.python.org/moin/PythonEditors] and Integrated Development Environments [https://wiki.python.org/moin/IntegratedDevelopmentEnvironments] for a comprehensive list.

The Python Language Reference

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in The Python Standard Library. For an informal introduction to the language, see The Python Tutorial. For C or C++ programmers, two additional manuals exist: Extending and Embedding the Python Interpreter describes the high-level picture of how to write a Python extension module, and the Python/C API Reference Manual describes the interfaces available to C/C++ programmers in detail.

1. Introduction

This reference manual describes the Python programming language. It is not intended as a tutorial.

While I am trying to be as precise as possible, I chose to use English rather than formal specifications for everything except syntax and lexical analysis. This should make the document more understandable to the average reader, but will leave room for ambiguities. Consequently, if you were coming from Mars and tried to re-implement Python from this document alone, you might have to guess things and in fact you would probably end up implementing quite a different language. On the other hand, if you are using Python and wonder what the precise rules about a particular area of the language are, you should definitely be able to find them here. If you would like to see a more formal definition of the language, maybe you could volunteer your time — or invent a cloning machine :-).

It is dangerous to add too many implementation details to a language reference document — the implementation may change, and other implementations of the same language may work differently. On the other hand, CPython is the one Python implementation in widespread use (although alternate implementations continue to gain support), and its particular quirks are sometimes worth being mentioned, especially where the implementation imposes additional limitations. Therefore, you'll find short "implementation notes" sprinkled throughout the text.

Every Python implementation comes with a number of built-in and standard modules. These are documented in The Python Standard Library. A few built-in modules are mentioned when they interact in a significant way with the language definition.

1.1. Alternate Implementations

Though there is one Python implementation which is by far the most popular, there are some alternate implementations which are of particular interest to different audiences.

Known implementations include:

CPython
: This is the original and most-maintained implementation of Python, written in C. New language features generally appear here first.

Jython
: Python implemented in Java. This implementation can be used as a scripting language for Java applications, or can be used to create applications using the Java class libraries. It is also often used to create tests for Java libraries. More information can be found at the Jython website [https://www.jython.org/].

Python for .NET
: This implementation actually uses the CPython implementation, but is a managed .NET application and makes .NET libraries available. It was created by Brian Lloyd. For more information, see the Python for .NET home page [https://pythonnet.github.io/].

IronPython
: An alternate Python for .NET. Unlike Python.NET, this is a complete Python implementation that generates IL, and compiles Python code directly to .NET assemblies. It was created by Jim Hugunin, the original creator of Jython. For more information, see the IronPython website [https://ironpython.net/].

PyPy
: An implementation of Python written completely in Python. It supports several advanced features not found in other implementations like stackless support and a Just in Time compiler. One of the goals of the project is to encourage experimentation with the language itself by making it easier to modify the interpreter (since it is written in Python).

> Additional information is available on the PyPy project's home page [https://pypy.org/].

Each of these implementations varies in some way from the language as documented in this manual, or introduces specific information beyond what's covered in the standard Python documentation. Please refer to the implementation-specific documentation to determine what else you need to know about the specific implementation you're using.

1.2. Notation

The descriptions of lexical analysis and syntax use a modified BNF grammar notation. This uses the following style of definition:

```
name       ::=  lc_letter (lc_letter | "_")*
lc_letter  ::=  "a"..."z"
```

The first line says that a `name` is an `lc_letter` followed by a sequence of zero or more `lc_letter`s and underscores. An `lc_letter` in turn is any of the single characters `'a'` through `'z'`. (This rule is actually adhered to for the names defined in lexical and grammar rules in this document.)

Each rule begins with a name (which is the name defined by the rule) and `::=`. A vertical bar (`|`) is used to separate alternatives; it is the least binding operator in this notation. A star (`*`) means zero or more repetitions of the preceding item; likewise, a plus (`+`) means one or more repetitions, and a phrase enclosed in square brackets (`[ ]`) means zero or one occurrences (in other words, the enclosed phrase is optional). The `*` and `+` operators bind as tightly as possible; parentheses are used for grouping. Literal strings are enclosed in quotes. White space is only meaningful to separate tokens. Rules are normally contained on a single line; rules with many alternatives may be formatted alternatively with each line after the first beginning with a vertical bar.

In lexical definitions (as the example above), two more conventions are used: Two literal characters separated by three dots mean a choice of any single character in the given (inclusive) range of

ASCII characters. A phrase between angular brackets (<. . .>) gives an informal description of the symbol defined; e.g., this could be used to describe the notion of ‘control character’ if needed.

Even though the notation used is almost the same, there is a big difference between the meaning of lexical and syntactic definitions: a lexical definition operates on the individual characters of the input source, while a syntax definition operates on the stream of tokens generated by the lexical analysis. All uses of BNF in the next chapter (“Lexical Analysis”) are lexical definitions; uses in subsequent chapters are syntactic definitions.

2. Lexical analysis

A Python program is read by a *parser*. Input to the parser is a stream of *tokens*, generated by the *lexical analyzer*. This chapter describes how the lexical analyzer breaks a file into tokens.

Python reads program text as Unicode code points; the encoding of a source file can be given by an encoding declaration and defaults to UTF-8, see **PEP 3120** [https://peps.python.org/pep-3120/] for details. If the source file cannot be decoded, a `SyntaxError` is raised.

2.1. Line structure

A Python program is divided into a number of *logical lines*.

2.1.1. Logical lines

The end of a logical line is represented by the token NEWLINE. Statements cannot cross logical line boundaries except where NEWLINE is allowed by the syntax (e.g., between statements in compound statements). A logical line is constructed from one or more *physical lines* by following the explicit or implicit *line joining* rules.

2.1.2. Physical lines

A physical line is a sequence of characters terminated by an end-of-line sequence. In source files and strings, any of the standard platform line termination sequences can be used - the Unix form using ASCII LF (linefeed), the Windows form using the ASCII sequence CR LF (return followed by linefeed), or the old Macintosh form using the ASCII CR (return) character. All of these forms can be used equally, regardless of platform. The end of input also serves as an implicit terminator for the final physical line.

When embedding Python, source code strings should be passed to Python APIs using the standard C conventions for newline characters (the `\n` character, representing ASCII LF, is the line terminator).

2.1.3. Comments

A comment starts with a hash character (`#`) that is not part of a string literal, and ends at the end of the physical line. A comment signifies the end of the logical line unless the implicit line joining rules are invoked. Comments are ignored by the syntax.

2.1.4. Encoding declarations

If a comment in the first or second line of the Python script matches the regular expression `coding[=:]\s*([-\w.]+)`, this comment is processed as an encoding declaration; the first group of this expression names the encoding of the source code file. The encoding declaration must appear on a line of its own. If it is the second line, the first line must also be a comment-only line. The recommended forms of an encoding expression are

```
# -*- coding: <encoding-name> -*-
```

which is recognized also by GNU Emacs, and

```
# vim:fileencoding=<encoding-name>
```

which is recognized by Bram Moolenaar's VIM.

If no encoding declaration is found, the default encoding is UTF-8. In addition, if the first bytes of the file are the UTF-8 byte-order mark (`b'\xef\xbb\xbf'`), the declared file encoding is UTF-8 (this is supported, among others, by Microsoft's **notepad**).

If an encoding is declared, the encoding name must be recognized by Python (see Standard Encodings). The encoding is used for all lexical analysis, including string literals, comments and identifiers.

2.1.5. Explicit line joining

Two or more physical lines may be joined into logical lines using backslash characters (\), as follows: when a physical line ends in a backslash that is not part of a string literal or comment, it is joined with the following forming a single logical line, deleting the backslash and the following end-of-line character. For example:

```
if 1900 < year < 2100 and 1 <= month <= 12 \
   and 1 <= day <= 31 and 0 <= hour < 24 \
   and 0 <= minute < 60 and 0 <= second < 60:   # Looks
        return 1
```

A line ending in a backslash cannot carry a comment. A backslash does not continue a comment. A backslash does not continue a token except for string literals (i.e., tokens other than string literals cannot be split across physical lines using a backslash). A backslash is illegal elsewhere on a line outside a string literal.

2.1.6. Implicit line joining

Expressions in parentheses, square brackets or curly braces can be split over more than one physical line without using backslashes. For example:

```
month_names = ['Januari', 'Februari', 'Maart',      # Th
               'April',   'Mei',      'Juni',       # Du
               'Juli',    'Augustus', 'September',  # fo
               'Oktober', 'November', 'December']   # of
```

Implicitly continued lines can carry comments. The indentation of the continuation lines is not important. Blank continuation lines are allowed. There is no NEWLINE token between implicit continuation lines. Implicitly continued lines can also occur within triple-quoted strings (see below); in that case they cannot carry comments.

2.1.7. Blank lines

A logical line that contains only spaces, tabs, formfeeds and possibly a comment, is ignored (i.e., no NEWLINE token is generated). During interactive input of statements, handling of a blank line may differ depending on the implementation of the read-

eval-print loop. In the standard interactive interpreter, an entirely blank logical line (i.e. one containing not even whitespace or a comment) terminates a multi-line statement.

2.1.8. Indentation

Leading whitespace (spaces and tabs) at the beginning of a logical line is used to compute the indentation level of the line, which in turn is used to determine the grouping of statements.

Tabs are replaced (from left to right) by one to eight spaces such that the total number of characters up to and including the replacement is a multiple of eight (this is intended to be the same rule as used by Unix). The total number of spaces preceding the first non-blank character then determines the line's indentation. Indentation cannot be split over multiple physical lines using backslashes; the whitespace up to the first backslash determines the indentation.

Indentation is rejected as inconsistent if a source file mixes tabs and spaces in a way that makes the meaning dependent on the worth of a tab in spaces; a `TabError` is raised in that case.

Cross-platform compatibility note: because of the nature of text editors on non-UNIX platforms, it is unwise to use a mixture of spaces and tabs for the indentation in a single source file. It should also be noted that different platforms may explicitly limit the maximum indentation level.

A formfeed character may be present at the start of the line; it will be ignored for the indentation calculations above. Formfeed characters occurring elsewhere in the leading whitespace have an undefined effect (for instance, they may reset the space count to zero).

The indentation levels of consecutive lines are used to generate INDENT and DEDENT tokens, using a stack, as follows.

Before the first line of the file is read, a single zero is pushed on the stack; this will never be popped off again. The numbers pushed on the stack will always be strictly increasing from bottom to top. At

the beginning of each logical line, the line's indentation level is compared to the top of the stack. If it is equal, nothing happens. If it is larger, it is pushed on the stack, and one INDENT token is generated. If it is smaller, it *must* be one of the numbers occurring on the stack; all numbers on the stack that are larger are popped off, and for each number popped off a DEDENT token is generated. At the end of the file, a DEDENT token is generated for each number remaining on the stack that is larger than zero.

Here is an example of a correctly (though confusingly) indented piece of Python code:

```
def perm(l):
        # Compute the list of all permutations of l
    if len(l) <= 1:
                  return [l]
    r = []
    for i in range(len(l)):
             s = l[:i] + l[i+1:]
             p = perm(s)
             for x in p:
              r.append(l[i:i+1] + x)
    return r
```

The following example shows various indentation errors:

```
 def perm(l):                           # error: first line
for i in range(len(l)):                 # error: not indente
    s = l[:i] + l[i+1:]
        p = perm(l[:i] + l[i+1:])   # error: unexpected
        for x in p:
                r.append(l[i:i+1] + x)
            return r                    # error: inconsister
```

(Actually, the first three errors are detected by the parser; only the last error is found by the lexical analyzer — the indentation of `return r` does not match a level popped off the stack.)

2.1.9. Whitespace between tokens

Except at the beginning of a logical line or in string literals, the whitespace characters space, tab and formfeed can be used interchangeably to separate tokens. Whitespace is needed between two tokens only if their concatenation could otherwise be interpreted as a different token (e.g., ab is one token, but a b is two tokens).

2.2. Other tokens

Besides NEWLINE, INDENT and DEDENT, the following categories of tokens exist: *identifiers*, *keywords*, *literals*, *operators*, and *delimiters*. Whitespace characters (other than line terminators, discussed earlier) are not tokens, but serve to delimit tokens. Where ambiguity exists, a token comprises the longest possible string that forms a legal token, when read from left to right.

2.3. Identifiers and keywords

Identifiers (also referred to as *names*) are described by the following lexical definitions.

The syntax of identifiers in Python is based on the Unicode standard annex UAX-31, with elaboration and changes as defined below; see also **PEP 3131** [https://peps.python.org/pep-3131/] for further details.

Within the ASCII range (U+0001..U+007F), the valid characters for identifiers are the same as in Python 2.x: the uppercase and lowercase letters `A` through `Z`, the underscore `_` and, except for the first character, the digits `0` through `9`.

Python 3.0 introduces additional characters from outside the ASCII range (see **PEP 3131** [https://peps.python.org/pep-3131/]). For these characters, the classification uses the version of the Unicode Character Database as included in the **`unicodedata`** module.

Identifiers are unlimited in length. Case is significant.

```
identifier   ::=  xid_start xid_continue*
id_start     ::=  <all characters in general categories
id_continue  ::=  <all characters in id_start, plus char
```

```
xid_start     ::=  <all characters in id_start whose NFKC
xid_continue  ::=  <all characters in id_continue whose N
```

The Unicode category codes mentioned above stand for:

- *Lu* - uppercase letters
- *Ll* - lowercase letters
- *Lt* - titlecase letters
- *Lm* - modifier letters
- *Lo* - other letters
- *Nl* - letter numbers
- *Mn* - nonspacing marks
- *Mc* - spacing combining marks
- *Nd* - decimal numbers
- *Pc* - connector punctuations
- *Other_ID_Start* - explicit list of characters in PropList.txt [https://www.unicode.org/Public/14.0.0/ucd/PropList.txt] to support backwards compatibility
- *Other_ID_Continue* - likewise

All identifiers are converted into the normal form NFKC while parsing; comparison of identifiers is based on NFKC.

A non-normative HTML file listing all valid identifier characters for Unicode 14.0.0 can be found at https://www.unicode.org/Public/14.0.0/ucd/DerivedCoreProperties.txt

2.3.1. Keywords

The following identifiers are used as reserved words, or *keywords* of the language, and cannot be used as ordinary identifiers. They must be spelled exactly as written here:

```
False      await      else       import     pass
None       break      except     in         raise
True       class      finally    is         return
and        continue   for        lambda     try
as         def        from       nonlocal   while
assert     del        global     not        with
async      elif       if         or         yield
```

2.3.2. Soft Keywords

New in version 3.10.

Some identifiers are only reserved under specific contexts. These are known as *soft keywords*. The identifiers `match`, `case` and `_` can syntactically act as keywords in contexts related to the pattern matching statement, but this distinction is done at the parser level, not when tokenizing.

As soft keywords, their use with pattern matching is possible while still preserving compatibility with existing code that uses `match`, `case` and `_` as identifier names.

2.3.3. Reserved classes of identifiers

Certain classes of identifiers (besides keywords) have special meanings. These classes are identified by the patterns of leading and trailing underscore characters:

`_*`

Not imported by `from module import *`.

`_`

In a `case` pattern within a **`match`** statement, `_` is a soft keyword that denotes a wildcard.

Separately, the interactive interpreter makes the result of the last evaluation available in the variable `_`. (It is stored in the **`builtins`** module, alongside built-in functions like `print`.)

Elsewhere, `_` is a regular identifier. It is often used to name "special" items, but it is not special to Python itself.

Note

The name `_` is often used in conjunction with internationalization; refer to the documentation for the **`gettext`** module for more information on this convention.

It is also commonly used for unused variables.

__*__

System-defined names, informally known as “dunder” names. These names are defined by the interpreter and its implementation (including the standard library). Current system names are discussed in the Special method names section and elsewhere. More will likely be defined in future versions of Python. *Any* use of __*__ names, in any context, that does not follow explicitly documented use, is subject to breakage without warning.

__*

Class-private names. Names in this category, when used within the context of a class definition, are re-written to use a mangled form to help avoid name clashes between “private” attributes of base and derived classes. See section Identifiers (Names).

2.4. Literals

Literals are notations for constant values of some built-in types.

2.4.1. String and Bytes literals

String literals are described by the following lexical definitions:

```
stringliteral   ::=  [stringprefix](shortstring | longst
stringprefix    ::=  "r" | "u" | "R" | "U" | "f" | "F"
                     | "fr" | "Fr" | "fR" | "FR" | "rf"
shortstring     ::=  "'" shortstringitem* "'" | '"' shor
longstring      ::=  "'''" longstringitem* "'''" | '"""'
shortstringitem ::=  shortstringchar | stringescapeseq
longstringitem  ::=  longstringchar | stringescapeseq
shortstringchar ::=  <any source character except "\" or
longstringchar  ::=  <any source character except "\">
stringescapeseq ::=  "\" <any source character>

bytesliteral    ::=  bytesprefix(shortbytes | longbytes)
bytesprefix     ::=  "b" | "B" | "br" | "Br" | "bR" | "BR
```

```
shortbytes     ::=  "'" shortbytesitem* "'" | '"' shortb
longbytes      ::=  "'''" longbytesitem* "'''" | '"""' l
shortbytesitem ::=  shortbyteschar | bytesescapeseq
longbytesitem  ::=  longbyteschar | bytesescapeseq
shortbyteschar ::=  <any ASCII character except "\" or n
longbyteschar  ::=  <any ASCII character except "\">
bytesescapeseq ::=  "\" <any ASCII character>
```

One syntactic restriction not indicated by these productions is that whitespace is not allowed between the **stringprefix** or **bytesprefix** and the rest of the literal. The source character set is defined by the encoding declaration; it is UTF-8 if no encoding declaration is given in the source file; see section Encoding declarations.

In plain English: Both types of literals can be enclosed in matching single quotes (`'`) or double quotes (`"`). They can also be enclosed in matching groups of three single or double quotes (these are generally referred to as *triple-quoted strings*). The backslash (`\`) character is used to escape characters that otherwise have a special meaning, such as newline, backslash itself, or the quote character.

Bytes literals are always prefixed with `'b'` or `'B'`; they produce an instance of the **bytes** type instead of the **str** type. They may only contain ASCII characters; bytes with a numeric value of 128 or greater must be expressed with escapes.

Both string and bytes literals may optionally be prefixed with a letter `'r'` or `'R'`; such strings are called *raw strings* and treat backslashes as literal characters. As a result, in string literals, `'\U'` and `'\u'` escapes in raw strings are not treated specially. Given that Python 2.x's raw unicode literals behave differently than Python 3.x's the `'ur'` syntax is not supported.

New in version 3.3: The `'rb'` prefix of raw bytes literals has been added as a synonym of `'br'`.

New in version 3.3: Support for the unicode legacy literal (`u'value'`) was reintroduced to simplify the maintenance of dual Python 2.x and 3.x codebases. See **PEP 414** [https://peps.python.org/pep-0414/] for more information.

A string literal with `'f'` or `'F'` in its prefix is a *formatted string literal*; see Formatted string literals. The `'f'` may be combined with `'r'`, but not with `'b'` or `'u'`, therefore raw formatted strings are possible, but formatted bytes literals are not.

In triple-quoted literals, unescaped newlines and quotes are allowed (and are retained), except that three unescaped quotes in a row terminate the literal. (A "quote" is the character used to open the literal, i.e. either `'` or `"`.)

Unless an `'r'` or `'R'` prefix is present, escape sequences in string and bytes literals are interpreted according to rules similar to those used by Standard C. The recognized escape sequences are:

Escape Sequence	Meaning	Notes
`\<newline>`	Backslash and newline ignored	(1)
`\\`	Backslash (`\`)	
`\'`	Single quote (`'`)	
`\"`	Double quote (`"`)	
`\a`	ASCII Bell (BEL)	
`\b`	ASCII Backspace (BS)	
`\f`	ASCII Formfeed (FF)	
`\n`	ASCII Linefeed (LF)	
`\r`	ASCII Carriage Return (CR)	
`\t`	ASCII Horizontal Tab (TAB)	
`\v`	ASCII Vertical Tab (VT)	
`\ooo`	Character with octal value *ooo*	(2,4)
`\xhh`	Character with hex value *hh*	(3,4)

Escape sequences only recognized in string literals are:

Escape Sequence	Meaning	Notes
`\N{name}`	Character named *name* in the Unicode database	(5)
`\uxxxx`	Character with 16-bit hex value *xxxx*	(6)
`\Uxxxxxxxx`	Character with 32-bit hex value *xxxxxxxx*	(7)

Notes:

1. A backslash can be added at the end of a line to ignore the newline:

```
>>> 'This string will not include \
... backslashes or newline characters.'
'This string will not include backslashes or newlin
```

The same result can be achieved using triple-quoted strings, or parentheses and string literal concatenation.

2. As in Standard C, up to three octal digits are accepted.

   Changed in version 3.11: Octal escapes with value larger than `0o377` produce a **DeprecationWarning**. In a future Python version they will be a **SyntaxWarning** and eventually a **SyntaxError**.

3. Unlike in Standard C, exactly two hex digits are required.

4. In a bytes literal, hexadecimal and octal escapes denote the byte with the given value. In a string literal, these escapes denote a Unicode character with the given value.

5. *Changed in version 3.3:* Support for name aliases 1 has been added.

6. Exactly four hex digits are required.

7. Any Unicode character can be encoded this way. Exactly eight hex digits are required.

Unlike Standard C, all unrecognized escape sequences are left in the string unchanged, i.e., *the backslash is left in the result.* (This behavior is useful when debugging: if an escape sequence is mistyped, the resulting output is more easily recognized as broken.) It is also important to note that the escape sequences only recognized in string literals fall into the category of unrecognized escapes for bytes literals.

> *Changed in version 3.6:* Unrecognized escape sequences produce a **DeprecationWarning**. In a future Python version they will be a **SyntaxWarning** and eventually a **SyntaxError**.

Even in a raw literal, quotes can be escaped with a backslash, but

the backslash remains in the result; for example, `r"\""` is a valid string literal consisting of two characters: a backslash and a double quote; `r"\"` is not a valid string literal (even a raw string cannot end in an odd number of backslashes). Specifically, *a raw literal cannot end in a single backslash* (since the backslash would escape the following quote character). Note also that a single backslash followed by a newline is interpreted as those two characters as part of the literal, *not* as a line continuation.

2.4.2. String literal concatenation

Multiple adjacent string or bytes literals (delimited by whitespace), possibly using different quoting conventions, are allowed, and their meaning is the same as their concatenation. Thus, `"hello" 'world'` is equivalent to `"helloworld"`. This feature can be used to reduce the number of backslashes needed, to split long strings conveniently across long lines, or even to add comments to parts of strings, for example:

```
re.compile("[A-Za-z_]"       # letter or underscore
           "[A-Za-z0-9_]*"   # letter, digit or underscc
          )
```

Note that this feature is defined at the syntactical level, but implemented at compile time. The '+' operator must be used to concatenate string expressions at run time. Also note that literal concatenation can use different quoting styles for each component (even mixing raw strings and triple quoted strings), and formatted string literals may be concatenated with plain string literals.

2.4.3. Formatted string literals

New in version 3.6.

A *formatted string literal* or *f-string* is a string literal that is prefixed with `'f'` or `'F'`. These strings may contain replacement fields, which are expressions delimited by curly braces `{}`. While other string literals always have a constant value, formatted strings are really expressions evaluated at run time.

Escape sequences are decoded like in ordinary string literals (except when a literal is also marked as a raw string). After decoding, the grammar for the contents of the string is:

```
f_string          ::=  (literal_char | "{{" | "}}" | rep
replacement_field ::=  "{" f_expression ["="] ["!" conve
f_expression      ::=  (conditional_expression | "*" or_
                         ("," conditional_expression | "
                       | yield_expression
conversion        ::=  "s" | "r" | "a"
format_spec       ::=  (literal_char | NULL | replacemen
literal_char      ::=  <any code point except "{", "}" c
```

The parts of the string outside curly braces are treated literally, except that any doubled curly braces `'{{'` or `'}}'` are replaced with the corresponding single curly brace. A single opening curly bracket `'{'` marks a replacement field, which starts with a Python expression. To display both the expression text and its value after evaluation, (useful in debugging), an equal sign `'='` may be added after the expression. A conversion field, introduced by an exclamation point `'!'` may follow. A format specifier may also be appended, introduced by a colon `':'`. A replacement field ends with a closing curly bracket `'}'`.

Expressions in formatted string literals are treated like regular Python expressions surrounded by parentheses, with a few exceptions. An empty expression is not allowed, and both `lambda` and assignment expressions `:=` must be surrounded by explicit parentheses. Replacement expressions can contain line breaks (e.g. in triple-quoted strings), but they cannot contain comments. Each expression is evaluated in the context where the formatted string literal appears, in order from left to right.

Changed in version 3.7: Prior to Python 3.7, an `await` expression and comprehensions containing an `async for` clause were illegal in the expressions in formatted string literals due to a problem with the implementation.

When the equal sign `'='` is provided, the output will have the expression text, the `'='` and the evaluated value. Spaces after the

opening brace `'{'`, within the expression and after the `'='` are all retained in the output. By default, the `'='` causes the **`repr()`** of the expression to be provided, unless there is a format specified. When a format is specified it defaults to the **`str()`** of the expression unless a conversion `'!r'` is declared.

New in version 3.8: The equal sign `'='`.

If a conversion is specified, the result of evaluating the expression is converted before formatting. Conversion `'!s'` calls **`str()`** on the result, `'!r'` calls **`repr()`**, and `'!a'` calls **`ascii()`**.

The result is then formatted using the **`format()`** protocol. The format specifier is passed to the **`__format__()`** method of the expression or conversion result. An empty string is passed when the format specifier is omitted. The formatted result is then included in the final value of the whole string.

Top-level format specifiers may include nested replacement fields. These nested fields may include their own conversion fields and format specifiers, but may not include more deeply nested replacement fields. The format specifier mini-language is the same as that used by the **`str.format()`** method.

Formatted string literals may be concatenated, but replacement fields cannot be split across literals.

Some examples of formatted string literals:

```
>>> name = "Fred"
>>> f"He said his name is {name!r}."
"He said his name is 'Fred'."
>>> f"He said his name is {repr(name)}."  # repr() is eq
"He said his name is 'Fred'."
>>> width = 10
>>> precision = 4
>>> value = decimal.Decimal("12.34567")
>>> f"result: {value:{width}.{precision}}"  # nested fie
'result:      12.35'
>>> today = datetime(year=2017, month=1, day=27)
>>> f"{today:%B %d, %Y}"  # using date format specifier
```

```
'January 27, 2017'
>>> f"{today=:%B %d, %Y}" # using date format specifier
'today=January 27, 2017'
>>> number = 1024
>>> f"{number:#0x}"  # using integer format specifier
'0x400'
>>> foo = "bar"
>>> f"{ foo = }" # preserves whitespace
" foo = 'bar'"
>>> line = "The mill's closed"
>>> f"{line = }"
'line = "The mill\'s closed"'
>>> f"{line = :20}"
"line = The mill's closed   "
>>> f"{line = !r:20}"
'line = "The mill\'s closed" '
```

A consequence of sharing the same syntax as regular string literals is that characters in the replacement fields must not conflict with the quoting used in the outer formatted string literal:

```
f"abc {a["x"]} def"    # error: outer string literal enc
f"abc {a['x']} def"    # workaround: use different quoti
```

Backslashes are not allowed in format expressions and will raise an error:

```
f"newline: {ord('\n')}"  # raises SyntaxError
```

To include a value in which a backslash escape is required, create a temporary variable.

```
>>> newline = ord('\n')
>>> f"newline: {newline}"
'newline: 10'
```

Formatted string literals cannot be used as docstrings, even if they do not include expressions.

```
>>> def foo():
```

```
...     f"Not a docstring"
...
>>> foo.__doc__ is None
True
```

See also **PEP 498** [https://peps.python.org/pep-0498/] for the proposal that added formatted string literals, and **`str.format()`**, which uses a related format string mechanism.

2.4.4. Numeric literals

There are three types of numeric literals: integers, floating point numbers, and imaginary numbers. There are no complex literals (complex numbers can be formed by adding a real number and an imaginary number).

Note that numeric literals do not include a sign; a phrase like `-1` is actually an expression composed of the unary operator '–' and the literal `1`.

2.4.5. Integer literals

Integer literals are described by the following lexical definitions:

```
integer      ::=  decinteger | bininteger | octinteger |
decinteger   ::=  nonzerodigit (["_"] digit)* | "0"+ (["
bininteger   ::=  "0" ("b" | "B") (["_"] bindigit)+
octinteger   ::=  "0" ("o" | "O") (["_"] octdigit)+
hexinteger   ::=  "0" ("x" | "X") (["_"] hexdigit)+
nonzerodigit ::=  "1"..."9"
digit        ::=  "0"..."9"
bindigit     ::=  "0" | "1"
octdigit     ::=  "0"..."7"
hexdigit     ::=  digit | "a"..."f" | "A"..."F"
```

There is no limit for the length of integer literals apart from what can be stored in available memory.

Underscores are ignored for determining the numeric value of the literal. They can be used to group digits for enhanced readability.

One underscore can occur between digits, and after base specifiers like `0x`.

Note that leading zeros in a non-zero decimal number are not allowed. This is for disambiguation with C-style octal literals, which Python used before version 3.0.

Some examples of integer literals:

```
7     2147483647                        0o177    0b10011
3     79228162514264337593543950336     0o377    0xdeadb
      100_000_000_000                   0b_1110_0101
```

Changed in version 3.6: Underscores are now allowed for grouping purposes in literals.

2.4.6. Floating point literals

Floating point literals are described by the following lexical definitions:

```
floatnumber   ::=  pointfloat | exponentfloat
pointfloat    ::=  [digitpart] fraction | digitpart "."
exponentfloat ::=  (digitpart | pointfloat) exponent
digitpart     ::=  digit (["_"] digit)*
fraction      ::=  "." digitpart
exponent      ::=  ("e" | "E") ["+" | "-"] digitpart
```

Note that the integer and exponent parts are always interpreted using radix 10. For example, `077e010` is legal, and denotes the same number as `77e10`. The allowed range of floating point literals is implementation-dependent. As in integer literals, underscores are supported for digit grouping.

Some examples of floating point literals:

```
3.14    10.    .001    1e100    3.14e-10    0e0    3.14_
```

Changed in version 3.6: Underscores are now allowed for grouping purposes in literals.

2.4.7. Imaginary literals

Imaginary literals are described by the following lexical definitions:

```
imagnumber ::=  (floatnumber | digitpart) ("j" | "J")
```

An imaginary literal yields a complex number with a real part of 0.0. Complex numbers are represented as a pair of floating point numbers and have the same restrictions on their range. To create a complex number with a nonzero real part, add a floating point number to it, e.g., `(3+4j)`. Some examples of imaginary literals:

```
3.14j   10.j    10j     .001j   1e100j   3.14e-10j   3.1
```

2.5. Operators

The following tokens are operators:

```
+       -       *       **      /       //      %       @
<<      >>      &       |       ^       ~       :=
<       >       <=      >=      ==      !=
```

2.6. Delimiters

The following tokens serve as delimiters in the grammar:

```
(       )       [       ]       {       }
,       :       .       ;       @       =       ->
+=      -=      *=      /=      //=     %=      @=
&=      |=      ^=      >>=     <<=     **=
```

The period can also occur in floating-point and imaginary literals. A sequence of three periods has a special meaning as an ellipsis literal. The second half of the list, the augmented assignment operators, serve lexically as delimiters, but also perform an operation.

The following printing ASCII characters have special meaning as part of other tokens or are otherwise significant to the lexical

analyzer:

```
'       "       #       \
```

The following printing ASCII characters are not used in Python. Their occurrence outside string literals and comments is an unconditional error:

```
$       ?       `
```

3. Data model

3.1. Objects, values and types

Objects are Python's abstraction for data. All data in a Python program is represented by objects or by relations between objects. (In a sense, and in conformance to Von Neumann's model of a "stored program computer", code is also represented by objects.)

Every object has an identity, a type and a value. An object's *identity* never changes once it has been created; you may think of it as the object's address in memory. The '**`is`**' operator compares the identity of two objects; the **`id()`** function returns an integer representing its identity.

CPython implementation detail: For CPython, `id(x)` is the memory address where `x` is stored.

An object's type determines the operations that the object supports (e.g., "does it have a length?") and also defines the possible values for objects of that type. The **`type()`** function returns an object's type (which is an object itself). Like its identity, an object's *type* is also unchangeable. 1

The *value* of some objects can change. Objects whose value can change are said to be *mutable*; objects whose value is unchangeable once they are created are called *immutable*. (The value of an immutable container object that contains a reference to a mutable object can change when the latter's value is changed; however the container is still considered immutable, because the collection of objects it contains cannot be changed. So, immutability is not strictly the same as having an unchangeable value, it is more subtle.) An object's mutability is determined by its type; for instance, numbers, strings and tuples are immutable, while dictionaries and lists are mutable.

Objects are never explicitly destroyed; however, when they become unreachable they may be garbage-collected. An implementation is allowed to postpone garbage collection or omit it altogether — it is a matter of implementation quality how garbage collection is implemented, as long as no objects are collected that are still reachable.

CPython implementation detail: CPython currently uses a reference-counting scheme with (optional) delayed detection of cyclically linked garbage, which collects most objects as soon as they become unreachable, but is not guaranteed to collect garbage containing circular references. See the documentation of the `gc` module for information on controlling the collection of cyclic garbage. Other implementations act differently and CPython may change. Do not depend on immediate finalization of objects when they become unreachable (so you should always close files explicitly).

Note that the use of the implementation's tracing or debugging facilities may keep objects alive that would normally be collectable. Also note that catching an exception with a '`try`…`except`' statement may keep objects alive.

Some objects contain references to "external" resources such as open files or windows. It is understood that these resources are freed when the object is garbage-collected, but since garbage collection is not guaranteed to happen, such objects also provide an explicit way to release the external resource, usually a `close()` method. Programs are strongly recommended to explicitly close such objects. The '`try`…`finally`' statement and the '`with`' statement provide convenient ways to do this.

Some objects contain references to other objects; these are called *containers*. Examples of containers are tuples, lists and dictionaries. The references are part of a container's value. In most cases, when we talk about the value of a container, we imply the values, not the identities of the contained objects; however, when we talk about the mutability of a container, only the identities of the immediately contained objects are implied. So, if an immutable container (like a tuple) contains a reference to a mutable object, its value changes if that mutable object is changed.

Types affect almost all aspects of object behavior. Even the importance of object identity is affected in some sense: for immutable types, operations that compute new values may actually return a reference to any existing object with the same type and value, while for mutable objects this is not allowed. E.g., after `a = 1; b = 1`, `a` and `b` may or may not refer to the same object with the value one, depending on the implementation, but after `c = []; d = []`, `c` and `d` are guaranteed to refer to two different, unique, newly created empty lists. (Note that `c = d = []` assigns the same object to both `c` and `d`.)

3.2. The standard type hierarchy

Below is a list of the types that are built into Python. Extension modules (written in C, Java, or other languages, depending on the implementation) can define additional types. Future versions of Python may add types to the type hierarchy (e.g., rational numbers, efficiently stored arrays of integers, etc.), although such additions will often be provided via the standard library instead.

Some of the type descriptions below contain a paragraph listing 'special attributes.' These are attributes that provide access to the implementation and are not intended for general use. Their definition may change in the future.

None

> This type has a single value. There is a single object with this value. This object is accessed through the built-in name `None`. It is used to signify the absence of a value in many situations, e.g., it is returned from functions that don't explicitly return anything. Its truth value is false.

NotImplemented

> This type has a single value. There is a single object with this value. This object is accessed through the built-in name `NotImplemented`. Numeric methods and rich comparison methods should return this value if they do not implement the operation for the operands provided. (The interpreter will then try the reflected operation, or some other fallback,

depending on the operator.) It should not be evaluated in a boolean context.

See Implementing the arithmetic operations for more details.

Changed in version 3.9: Evaluating `NotImplemented` in a boolean context is deprecated. While it currently evaluates as true, it will emit a **`DeprecationWarning`**. It will raise a **`TypeError`** in a future version of Python.

Ellipsis

This type has a single value. There is a single object with this value. This object is accessed through the literal `...` or the built-in name `Ellipsis`. Its truth value is true.

`numbers.Number`

These are created by numeric literals and returned as results by arithmetic operators and arithmetic built-in functions. Numeric objects are immutable; once created their value never changes. Python numbers are of course strongly related to mathematical numbers, but subject to the limitations of numerical representation in computers.

The string representations of the numeric classes, computed by **`__repr__()`** and **`__str__()`**, have the following properties:

- They are valid numeric literals which, when passed to their class constructor, produce an object having the value of the original numeric.
- The representation is in base 10, when possible.
- Leading zeros, possibly excepting a single zero before a decimal point, are not shown.
- Trailing zeros, possibly excepting a single zero after a decimal point, are not shown.
- A sign is shown only when the number is negative.

Python distinguishes between integers, floating point numbers, and complex numbers:

`numbers.Integral`

These represent elements from the mathematical set of integers (positive and negative).

There are two types of integers:

Integers (**`int`**)

These represent numbers in an unlimited range, subject to available (virtual) memory only. For the purpose of shift and mask operations, a binary representation is assumed, and negative numbers are represented in a variant of 2's complement which gives the illusion of an infinite string of sign bits extending to the left.

Booleans (**`bool`**)

These represent the truth values False and True. The two objects representing the values `False` and `True` are the only Boolean objects. The Boolean type is a subtype of the integer type, and Boolean values behave like the values 0 and 1, respectively, in almost all contexts, the exception being that when converted to a string, the strings `"False"` or `"True"` are returned, respectively.

The rules for integer representation are intended to give the most meaningful interpretation of shift and mask operations involving negative integers.

`numbers.Real` (**`float`**)

These represent machine-level double precision floating point numbers. You are at the mercy of the underlying machine architecture (and C or Java implementation) for the accepted range and handling of overflow. Python does not support single-precision floating point numbers; the savings in processor and memory usage that are usually the reason for using these are dwarfed by the overhead of using objects in Python, so there is no reason to complicate the language with two kinds of floating point numbers.

numbers.Complex (**complex**)

These represent complex numbers as a pair of machine-level double precision floating point numbers. The same caveats apply as for floating point numbers. The real and imaginary parts of a complex number `z` can be retrieved through the read-only attributes `z.real` and `z.imag`.

Sequences

These represent finite ordered sets indexed by non-negative numbers. The built-in function **`len()`** returns the number of items of a sequence. When the length of a sequence is *n*, the index set contains the numbers 0, 1, …, *n*-1. Item *i* of sequence *a* is selected by `a[i]`.

Sequences also support slicing: `a[i:j]` selects all items with index *k* such that *i* `<=` *k* `<` *j*. When used as an expression, a slice is a sequence of the same type. This implies that the index set is renumbered so that it starts at 0.

Some sequences also support "extended slicing" with a third "step" parameter: `a[i:j:k]` selects all items of *a* with index *x* where `x = i + n*k`, *n* `>= 0` and *i* `<=` *x* `<` *j*.

Sequences are distinguished according to their mutability:

Immutable sequences

An object of an immutable sequence type cannot change once it is created. (If the object contains references to other objects, these other objects may be mutable and may be changed; however, the collection of objects directly referenced by an immutable object cannot change.)

The following types are immutable sequences:

Strings

A string is a sequence of values that represent Unicode code points. All the code points in the range `U+0000 - U+10FFFF` can be represented

in a string. Python doesn't have a char type; instead, every code point in the string is represented as a string object with length `1`. The built-in function **`ord()`** converts a code point from its string form to an integer in the range `0 - 10FFFF`; **`chr()`** converts an integer in the range `0 - 10FFFF` to the corresponding length `1` string object. **`str.encode()`** can be used to convert a **`str`** to **`bytes`** using the given text encoding, and **`bytes.decode()`** can be used to achieve the opposite.

Tuples

The items of a tuple are arbitrary Python objects. Tuples of two or more items are formed by comma-separated lists of expressions. A tuple of one item (a 'singleton') can be formed by affixing a comma to an expression (an expression by itself does not create a tuple, since parentheses must be usable for grouping of expressions). An empty tuple can be formed by an empty pair of parentheses.

Bytes

A bytes object is an immutable array. The items are 8-bit bytes, represented by integers in the range 0 <= x < 256. Bytes literals (like `b'abc'`) and the built-in **`bytes()`** constructor can be used to create bytes objects. Also, bytes objects can be decoded to strings via the **`decode()`** method.

Mutable sequences

Mutable sequences can be changed after they are created. The subscription and slicing notations can be used as the target of assignment and **`del`** (delete) statements.

There are currently two intrinsic mutable sequence types:

Lists

The items of a list are arbitrary Python objects. Lists are formed by placing a comma-separated list of expressions in square brackets. (Note that there are no special cases needed to form lists of length 0 or 1.)

Byte Arrays

A bytearray object is a mutable array. They are created by the built-in **`bytearray()`** constructor. Aside from being mutable (and hence unhashable), byte arrays otherwise provide the same interface and functionality as immutable **`bytes`** objects.

The extension module **`array`** provides an additional example of a mutable sequence type, as does the **`collections`** module.

Set types

These represent unordered, finite sets of unique, immutable objects. As such, they cannot be indexed by any subscript. However, they can be iterated over, and the built-in function **`len()`** returns the number of items in a set. Common uses for sets are fast membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference.

For set elements, the same immutability rules apply as for dictionary keys. Note that numeric types obey the normal rules for numeric comparison: if two numbers compare equal (e.g., `1` and `1.0`), only one of them can be contained in a set.

There are currently two intrinsic set types:

Sets

These represent a mutable set. They are created by the built-in **`set()`** constructor and can be modified

afterwards by several methods, such as **`add()`**.

Frozen sets

These represent an immutable set. They are created by the built-in **`frozenset()`** constructor. As a frozenset is immutable and hashable, it can be used again as an element of another set, or as a dictionary key.

Mappings

These represent finite sets of objects indexed by arbitrary index sets. The subscript notation `a[k]` selects the item indexed by `k` from the mapping `a`; this can be used in expressions and as the target of assignments or **`del`** statements. The built-in function **`len()`** returns the number of items in a mapping.

There is currently a single intrinsic mapping type:

Dictionaries

These represent finite sets of objects indexed by nearly arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity, the reason being that the efficient implementation of dictionaries requires a key's hash value to remain constant. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g., `1` and `1.0`) then they can be used interchangeably to index the same dictionary entry.

Dictionaries preserve insertion order, meaning that keys will be produced in the same order they were added sequentially over the dictionary. Replacing an existing key does not change the order, however removing a key and re-inserting it will add it to the end instead of keeping its old place.

Dictionaries are mutable; they can be created by the `{...}` notation (see section Dictionary displays).

The extension modules `dbm.ndbm` and `dbm.gnu` provide additional examples of mapping types, as does the `collections` module.

Changed in version 3.7: Dictionaries did not preserve insertion order in versions of Python before 3.6. In CPython 3.6, insertion order was preserved, but it was considered an implementation detail at that time rather than a language guarantee.

Callable types

These are the types to which the function call operation (see section Calls) can be applied:

User-defined functions

A user-defined function object is created by a function definition (see section Function definitions). It should be called with an argument list containing the same number of items as the function's formal parameter list.

Special attributes:

Attribute	Meaning
`__doc__`	The function's documentation string, or `None` if unavailable; not inherited by subclasses.
`__name__`	The function's name.
`__qualname__`	The function's qualified name. *New in version 3.3.*
`__module__`	The name of the module the function was defined in, or `None` if unavailable.
`__defaults__`	A tuple containing default argument values for those arguments that have defaults, or `None` if no arguments have a default value.
`__code__`	The code object representing the compiled function body.
`__globals__`	A reference to the dictionary that holds the function's global variables — the global namespace of the module in which the function was defined.
`__dict__`	The namespace supporting arbitrary function attributes.

Read-only tuple of cells that contain bindings for the function's free variables. See below for information on the `cell_contents` attribute.

Writable dictionary annotations of parameters. The keys of the dict are the parameter names, and `'return'` for the return annotation, if provided. For more information on working with this attribute, see Annotations Best Practices.

Writable tuple containing defaults for keyword-only parameters.

Most of the attributes labelled "Writable" check the type of the assigned value.

Function objects also support getting and setting arbitrary attributes, which can be used, for example, to attach metadata to functions. Regular attribute dot-notation is used to get and set such attributes. *Note that the current implementation only supports function attributes on user-defined functions. Function attributes on built-in functions may be supported in the future.*

A cell object has the attribute `cell_contents`. This can be used to get the value of the cell, as well as set the value.

Additional information about a function's definition can be retrieved from its code object; see the description of internal types below. The **`cell`** type can be accessed in the **`types`** module.

Instance methods

An instance method object combines a class, a class instance and any callable object (normally a user-defined function).

Special read-only attributes: **`__self__`** is the class instance object, **`__func__`** is the function object; **`__doc__`** is the method's documentation (same as `__func__.__doc__`); **`__name__`** is the method name (same as `__func__.__name__`); **`__module__`** is the

name of the module the method was defined in, or `None` if unavailable.

Methods also support accessing (but not setting) the arbitrary function attributes on the underlying function object.

User-defined method objects may be created when getting an attribute of a class (perhaps via an instance of that class), if that attribute is a user-defined function object or a class method object.

When an instance method object is created by retrieving a user-defined function object from a class via one of its instances, its **`__self__`** attribute is the instance, and the method object is said to be bound. The new method's **`__func__`** attribute is the original function object.

When an instance method object is created by retrieving a class method object from a class or instance, its **`__self__`** attribute is the class itself, and its **`__func__`** attribute is the function object underlying the class method.

When an instance method object is called, the underlying function (**`__func__`**) is called, inserting the class instance (**`__self__`**) in front of the argument list. For instance, when **`C`** is a class which contains a definition for a function **`f()`**, and `x` is an instance of **`C`**, calling `x.f(1)` is equivalent to calling `C.f(x, 1)`.

When an instance method object is derived from a class method object, the "class instance" stored in **`__self__`** will actually be the class itself, so that calling either `x.f(1)` or `C.f(1)` is equivalent to calling `f(C,1)` where `f` is the underlying function.

Note that the transformation from function object to instance method object happens each time the attribute

is retrieved from the instance. In some cases, a fruitful optimization is to assign the attribute to a local variable and call that local variable. Also notice that this transformation only happens for user-defined functions; other callable objects (and all non-callable objects) are retrieved without transformation. It is also important to note that user-defined functions which are attributes of a class instance are not converted to bound methods; this *only* happens when the function is an attribute of the class.

Generator functions

A function or method which uses the **`yield`** statement (see section The yield statement) is called a *generator function*. Such a function, when called, always returns an iterator object which can be used to execute the body of the function: calling the iterator's **`iterator.__next__()`** method will cause the function to execute until it provides a value using the **`yield`** statement. When the function executes a **`return`** statement or falls off the end, a **`StopIteration`** exception is raised and the iterator will have reached the end of the set of values to be returned.

Coroutine functions

A function or method which is defined using **`async def`** is called a *coroutine function*. Such a function, when called, returns a coroutine object. It may contain **`await`** expressions, as well as **`async with`** and **`async for`** statements. See also the Coroutine Objects section.

Asynchronous generator functions

A function or method which is defined using **`async def`** and which uses the **`yield`** statement is called a *asynchronous generator function*. Such a function, when called, returns an asynchronous iterator object which can be used in an **`async for`** statement to execute the body of the function.

Calling the asynchronous iterator's `aiterator.__anext__` method will return an awaitable which when awaited will execute until it provides a value using the `yield` expression. When the function executes an empty `return` statement or falls off the end, a `StopAsyncIteration` exception is raised and the asynchronous iterator will have reached the end of the set of values to be yielded.

Built-in functions

A built-in function object is a wrapper around a C function. Examples of built-in functions are `len()` and `math.sin()` (`math` is a standard built-in module). The number and type of the arguments are determined by the C function. Special read-only attributes: **`__doc__`** is the function's documentation string, or `None` if unavailable; `__name__` is the function's name; **`__self__`** is set to `None` (but see the next item); **`__module__`** is the name of the module the function was defined in or `None` if unavailable.

Built-in methods

This is really a different disguise of a built-in function, this time containing an object passed to the C function as an implicit extra argument. An example of a built-in method is `alist.append()`, assuming *alist* is a list object. In this case, the special read-only attribute **`__self__`** is set to the object denoted by *alist*.

Classes

Classes are callable. These objects normally act as factories for new instances of themselves, but variations are possible for class types that override `__new__()`. The arguments of the call are passed to **`__new__()`** and, in the typical case, to `__init__()` to initialize the new instance.

Class Instances

Instances of arbitrary classes can be made callable by defining a `__call__()` method in their class.

Modules

Modules are a basic organizational unit of Python code, and are created by the import system as invoked either by the **`import`** statement, or by calling functions such as **`importlib.import_module()`** and built-in **`__import__()`**. A module object has a namespace implemented by a dictionary object (this is the dictionary referenced by the `__globals__` attribute of functions defined in the module). Attribute references are translated to lookups in this dictionary, e.g., `m.x` is equivalent to `m.__dict__["x"]`. A module object does not contain the code object used to initialize the module (since it isn't needed once the initialization is done).

Attribute assignment updates the module's namespace dictionary, e.g., `m.x = 1` is equivalent to `m.__dict__["x"] = 1`.

Predefined (writable) attributes:

`__name__`
The module's name.

`__doc__`
The module's documentation string, or `None` if unavailable.

`__file__`
The pathname of the file from which the module was loaded, if it was loaded from a file. The **`__file__`** attribute may be missing for certain types of modules, such as C modules that are statically linked into the interpreter. For extension modules loaded dynamically from a shared library, it's the pathname of the shared library file.

`__annotations__`
A dictionary containing variable

annotations collected during module body execution. For best practices on working with **__annotations__**, please see Annotations Best Practices.

Special read-only attribute: **__dict__** is the module's namespace as a dictionary object.

CPython implementation detail: Because of the way CPython clears module dictionaries, the module dictionary will be cleared when the module falls out of scope even if the dictionary still has live references. To avoid this, copy the dictionary or keep the module around while using its dictionary directly.

Custom classes

Custom class types are typically created by class definitions (see section Class definitions). A class has a namespace implemented by a dictionary object. Class attribute references are translated to lookups in this dictionary, e.g., `C.x` is translated to `C.__dict__["x"]` (although there are a number of hooks which allow for other means of locating attributes). When the attribute name is not found there, the attribute search continues in the base classes. This search of the base classes uses the C3 method resolution order which behaves correctly even in the presence of 'diamond' inheritance structures where there are multiple inheritance paths leading back to a common ancestor. Additional details on the C3 MRO used by Python can be found in the documentation accompanying the 2.3 release at https://www.python.org/download/releases/2.3/mro/.

When a class attribute reference (for class **C**, say) would yield a class method object, it is transformed into an instance method object whose **__self__** attribute is **C**. When it would yield a static method object, it is transformed into the object wrapped by the static method object. See section Implementing Descriptors for another way in which attributes retrieved from a class may differ from those actually contained in its **__dict__**.

Class attribute assignments update the class's dictionary, never the dictionary of a base class.

A class object can be called (see above) to yield a class instance (see below).

Special attributes:

__name__
The class name.

__module__
The name of the module in which the class was defined.

__dict__
The dictionary containing the class's namespace.

__bases__
A tuple containing the base classes, in the order of their occurrence in the base class list.

__doc__
The class's documentation string, or `None` if undefined.

__annotations__
A dictionary containing variable annotations collected during class body execution. For best practices on working with **__annotations__**, please see Annotations Best Practices.

Class instances

A class instance is created by calling a class object (see above). A class instance has a namespace implemented as a dictionary which is the first place in which attribute references are searched. When an attribute is not found there, and the instance's class has an attribute by that name, the

search continues with the class attributes. If a class attribute is found that is a user-defined function object, it is transformed into an instance method object whose **__self__** attribute is the instance. Static method and class method objects are also transformed; see above under "Classes". See section Implementing Descriptors for another way in which attributes of a class retrieved via its instances may differ from the objects actually stored in the class's **__dict__**. If no class attribute is found, and the object's class has a **__getattr__()** method, that is called to satisfy the lookup.

Attribute assignments and deletions update the instance's dictionary, never a class's dictionary. If the class has a **__setattr__()** or **__delattr__()** method, this is called instead of updating the instance dictionary directly.

Class instances can pretend to be numbers, sequences, or mappings if they have methods with certain special names. See section Special method names.

Special attributes: **__dict__** is the attribute dictionary; **__class__** is the instance's class.

I/O objects (also known as file objects)

A file object represents an open file. Various shortcuts are available to create file objects: the **open()** built-in function, and also **os.popen()**, **os.fdopen()**, and the **makefile()** method of socket objects (and perhaps by other functions or methods provided by extension modules).

The objects `sys.stdin`, `sys.stdout` and `sys.stderr` are initialized to file objects corresponding to the interpreter's standard input, output and error streams; they are all open in text mode and therefore follow the interface defined by the **io.TextIOBase** abstract class.

Internal types

A few types used internally by the interpreter are exposed to the user. Their definitions may change with future versions of

the interpreter, but they are mentioned here for completeness.

Code objects

Code objects represent *byte-compiled* executable Python code, or bytecode. The difference between a code object and a function object is that the function object contains an explicit reference to the function's globals (the module in which it was defined), while a code object contains no context; also the default argument values are stored in the function object, not in the code object (because they represent values calculated at run-time). Unlike function objects, code objects are immutable and contain no references (directly or indirectly) to mutable objects.

Special read-only attributes: **`co_name`** gives the function name; **`co_qualname`** gives the fully qualified function name; **`co_argcount`** is the total number of positional arguments (including positional-only arguments and arguments with default values); **`co_posonlyargcount`** is the number of positional-only arguments (including arguments with default values); **`co_kwonlyargcount`** is the number of keyword-only arguments (including arguments with default values); **`co_nlocals`** is the number of local variables used by the function (including arguments); **`co_varnames`** is a tuple containing the names of the local variables (starting with the argument names); **`co_cellvars`** is a tuple containing the names of local variables that are referenced by nested functions; **`co_freevars`** is a tuple containing the names of free variables; **`co_code`** is a string representing the sequence of bytecode instructions; **`co_consts`** is a tuple containing the literals used by the bytecode; **`co_names`** is a tuple containing the names used by the bytecode; **`co_filename`** is the filename from which the code was compiled; **`co_firstlineno`** is the first line number of the function; **`co_lnotab`** is a string encoding the mapping from bytecode offsets to line

numbers (for details see the source code of the interpreter); **`co_stacksize`** is the required stack size; **`co_flags`** is an integer encoding a number of flags for the interpreter.

The following flag bits are defined for **`co_flags`**: bit `0x04` is set if the function uses the `*arguments` syntax to accept an arbitrary number of positional arguments; bit `0x08` is set if the function uses the `**keywords` syntax to accept arbitrary keyword arguments; bit `0x20` is set if the function is a generator.

Future feature declarations (`from __future__ import division`) also use bits in **`co_flags`** to indicate whether a code object was compiled with a particular feature enabled: bit `0x2000` is set if the function was compiled with future division enabled; bits `0x10` and `0x1000` were used in earlier versions of Python.

Other bits in **`co_flags`** are reserved for internal use.

If a code object represents a function, the first item in **`co_consts`** is the documentation string of the function, or `None` if undefined.

codeobject.co_positions()

Returns an iterable over the source code positions of each bytecode instruction in the code object.

The iterator returns tuples containing the `(start_line, end_line, start_column, end_column)`. The *i-th* tuple corresponds to the position of the source code that compiled to the *i-th* instruction. Column information is 0-indexed utf-8 byte offsets on the given source line.

This positional information can be missing. A non-exhaustive lists of cases where this may happen:

- Running the interpreter with **-X** `no_debug_ranges`.
- Loading a pyc file compiled while using **-X** `no_debug_ranges`.
- Position tuples corresponding to artificial instructions.
- Line and column numbers that can't be represented due to implementation specific limitations.

When this occurs, some or all of the tuple elements can be **None**.

New in version 3.11.

Note

This feature requires storing column positions in code objects which may result in a small increase of disk usage of compiled Python files or interpreter memory usage. To avoid storing the extra information and/or deactivate printing the extra traceback information, the **-X** `no_debug_ranges` command line flag or the **PYTHONNODEBUGRANGES** environment variable can be used.

Frame objects

Frame objects represent execution frames. They may occur in traceback objects (see below), and are also passed to registered trace functions.

Special read-only attributes: **f_back** is to the previous stack frame (towards the caller), or `None` if this is the bottom stack frame; **f_code** is the code object being executed in this frame; **f_locals** is the dictionary used to look up local variables; **f_globals** is used for global variables; **f_builtins** is used for built-in (intrinsic) names; **f_lasti** gives the precise

instruction (this is an index into the bytecode string of the code object).

Accessing `f_code` raises an auditing event `object.__getattr__` with arguments `obj` and `"f_code"`.

Special writable attributes: **`f_trace`**, if not `None`, is a function called for various events during code execution (this is used by the debugger). Normally an event is triggered for each new source line - this can be disabled by setting **`f_trace_lines`** to **`False`**.

Implementations *may* allow per-opcode events to be requested by setting **`f_trace_opcodes`** to **`True`**. Note that this may lead to undefined interpreter behaviour if exceptions raised by the trace function escape to the function being traced.

`f_lineno` is the current line number of the frame — writing to this from within a trace function jumps to the given line (only for the bottom-most frame). A debugger can implement a Jump command (aka Set Next Statement) by writing to f_lineno.

Frame objects support one method:

frame.clear()

This method clears all references to local variables held by the frame. Also, if the frame belonged to a generator, the generator is finalized. This helps break reference cycles involving frame objects (for example when catching an exception and storing its traceback for later use).

`RuntimeError` is raised if the frame is currently executing.

New in version 3.4.

Traceback objects

Traceback objects represent a stack trace of an exception. A traceback object is implicitly created when an exception occurs, and may also be explicitly created by calling **types.TracebackType**.

For implicitly created tracebacks, when the search for an exception handler unwinds the execution stack, at each unwound level a traceback object is inserted in front of the current traceback. When an exception handler is entered, the stack trace is made available to the program. (See section The try statement.) It is accessible as the third item of the tuple returned by `sys.exc_info()`, and as the `__traceback__` attribute of the caught exception.

When the program contains no suitable handler, the stack trace is written (nicely formatted) to the standard error stream; if the interpreter is interactive, it is also made available to the user as `sys.last_traceback`.

For explicitly created tracebacks, it is up to the creator of the traceback to determine how the `tb_next` attributes should be linked to form a full stack trace.

Special read-only attributes: **tb_frame** points to the execution frame of the current level; **tb_lineno** gives the line number where the exception occurred; **tb_lasti** indicates the precise instruction. The line number and last instruction in the traceback may differ from the line number of its frame object if the exception occurred in a **try** statement with no matching except clause or with a finally clause.

Accessing `tb_frame` raises an auditing event `object.__getattr__` with arguments `obj` and `"tb_frame"`.

Special writable attribute: **tb_next** is the next level in the stack trace (towards the frame where the exception occurred), or `None` if there is no next level.

Changed in version 3.7: Traceback objects can now be explicitly instantiated from Python code, and the `tb_next` attribute of existing instances can be updated.

Slice objects

Slice objects are used to represent slices for **`__getitem__()`** methods. They are also created by the built-in **`slice()`** function.

Special read-only attributes: **`start`** is the lower bound; **`stop`** is the upper bound; **`step`** is the step value; each is `None` if omitted. These attributes can have any type.

Slice objects support one method:

slice.indices(*self*, *length*)

This method takes a single integer argument *length* and computes information about the slice that the slice object would describe if applied to a sequence of *length* items. It returns a tuple of three integers; respectively these are the *start* and *stop* indices and the *step* or stride length of the slice. Missing or out-of-bounds indices are handled in a manner consistent with regular slices.

Static method objects

Static method objects provide a way of defeating the transformation of function objects to method objects described above. A static method object is a wrapper around any other object, usually a user-defined method object. When a static method object is retrieved from a class or a class instance, the object actually returned is the wrapped object, which is not subject to any further transformation. Static method objects are also callable. Static method objects are created by the built-in **`staticmethod()`** constructor.

Class method objects

A class method object, like a static method object, is a wrapper around another object that alters the way in which that object is retrieved from classes and class instances. The behaviour of class method objects upon such retrieval is described above, under “User-defined methods”. Class method objects are created by the built-in **`classmethod()`** constructor.

3.3. Special method names

A class can implement certain operations that are invoked by special syntax (such as arithmetic operations or subscripting and slicing) by defining methods with special names. This is Python’s approach to *operator overloading*, allowing classes to define their own behavior with respect to language operators. For instance, if a class defines a method named **`__getitem__()`**, and `x` is an instance of this class, then `x[i]` is roughly equivalent to `type(x).__getitem__(x, i)`. Except where mentioned, attempts to execute an operation raise an exception when no appropriate method is defined (typically **`AttributeError`** or **`TypeError`**).

Setting a special method to `None` indicates that the corresponding operation is not available. For example, if a class sets **`__iter__()`** to `None`, the class is not iterable, so calling **`iter()`** on its instances will raise a **`TypeError`** (without falling back to **`__getitem__()`**). [2]

When implementing a class that emulates any built-in type, it is important that the emulation only be implemented to the degree that it makes sense for the object being modelled. For example, some sequences may work well with retrieval of individual elements, but extracting a slice may not make sense. (One example of this is the **`NodeList`** interface in the W3C’s Document Object Model.)

3.3.1. Basic customization

object.__new__(*cls*[, ...])

Called to create a new instance of class *cls*. **__new__()** is a static method (special-cased so you need not declare it as such) that takes the class of which an instance was requested as its first argument. The remaining arguments are those passed to the object constructor expression (the call to the class). The return value of **__new__()** should be the new object instance (usually an instance of *cls*).

Typical implementations create a new instance of the class by invoking the superclass's **__new__()** method using `super().__new__(cls[, ...])` with appropriate arguments and then modifying the newly created instance as necessary before returning it.

If **__new__()** is invoked during object construction and it returns an instance of *cls*, then the new instance's **__init__()** method will be invoked like `__init__(self[, ...])`, where *self* is the new instance and the remaining arguments are the same as were passed to the object constructor.

If **__new__()** does not return an instance of *cls*, then the new instance's **__init__()** method will not be invoked.

__new__() is intended mainly to allow subclasses of immutable types (like int, str, or tuple) to customize instance creation. It is also commonly overridden in custom metaclasses in order to customize class creation.

object.__init__(*self*[, ...])

Called after the instance has been created (by **__new__()**), but before it is returned to the caller. The arguments are those passed to the class constructor expression. If a base class has an **__init__()** method, the derived class's **__init__()** method, if any, must explicitly call it to ensure proper initialization of the base class part of the instance; for example: `super().__init__([args...])`.

Because **__new__()** and **__init__()** work together in constructing objects (**__new__()** to create it, and

__init__() to customize it), no non-`None` value may be returned by **__init__()**; doing so will cause a **TypeError** to be raised at runtime.

object.__del__(*self*)

Called when the instance is about to be destroyed. This is also called a finalizer or (improperly) a destructor. If a base class has a **__del__()** method, the derived class's **__del__()** method, if any, must explicitly call it to ensure proper deletion of the base class part of the instance.

It is possible (though not recommended!) for the **__del__()** method to postpone destruction of the instance by creating a new reference to it. This is called object *resurrection*. It is implementation-dependent whether **__del__()** is called a second time when a resurrected object is about to be destroyed; the current CPython implementation only calls it once.

It is not guaranteed that **__del__()** methods are called for objects that still exist when the interpreter exits.

Note

`del x` doesn't directly call `x.__del__()` — the former decrements the reference count for `x` by one, and the latter is only called when `x`'s reference count reaches zero.

CPython implementation detail: It is possible for a reference cycle to prevent the reference count of an object from going to zero. In this case, the cycle will be later detected and deleted by the cyclic garbage collector. A common cause of reference cycles is when an exception has been caught in a local variable. The frame's locals then reference the exception, which references its own traceback, which references the locals of all frames caught in the traceback.

See also

Documentation for the **gc** module.

Warning

Due to the precarious circumstances under which **__del__()** methods are invoked, exceptions that occur during their execution are ignored, and a warning is printed to `sys.stderr` instead. In particular:

- **__del__()** can be invoked when arbitrary code is being executed, including from any arbitrary thread. If **__del__()** needs to take a lock or invoke any other blocking resource, it may deadlock as the resource may already be taken by the code that gets interrupted to execute **__del__()**.
- **__del__()** can be executed during interpreter shutdown. As a consequence, the global variables it needs to access (including other modules) may already have been deleted or set to `None`. Python guarantees that globals whose name begins with a single underscore are deleted from their module before other globals are deleted; if no other references to such globals exist, this may help in assuring that imported modules are still available at the time when the **__del__()** method is called.

object.__repr__(*self*)

Called by the **repr()** built-in function to compute the "official" string representation of an object. If at all possible, this should look like a valid Python expression that could be used to recreate an object with the same value (given an appropriate environment). If this is not possible, a string of the form `<...some useful description...>` should be returned. The return value must be a string object. If a class defines **__repr__()** but not **__str__()**, then **__repr__()** is also used when an "informal" string

representation of instances of that class is required.

This is typically used for debugging, so it is important that the representation is information-rich and unambiguous.

object.__str__(*self*)

Called by `str(object)` and the built-in functions `format()` and `print()` to compute the "informal" or nicely printable string representation of an object. The return value must be a string object.

This method differs from `object.__repr__()` in that there is no expectation that `__str__()` return a valid Python expression: a more convenient or concise representation can be used.

The default implementation defined by the built-in type `object` calls `object.__repr__()`.

object.__bytes__(*self*)

Called by bytes to compute a byte-string representation of an object. This should return a `bytes` object.

object.__format__(*self*, *format_spec*)

Called by the `format()` built-in function, and by extension, evaluation of formatted string literals and the `str.format()` method, to produce a "formatted" string representation of an object. The *format_spec* argument is a string that contains a description of the formatting options desired. The interpretation of the *format_spec* argument is up to the type implementing `__format__()`, however most classes will either delegate formatting to one of the built-in types, or use a similar formatting option syntax.

See Format Specification Mini-Language for a description of

the standard formatting syntax.

The return value must be a string object.

Changed in version 3.4: The _format_ method of `object` itself raises a **`TypeError`** if passed any non-empty string.

Changed in version 3.7: `object.__format__(x, '')` is now equivalent to `str(x)` rather than `format(str(x), '')`.

object._lt_(*self*, *other*)
object._le_(*self*, *other*)
object._eq_(*self*, *other*)
object._ne_(*self*, *other*)
object._gt_(*self*, *other*)
object._ge_(*self*, *other*)

These are the so-called “rich comparison” methods. The correspondence between operator symbols and method names is as follows: `x<y` calls `x.__lt__(y)`, `x<=y` calls `x.__le__(y)`, `x==y` calls `x.__eq__(y)`, `x!=y` calls `x.__ne__(y)`, `x>y` calls `x.__gt__(y)`, and `x>=y` calls `x.__ge__(y)`.

A rich comparison method may return the singleton `NotImplemented` if it does not implement the operation for a given pair of arguments. By convention, `False` and `True` are returned for a successful comparison. However, these methods can return any value, so if the comparison operator is used in a Boolean context (e.g., in the condition of an `if` statement), Python will call **`bool()`** on the value to determine if the result is true or false.

By default, `object` implements **`__eq__()`** by using `is`, returning `NotImplemented` in the case of a false comparison: `True if x is y else NotImplemented`. For **`__ne__()`**, by default it delegates to **`__eq__()`** and inverts the result unless it is `NotImplemented`. There are no other implied relationships among the comparison

operators or default implementations; for example, the truth of `(x<y or x==y)` does not imply `x<=y`. To automatically generate ordering operations from a single root operation, see **`functools.total_ordering()`**.

See the paragraph on **`__hash__()`** for some important notes on creating hashable objects which support custom comparison operations and are usable as dictionary keys.

There are no swapped-argument versions of these methods (to be used when the left argument does not support the operation but the right argument does); rather, **`__lt__()`** and **`__gt__()`** are each other's reflection, **`__le__()`** and **`__ge__()`** are each other's reflection, and **`__eq__()`** and **`__ne__()`** are their own reflection. If the operands are of different types, and right operand's type is a direct or indirect subclass of the left operand's type, the reflected method of the right operand has priority, otherwise the left operand's method has priority. Virtual subclassing is not considered.

object.__hash__(*self*)

Called by built-in function **`hash()`** and for operations on members of hashed collections including **`set`**, **`frozenset`**, and **`dict`**. The `__hash__()` method should return an integer. The only required property is that objects which compare equal have the same hash value; it is advised to mix together the hash values of the components of the object that also play a part in comparison of objects by packing them into a tuple and hashing the tuple. Example:

```
def __hash__(self):
    return hash((self.name, self.nick, self.color))
```

Note

`hash()` truncates the value returned from an object's custom **`__hash__()`** method to the size of a **`Py_ssize_t`**. This is typically 8 bytes on 64-bit builds and 4 bytes on 32-bit builds. If an object's **`__hash__()`** must interoperate on builds of different bit sizes, be sure to

check the width on all supported builds. An easy way to do this is with `python -c "import sys; print(sys.hash_info.width)"`.

If a class does not define an **`__eq__()`** method it should not define a **`__hash__()`** operation either; if it defines **`__eq__()`** but not **`__hash__()`**, its instances will not be usable as items in hashable collections. If a class defines mutable objects and implements an **`__eq__()`** method, it should not implement **`__hash__()`**, since the implementation of hashable collections requires that a key's hash value is immutable (if the object's hash value changes, it will be in the wrong hash bucket).

User-defined classes have **`__eq__()`** and **`__hash__()`** methods by default; with them, all objects compare unequal (except with themselves) and `x.__hash__()` returns an appropriate value such that `x == y` implies both that `x is y` and `hash(x) == hash(y)`.

A class that overrides **`__eq__()`** and does not define **`__hash__()`** will have its **`__hash__()`** implicitly set to `None`. When the **`__hash__()`** method of a class is `None`, instances of the class will raise an appropriate **`TypeError`** when a program attempts to retrieve their hash value, and will also be correctly identified as unhashable when checking `isinstance(obj, collections.abc.Hashable)`.

If a class that overrides **`__eq__()`** needs to retain the implementation of **`__hash__()`** from a parent class, the interpreter must be told this explicitly by setting `__hash__ = <ParentClass>.__hash__`.

If a class that does not override **`__eq__()`** wishes to suppress hash support, it should include `__hash__ = None` in the class definition. A class which defines its own **`__hash__()`** that explicitly raises a **`TypeError`** would be incorrectly identified as hashable by an `isinstance(obj, collections.abc.Hashable)` call.

Note

By default, the **__hash__()** values of str and bytes objects are "salted" with an unpredictable random value. Although they remain constant within an individual Python process, they are not predictable between repeated invocations of Python.

This is intended to provide protection against a denial-of-service caused by carefully chosen inputs that exploit the worst case performance of a dict insertion, O(n^2) complexity. See http://www.ocert.org/advisories/ocert-2011-003.html for details.

Changing hash values affects the iteration order of sets. Python has never made guarantees about this ordering (and it typically varies between 32-bit and 64-bit builds).

See also **PYTHONHASHSEED**.

Changed in version 3.3: Hash randomization is enabled by default.

object.__bool__(*self*)

Called to implement truth value testing and the built-in operation `bool()`; should return `False` or `True`. When this method is not defined, **__len__()** is called, if it is defined, and the object is considered true if its result is nonzero. If a class defines neither **__len__()** nor **__bool__()**, all its instances are considered true.

3.3.2. Customizing attribute access

The following methods can be defined to customize the meaning of attribute access (use of, assignment to, or deletion of `x.name`) for class instances.

object.__getattr__(*self*, *name*)

Called when the default attribute access fails with an **AttributeError** (either **__getattribute__()** raises an

AttributeError because *name* is not an instance attribute or an attribute in the class tree for `self`; or **__get__()** of a *name* property raises **AttributeError**). This method should either return the (computed) attribute value or raise an **AttributeError** exception.

Note that if the attribute is found through the normal mechanism, **__getattr__()** is not called. (This is an intentional asymmetry between **__getattr__()** and **__setattr__()**.) This is done both for efficiency reasons and because otherwise **__getattr__()** would have no way to access other attributes of the instance. Note that at least for instance variables, you can fake total control by not inserting any values in the instance attribute dictionary (but instead inserting them in another object). See the **__getattribute__()** method below for a way to actually get total control over attribute access.

object.__getattribute__(*self*, *name*)

Called unconditionally to implement attribute accesses for instances of the class. If the class also defines **__getattr__()**, the latter will not be called unless **__getattribute__()** either calls it explicitly or raises an **AttributeError**. This method should return the (computed) attribute value or raise an **AttributeError** exception. In order to avoid infinite recursion in this method, its implementation should always call the base class method with the same name to access any attributes it needs, for example, `object.__getattribute__(self, name)`.

Note

This method may still be bypassed when looking up special methods as the result of implicit invocation via language syntax or built-in functions. See Special method lookup.

For certain sensitive attribute accesses, raises an auditing event `object.__getattr__` with arguments `obj` and `name`.

object.__setattr__(*self*, *name*, *value*)

Called when an attribute assignment is attempted. This is called instead of the normal mechanism (i.e. store the value in the instance dictionary). *name* is the attribute name, *value* is the value to be assigned to it.

If **`__setattr__()`** wants to assign to an instance attribute, it should call the base class method with the same name, for example, `object.__setattr__(self, name, value)`.

For certain sensitive attribute assignments, raises an auditing event `object.__setattr__` with arguments `obj`, `name`, `value`.

object.__delattr__(*self*, *name*)

Like **`__setattr__()`** but for attribute deletion instead of assignment. This should only be implemented if `del obj.name` is meaningful for the object.

For certain sensitive attribute deletions, raises an auditing event `object.__delattr__` with arguments `obj` and `name`.

object.__dir__(*self*)

Called when **`dir()`** is called on the object. A sequence must be returned. **`dir()`** converts the returned sequence to a list and sorts it.

3.3.2.1. Customizing module attribute access

Special names `__getattr__` and `__dir__` can be also used to customize access to module attributes. The `__getattr__` function at the module level should accept one argument which is the name of an attribute and return the computed value or raise an

AttributeError. If an attribute is not found on a module object through the normal lookup, i.e. **object.__getattribute__()**, then `__getattr__` is searched in the module `__dict__` before raising an **AttributeError**. If found, it is called with the attribute name and the result is returned.

The `__dir__` function should accept no arguments, and return a sequence of strings that represents the names accessible on module. If present, this function overrides the standard **dir()** search on a module.

For a more fine grained customization of the module behavior (setting attributes, properties, etc.), one can set the `__class__` attribute of a module object to a subclass of **types.ModuleType**. For example:

```
import sys
from types import ModuleType

class VerboseModule(ModuleType):
    def __repr__(self):
        return f'Verbose {self.__name__}'

    def __setattr__(self, attr, value):
        print(f'Setting {attr}...')
        super().__setattr__(attr, value)

sys.modules[__name__].__class__ = VerboseModule
```

Note

Defining module `__getattr__` and setting module `__class__` only affect lookups made using the attribute access syntax – directly accessing the module globals (whether by code within the module, or via a reference to the module's globals dictionary) is unaffected.

Changed in version 3.5: `__class__` module attribute is now writable.

New in version 3.7: `__getattr__` and `__dir__` module attributes.

See also

PEP 562 [https://peps.python.org/pep-0562/] **- Module _getattr_ and _dir_**
Describes the `__getattr__` and `__dir__` functions on modules.

3.3.2.2. Implementing Descriptors

The following methods only apply when an instance of the class containing the method (a so-called *descriptor* class) appears in an *owner* class (the descriptor must be in either the owner's class dictionary or in the class dictionary for one of its parents). In the examples below, "the attribute" refers to the attribute whose name is the key of the property in the owner class' **`__dict__`**.

object._get_(*self*, *instance*, *owner*=*None*)

Called to get the attribute of the owner class (class attribute access) or of an instance of that class (instance attribute access). The optional *owner* argument is the owner class, while *instance* is the instance that the attribute was accessed through, or `None` when the attribute is accessed through the *owner*.

This method should return the computed attribute value or raise an **`AttributeError`** exception.

PEP 252 [https://peps.python.org/pep-0252/] specifies that **`__get__()`** is callable with one or two arguments. Python's own built-in descriptors support this specification; however, it is likely that some third-party tools have descriptors that require both arguments. Python's own **`__getattribute__()`** implementation always passes in both arguments whether they are required or not.

object._set_(*self*, *instance*, *value*)

Called to set the attribute on an instance *instance* of the owner class to a new value, *value*.

Note, adding **`__set__()`** or **`__delete__()`** changes the kind of descriptor to a "data descriptor". See Invoking Descriptors for more details.

object.__delete__(*self*, *instance*)

Called to delete the attribute on an instance *instance* of the owner class.

The attribute **`__objclass__`** is interpreted by the **`inspect`** module as specifying the class where this object was defined (setting this appropriately can assist in runtime introspection of dynamic class attributes). For callables, it may indicate that an instance of the given type (or a subclass) is expected or required as the first positional argument (for example, CPython sets this attribute for unbound methods that are implemented in C).

3.3.2.3. Invoking Descriptors

In general, a descriptor is an object attribute with "binding behavior", one whose attribute access has been overridden by methods in the descriptor protocol: **`__get__()`**, **`__set__()`**, and **`__delete__()`**. If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the base classes of `type(a)` excluding metaclasses.

However, if the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined and how they were called.

The starting point for descriptor invocation is a binding, `a.x`. How

the arguments are assembled depends on `a`:

Direct Call
: The simplest and least common call is when user code directly invokes a descriptor method: `x.__get__(a)`.

Instance Binding
: If binding to an object instance, `a.x` is transformed into the call: `type(a).__dict__['x'].__get__(a, type(a))`.

Class Binding
: If binding to a class, `A.x` is transformed into the call: `A.__dict__['x'].__get__(None, A)`.

Super Binding
: A dotted lookup such as `super(A, a).x` searches `a.__class__.__mro__` for a base class `B` following `A` and then returns `B.__dict__['x'].__get__(a, A)`. If not a descriptor, `x` is returned unchanged.

For instance bindings, the precedence of descriptor invocation depends on which descriptor methods are defined. A descriptor can define any combination of **`__get__()`**, **`__set__()`** and **`__delete__()`**. If it does not define **`__get__()`**, then accessing the attribute will return the descriptor object itself unless there is a value in the object's instance dictionary. If the descriptor defines **`__set__()`** and/or **`__delete__()`**, it is a data descriptor; if it defines neither, it is a non-data descriptor. Normally, data descriptors define both **`__get__()`** and **`__set__()`**, while non-data descriptors have just the **`__get__()`** method. Data descriptors with **`__get__()`** and **`__set__()`** (and/or **`__delete__()`**) defined always override a redefinition in an instance dictionary. In contrast, non-data descriptors can be overridden by instances.

Python methods (including those decorated with **`@staticmethod`** and **`@classmethod`**) are implemented as non-data descriptors. Accordingly, instances can redefine and override methods. This allows individual instances to acquire behaviors that differ from other instances of the same class.

The **property()** function is implemented as a data descriptor. Accordingly, instances cannot override the behavior of a property.

3.3.2.4. _slots_

*_slots_* allow us to explicitly declare data members (like properties) and deny the creation of **__dict__** and *_weakref_* (unless explicitly declared in *_slots_* or available in a parent.)

The space saved over using **__dict__** can be significant. Attribute lookup speed can be significantly improved as well.

object._slots_

> This class variable can be assigned a string, iterable, or sequence of strings with variable names used by instances. *_slots_* reserves space for the declared variables and prevents the automatic creation of **__dict__** and *_weakref_* for each instance.

3.3.2.4.1. Notes on using *_slots_*

- When inheriting from a class without *_slots_*, the **__dict__** and *_weakref_* attribute of the instances will always be accessible.
- Without a **__dict__** variable, instances cannot be assigned new variables not listed in the *_slots_* definition. Attempts to assign to an unlisted variable name raises **AttributeError**. If dynamic assignment of new variables is desired, then add `'__dict__'` to the sequence of strings in the *_slots_* declaration.
- Without a *_weakref_* variable for each instance, classes defining *_slots_* do not support **weak references** to its instances. If weak reference support is needed, then add `'__weakref__'` to the sequence of strings in the *_slots_* declaration.
- *_slots_* are implemented at the class level by creating descriptors for each variable name. As a result, class attributes cannot be used to set default values for instance variables defined by *_slots_*; otherwise, the class attribute would overwrite the descriptor assignment.

- The action of a *_slots_* declaration is not limited to the class where it is defined. *_slots_* declared in parents are available in child classes. However, child subclasses will get a **`__dict__`** and *_weakref_* unless they also define *_slots_* (which should only contain names of any *additional* slots).
- If a class defines a slot also defined in a base class, the instance variable defined by the base class slot is inaccessible (except by retrieving its descriptor directly from the base class). This renders the meaning of the program undefined. In the future, a check may be added to prevent this.
- Nonempty *_slots_* does not work for classes derived from "variable-length" built-in types such as **`int`**, **`bytes`** and **`tuple`**.
- Any non-string iterable may be assigned to *_slots_*.
- If a **`dictionary`** is used to assign *_slots_*, the dictionary keys will be used as the slot names. The values of the dictionary can be used to provide per-attribute docstrings that will be recognised by **`inspect.getdoc()`** and displayed in the output of **`help()`**.
- **`__class__`** assignment works only if both classes have the same *_slots_*.
- Multiple inheritance with multiple slotted parent classes can be used, but only one parent is allowed to have attributes created by slots (the other bases must have empty slot layouts) - violations raise **`TypeError`**.
- If an iterator is used for *_slots_* then a descriptor is created for each of the iterator's values. However, the *_slots_* attribute will be an empty iterator.

3.3.3. Customizing class creation

Whenever a class inherits from another class, **`__init_subclass__()`** is called on the parent class. This way, it is possible to write classes which change the behavior of subclasses. This is closely related to class decorators, but where class decorators only affect the specific class they're applied to, `__init_subclass__` solely applies to future subclasses of the class defining the method.

classmethod object.__init_subclass__(*cls*)

This method is called whenever the containing class is subclassed. *cls* is then the new subclass. If defined as a normal instance method, this method is implicitly converted to a class method.

Keyword arguments which are given to a new class are passed to the parent's class `__init_subclass__`. For compatibility with other classes using `__init_subclass__`, one should take out the needed keyword arguments and pass the others over to the base class, as in:

```
class Philosopher:
    def __init_subclass__(cls, /, default_name, **k
        super().__init_subclass__(**kwargs)
        cls.default_name = default_name

class AustralianPhilosopher(Philosopher, default_na
    pass
```

The default implementation `object.__init_subclass__` does nothing, but raises an error if it is called with any arguments.

Note

The metaclass hint `metaclass` is consumed by the rest of the type machinery, and is never passed to `__init_subclass__` implementations. The actual metaclass (rather than the explicit hint) can be accessed as `type(cls)`.

New in version 3.6.

When a class is created, **`type.__new__()`** scans the class variables and makes callbacks to those with a **`__set_name__()`** hook.

object.__set_name__(*self*, *owner*, *name*)

Automatically called at the time the owning class *owner* is

created. The object has been assigned to *name* in that class:

```
class A:
    x = C()  # Automatically calls: x.__set_name__(
```

If the class variable is assigned after the class is created, **`__set_name__()`** will not be called automatically. If needed, **`__set_name__()`** can be called directly:

```
class A:
   pass

c = C()
A.x = c                   # The hook is not called
c.__set_name__(A, 'x')    # Manually invoke the hook
```

See Creating the class object for more details.

New in version 3.6.

3.3.3.1. Metaclasses

By default, classes are constructed using **`type()`**. The class body is executed in a new namespace and the class name is bound locally to the result of `type(name, bases, namespace)`.

The class creation process can be customized by passing the `metaclass` keyword argument in the class definition line, or by inheriting from an existing class that included such an argument. In the following example, both `MyClass` and `MySubclass` are instances of `Meta`:

```
class Meta(type):
    pass

class MyClass(metaclass=Meta):
    pass

class MySubclass(MyClass):
    pass
```

Any other keyword arguments that are specified in the class definition are passed through to all metaclass operations described below.

When a class definition is executed, the following steps occur:

- MRO entries are resolved;
- the appropriate metaclass is determined;
- the class namespace is prepared;
- the class body is executed;
- the class object is created.

3.3.3.2. Resolving MRO entries

If a base that appears in class definition is not an instance of **`type`**, then an `__mro_entries__` method is searched on it. If found, it is called with the original bases tuple. This method must return a tuple of classes that will be used instead of this base. The tuple may be empty, in such case the original base is ignored.

See also

PEP 560 [https://peps.python.org/pep-0560/] - Core support for typing module and generic types

3.3.3.3. Determining the appropriate metaclass

The appropriate metaclass for a class definition is determined as follows:

- if no bases and no explicit metaclass are given, then **`type()`** is used;
- if an explicit metaclass is given and it is *not* an instance of **`type()`**, then it is used directly as the metaclass;
- if an instance of **`type()`** is given as the explicit metaclass, or bases are defined, then the most derived metaclass is used.

The most derived metaclass is selected from the explicitly specified metaclass (if any) and the metaclasses (i.e. `type(cls)`) of all

specified base classes. The most derived metaclass is one which is a subtype of *all* of these candidate metaclasses. If none of the candidate metaclasses meets that criterion, then the class definition will fail with `TypeError`.

3.3.3.4. Preparing the class namespace

Once the appropriate metaclass has been identified, then the class namespace is prepared. If the metaclass has a `__prepare__` attribute, it is called as `namespace = metaclass.__prepare__(name, bases, **kwds)` (where the additional keyword arguments, if any, come from the class definition). The `__prepare__` method should be implemented as a **`classmethod`**. The namespace returned by `__prepare__` is passed in to `__new__`, but when the final class object is created the namespace is copied into a new `dict`.

If the metaclass has no `__prepare__` attribute, then the class namespace is initialised as an empty ordered mapping.

See also

PEP 3115 [https://peps.python.org/pep-3115/] - Metaclasses in Python 3000
Introduced the `__prepare__` namespace hook

3.3.3.5. Executing the class body

The class body is executed (approximately) as `exec(body, globals(), namespace)`. The key difference from a normal call to **`exec()`** is that lexical scoping allows the class body (including any methods) to reference names from the current and outer scopes when the class definition occurs inside a function.

However, even when the class definition occurs inside the function, methods defined inside the class still cannot see names defined at the class scope. Class variables must be accessed through the first parameter of instance or class methods, or through the implicit lexically scoped `__class__` reference described in the next

section.

3.3.3.6. Creating the class object

Once the class namespace has been populated by executing the class body, the class object is created by calling `metaclass(name, bases, namespace, **kwds)` (the additional keywords passed here are the same as those passed to `__prepare__`).

This class object is the one that will be referenced by the zero-argument form of **`super()`**. `__class__` is an implicit closure reference created by the compiler if any methods in a class body refer to either `__class__` or `super`. This allows the zero argument form of **`super()`** to correctly identify the class being defined based on lexical scoping, while the class or instance that was used to make the current call is identified based on the first argument passed to the method.

CPython implementation detail: In CPython 3.6 and later, the `__class__` cell is passed to the metaclass as a `__classcell__` entry in the class namespace. If present, this must be propagated up to the `type.__new__` call in order for the class to be initialised correctly. Failing to do so will result in a **`RuntimeError`** in Python 3.8.

When using the default metaclass **`type`**, or any metaclass that ultimately calls `type.__new__`, the following additional customization steps are invoked after creating the class object:

1. The `type.__new__` method collects all of the attributes in the class namespace that define a **`__set_name__()`** method;
2. Those `__set_name__` methods are called with the class being defined and the assigned name of that particular attribute;
3. The **`__init_subclass__()`** hook is called on the immediate parent of the new class in its method resolution order.

After the class object is created, it is passed to the class decorators included in the class definition (if any) and the resulting object is

bound in the local namespace as the defined class.

When a new class is created by `type.__new__`, the object provided as the namespace parameter is copied to a new ordered mapping and the original object is discarded. The new copy is wrapped in a read-only proxy, which becomes the **`__dict__`** attribute of the class object.

PEP 3135 [https://peps.python.org/pep-3135/] - **New super**
Describes the implicit `__class__` closure reference

3.3.3.7. Uses for metaclasses

The potential uses for metaclasses are boundless. Some ideas that have been explored include enum, logging, interface checking, automatic delegation, automatic property creation, proxies, frameworks, and automatic resource locking/synchronization.

3.3.4. Customizing instance and subclass checks

The following methods are used to override the default behavior of the **`isinstance()`** and **`issubclass()`** built-in functions.

In particular, the metaclass **`abc.ABCMeta`** implements these methods in order to allow the addition of Abstract Base Classes (ABCs) as "virtual base classes" to any class or type (including built-in types), including other ABCs.

class._instancecheck_(*self*, *instance*)

Return true if *instance* should be considered a (direct or indirect) instance of *class*. If defined, called to implement `isinstance(instance, class)`.

class._subclasscheck_(*self*, *subclass*)

Return true if *subclass* should be considered a (direct or indirect) subclass of *class*. If defined, called to implement

```
issubclass(subclass, class).
```

Note that these methods are looked up on the type (metaclass) of a class. They cannot be defined as class methods in the actual class. This is consistent with the lookup of special methods that are called on instances, only in this case the instance is itself a class.

See also

PEP 3119 [https://peps.python.org/pep-3119/] - Introducing Abstract Base Classes
Includes the specification for customizing `isinstance()` and `issubclass()` behavior through `__instancecheck__()` and `__subclasscheck__()`, with motivation for this functionality in the context of adding Abstract Base Classes (see the `abc` module) to the language.

3.3.5. Emulating generic types

When using type annotations, it is often useful to *parameterize* a generic type using Python's square-brackets notation. For example, the annotation `list[int]` might be used to signify a `list` in which all the elements are of type `int`.

See also

PEP 484 [https://peps.python.org/pep-0484/] - Type Hints
Introducing Python's framework for type annotations

Generic Alias Types
Documentation for objects representing parameterized generic classes

Generics, user-defined generics and `typing.Generic`
Documentation on how to implement generic classes that can be parameterized at runtime and understood by static type-checkers.

A class can *generally* only be parameterized if it defines the special class method `__class_getitem__()`.

classmethod object.__class_getitem__(*cls*, *key*)

> Return an object representing the specialization of a generic class by type arguments found in *key*.
>
> When defined on a class, `__class_getitem__()` is automatically a class method. As such, there is no need for it to be decorated with **`@classmethod`** when it is defined.

3.3.5.1. The purpose of *__class_getitem__*

The purpose of **`__class_getitem__()`** is to allow runtime parameterization of standard-library generic classes in order to more easily apply type hints to these classes.

To implement custom generic classes that can be parameterized at runtime and understood by static type-checkers, users should either inherit from a standard library class that already implements **`__class_getitem__()`**, or inherit from **`typing.Generic`**, which has its own implementation of `__class_getitem__()`.

Custom implementations of **`__class_getitem__()`** on classes defined outside of the standard library may not be understood by third-party type-checkers such as mypy. Using `__class_getitem__()` on any class for purposes other than type hinting is discouraged.

3.3.5.2. *__class_getitem__* versus *__getitem__*

Usually, the subscription of an object using square brackets will call the **`__getitem__()`** instance method defined on the object's class. However, if the object being subscribed is itself a class, the class method **`__class_getitem__()`** may be called instead. `__class_getitem__()` should return a GenericAlias object if it is properly defined.

Presented with the expression `obj[x]`, the Python interpreter follows something like the following process to decide whether

`__getitem__()` or **`__class_getitem__()`** should be called:

```
from inspect import isclass

def subscribe(obj, x):
    """Return the result of the expression 'obj[x]'"""

    class_of_obj = type(obj)

    # If the class of obj defines __getitem__,
    # call class_of_obj.__getitem__(obj, x)
    if hasattr(class_of_obj, '__getitem__'):
        return class_of_obj.__getitem__(obj, x)

    # Else, if obj is a class and defines __class_getite
    # call obj.__class_getitem__(x)
    elif isclass(obj) and hasattr(obj, '__class_getitem_
        return obj.__class_getitem__(x)

    # Else, raise an exception
    else:
        raise TypeError(
            f"'{class_of_obj.__name__}' object is not su
        )
```

In Python, all classes are themselves instances of other classes. The class of a class is known as that class's metaclass, and most classes have the **`type`** class as their metaclass. **`type`** does not define **`__getitem__()`**, meaning that expressions such as `list[int]`, `dict[str, float]` and `tuple[str, bytes]` all result in **`__class_getitem__()`** being called:

```
>>> # list has class "type" as its metaclass, like most
>>> type(list)
<class 'type'>
>>> type(dict) == type(list) == type(tuple) == type(str)
True
>>> # "list[int]" calls "list.__class_getitem__(int)"
>>> list[int]
```

```
list[int]
>>> # list.__class_getitem__ returns a GenericAlias obje
>>> type(list[int])
<class 'types.GenericAlias'>
```

However, if a class has a custom metaclass that defines **__getitem__()**, subscribing the class may result in different behaviour. An example of this can be found in the **enum** module:

```
>>> from enum import Enum
>>> class Menu(Enum):
...     """A breakfast menu"""
...     SPAM = 'spam'
...     BACON = 'bacon'
...
>>> # Enum classes have a custom metaclass:
>>> type(Menu)
<class 'enum.EnumMeta'>
>>> # EnumMeta defines __getitem__,
>>> # so __class_getitem__ is not called,
>>> # and the result is not a GenericAlias object:
>>> Menu['SPAM']
<Menu.SPAM: 'spam'>
>>> type(Menu['SPAM'])
<enum 'Menu'>
```

PEP 560 **[https://peps.python.org/pep-0560/]** **- Core Support for typing module and generic types**
Introducing **__class_getitem__()**, and outlining when a subscription results in `__class_getitem__()` being called instead of **__getitem__()**

3.3.6. Emulating callable objects

object.__call__(*self*[, *args*...])

Called when the instance is “called” as a function; if this

method is defined, `x(arg1, arg2, ...)` roughly translates to `type(x).__call__(x, arg1, ...)`.

3.3.7. Emulating container types

The following methods can be defined to implement container objects. Containers usually are sequences (such as **lists** or **tuples**) or mappings (like **dictionaries**), but can represent other containers as well. The first set of methods is used either to emulate a sequence or to emulate a mapping; the difference is that for a sequence, the allowable keys should be the integers *k* for which `0 <= k < N` where *N* is the length of the sequence, or **slice** objects, which define a range of items. It is also recommended that mappings provide the methods **keys()**, **values()**, **items()**, **get()**, **clear()**, **setdefault()**, **pop()**, **popitem()**, **copy()**, and **update()** behaving similar to those for Python's standard **dictionary** objects. The **collections.abc** module provides a **MutableMapping** abstract base class to help create those methods from a base set of **__getitem__()**, **__setitem__()**, **__delitem__()**, and **keys()**. Mutable sequences should provide methods **append()**, **count()**, **index()**, **extend()**, **insert()**, **pop()**, **remove()**, **reverse()** and **sort()**, like Python standard **list** objects. Finally, sequence types should implement addition (meaning concatenation) and multiplication (meaning repetition) by defining the methods **__add__()**, **__radd__()**, **__iadd__()**, **__mul__()**, **__rmul__()** and **__imul__()** described below; they should not define other numerical operators. It is recommended that both mappings and sequences implement the **__contains__()** method to allow efficient use of the `in` operator; for mappings, `in` should search the mapping's keys; for sequences, it should search through the values. It is further recommended that both mappings and sequences implement the **__iter__()** method to allow efficient iteration through the container; for mappings, **__iter__()** should iterate through the object's keys; for sequences, it should iterate through the values.

object.__len__(*self*)

Called to implement the built-in function **len()**. Should

return the length of the object, an integer >= 0. Also, an object that doesn't define a **__bool__()** method and whose **__len__()** method returns zero is considered to be false in a Boolean context.

CPython implementation detail: In CPython, the length is required to be at most **sys.maxsize**. If the length is larger than **sys.maxsize** some features (such as **len()**) may raise **OverflowError**. To prevent raising **OverflowError** by truth value testing, an object must define a **__bool__()** method.

object.__length_hint__(*self*)

Called to implement **operator.length_hint()**. Should return an estimated length for the object (which may be greater or less than the actual length). The length must be an integer >= 0. The return value may also be **NotImplemented**, which is treated the same as if the `__length_hint__` method didn't exist at all. This method is purely an optimization and is never required for correctness.

New in version 3.4.

Note

Slicing is done exclusively with the following three methods. A call like

```
a[1:2] = b
```

is translated to

```
a[slice(1, 2, None)] = b
```

and so forth. Missing slice items are always filled in with `None`.

object.__getitem__(*self*, *key*)

Called to implement evaluation of `self[key]`. For sequence types, the accepted keys should be integers and slice objects.

Note that the special interpretation of negative indexes (if the class wishes to emulate a sequence type) is up to the **`__getitem__()`** method. If *key* is of an inappropriate type, **`TypeError`** may be raised; if of a value outside the set of indexes for the sequence (after any special interpretation of negative values), **`IndexError`** should be raised. For mapping types, if *key* is missing (not in the container), **`KeyError`** should be raised.

Note

`for` loops expect that an **`IndexError`** will be raised for illegal indexes to allow proper detection of the end of the sequence.

Note

When subscripting a *class*, the special class method **`__class_getitem__()`** may be called instead of `__getitem__()`. See _class_getitem_ versus _getitem_ for more details.

object._setitem_(*self*, *key*, *value*)

Called to implement assignment to `self[key]`. Same note as for **`__getitem__()`**. This should only be implemented for mappings if the objects support changes to the values for keys, or if new keys can be added, or for sequences if elements can be replaced. The same exceptions should be raised for improper *key* values as for the **`__getitem__()`** method.

object._delitem_(*self*, *key*)

Called to implement deletion of `self[key]`. Same note as for **`__getitem__()`**. This should only be implemented for mappings if the objects support removal of keys, or for sequences if elements can be removed from the sequence. The same exceptions should be raised for improper *key* values as

for the **__getitem__()** method.

object._missing_(*self*, *key*)

Called by **dict.__getitem__()** to implement `self[key]` for dict subclasses when key is not in the dictionary.

object._iter_(*self*)

This method is called when an iterator is required for a container. This method should return a new iterator object that can iterate over all the objects in the container. For mappings, it should iterate over the keys of the container.

object._reversed_(*self*)

Called (if present) by the **reversed()** built-in to implement reverse iteration. It should return a new iterator object that iterates over all the objects in the container in reverse order.

If the **__reversed__()** method is not provided, the **reversed()** built-in will fall back to using the sequence protocol (**__len__()** and **__getitem__()**). Objects that support the sequence protocol should only provide **__reversed__()** if they can provide an implementation that is more efficient than the one provided by **reversed()**.

The membership test operators (**in** and **not in**) are normally implemented as an iteration through a container. However, container objects can supply the following special method with a more efficient implementation, which also does not require the object be iterable.

object._contains_(*self*, *item*)

Called to implement membership test operators. Should return true if *item* is in *self*, false otherwise. For mapping objects, this should consider the keys of the mapping rather than the values or the key-item pairs.

For objects that don't define **__contains__()**, the membership test first tries iteration via **__iter__()**, then

the old sequence iteration protocol via **`__getitem__()`**, see this section in the language reference.

3.3.8. Emulating numeric types

The following methods can be defined to emulate numeric objects. Methods corresponding to operations that are not supported by the particular kind of number implemented (e.g., bitwise operations for non-integral numbers) should be left undefined.

object.__add__(*self*, *other*)
object.__sub__(*self*, *other*)
object.__mul__(*self*, *other*)
object.__matmul__(*self*, *other*)
object.__truediv__(*self*, *other*)
object.__floordiv__(*self*, *other*)
object.__mod__(*self*, *other*)
object.__divmod__(*self*, *other*)
object.__pow__(*self*, *other*[, *modulo*])
object.__lshift__(*self*, *other*)
object.__rshift__(*self*, *other*)
object.__and__(*self*, *other*)
object.__xor__(*self*, *other*)
object.__or__(*self*, *other*)

These methods are called to implement the binary arithmetic operations (`+`, `-`, `*`, `@`, `/`, `//`, `%`, **`divmod()`**, **`pow()`**, `**`, `<<`, `>>`, `&`, `^`, `|`). For instance, to evaluate the expression `x + y`, where *x* is an instance of a class that has an **`__add__()`** method, `type(x).__add__(x, y)` is called. The **`__divmod__()`** method should be the equivalent to using **`__floordiv__()`** and **`__mod__()`**; it should not be related to **`__truediv__()`**. Note that **`__pow__()`** should be defined to accept an optional third argument if the ternary version of the built-in **`pow()`** function is to be supported.

If one of those methods does not support the operation with the supplied arguments, it should return `NotImplemented`.

object.__radd__(*self*, *other*)
object.__rsub__(*self*, *other*)
object.__rmul__(*self*, *other*)
object.__rmatmul__(*self*, *other*)
object.__rtruediv__(*self*, *other*)
object.__rfloordiv__(*self*, *other*)
object.__rmod__(*self*, *other*)
object.__rdivmod__(*self*, *other*)
object.__rpow__(*self*, *other*[, *modulo*])
object.__rlshift__(*self*, *other*)
object.__rrshift__(*self*, *other*)
object.__rand__(*self*, *other*)
object.__rxor__(*self*, *other*)
object.__ror__(*self*, *other*)

These methods are called to implement the binary arithmetic operations (`+`, `-`, `*`, `@`, `/`, `//`, `%`, **`divmod()`**, **`pow()`**, `**`, `<<`, `>>`, `&`, `^`, `|`) with reflected (swapped) operands. These functions are only called if the left operand does not support the corresponding operation 3 and the operands are of different types. 4 For instance, to evaluate the expression `x - y`, where *y* is an instance of a class that has an **`__rsub__()`** method, `type(y).__rsub__(y, x)` is called if `type(x).__sub__(x, y)` returns *NotImplemented*.

Note that ternary **`pow()`** will not try calling **`__rpow__()`** (the coercion rules would become too complicated).

Note

If the right operand's type is a subclass of the left operand's type and that subclass provides a different implementation of the reflected method for the operation, this method will be called before the left operand's non-reflected method. This behavior allows subclasses to override their ancestors' operations.

object._iadd_(*self*, *other*)
object._isub_(*self*, *other*)
object._imul_(*self*, *other*)
object._imatmul_(*self*, *other*)
object._itruediv_(*self*, *other*)
object._ifloordiv_(*self*, *other*)
object._imod_(*self*, *other*)
object._ipow_(*self*, *other*[, *modulo*])
object._ilshift_(*self*, *other*)
object._irshift_(*self*, *other*)
object._iand_(*self*, *other*)
object._ixor_(*self*, *other*)
object._ior_(*self*, *other*)

These methods are called to implement the augmented arithmetic assignments (`+=`, `-=`, `*=`, `@=`, `/=`, `//=`, `%=`, `**=`, `<<=`, `>>=`, `&=`, `^=`, `|=`). These methods should attempt to do the operation in-place (modifying *self*) and return the result (which could be, but does not have to be, *self*). If a specific method is not defined, the augmented assignment falls back to the normal methods. For instance, if *x* is an instance of a class with an **`__iadd__()`** method, `x += y` is equivalent to `x = x.__iadd__(y)` . Otherwise, `x.__add__(y)` and `y.__radd__(x)` are considered, as with the evaluation of `x + y`. In certain situations, augmented assignment can result in unexpected errors (see Why does a_tuple[i] += ['item'] raise an exception when the addition works?), but this behavior is in fact part of the data model.

object._neg_(*self*)
object._pos_(*self*)
object._abs_(*self*)
object._invert_(*self*)

Called to implement the unary arithmetic operations (`-`, `+`, **`abs()`** and `~`).

object._complex_(*self*)
object._int_(*self*)
object._float_(*self*)

Called to implement the built-in functions **complex()**, **int()** and **float()**. Should return a value of the appropriate type.

object._index_(*self*)

Called to implement **operator.index()**, and whenever Python needs to losslessly convert the numeric object to an integer object (such as in slicing, or in the built-in **bin()**, **hex()** and **oct()** functions). Presence of this method indicates that the numeric object is an integer type. Must return an integer.

If **__int__()**, **__float__()** and **__complex__()** are not defined then corresponding built-in functions **int()**, **float()** and **complex()** fall back to **__index__()**.

object._round_(*self*[, *ndigits*])
object._trunc_(*self*)
object._floor_(*self*)
object._ceil_(*self*)

Called to implement the built-in function **round()** and **math** functions **trunc()**, **floor()** and **ceil()**. Unless *ndigits* is passed to **__round__()** all these methods should return the value of the object truncated to an **Integral** (typically an **int**).

The built-in function **int()** falls back to **__trunc__()** if neither **__int__()** nor **__index__()** is defined.

Changed in version 3.11: The delegation of **int()** to **__trunc__()** is deprecated.

3.3.9. With Statement Context Managers

A *context manager* is an object that defines the runtime context to be

established when executing a **with** statement. The context manager handles the entry into, and the exit from, the desired runtime context for the execution of the block of code. Context managers are normally invoked using the **with** statement (described in section The with statement), but can also be used by directly invoking their methods.

Typical uses of context managers include saving and restoring various kinds of global state, locking and unlocking resources, closing opened files, etc.

For more information on context managers, see Context Manager Types.

object.__enter__(*self*)

Enter the runtime context related to this object. The **with** statement will bind this method's return value to the target(s) specified in the **as** clause of the statement, if any.

object.__exit__(*self*, *exc_type*, *exc_value*, *traceback*)

Exit the runtime context related to this object. The parameters describe the exception that caused the context to be exited. If the context was exited without an exception, all three arguments will be **None**.

If an exception is supplied, and the method wishes to suppress the exception (i.e., prevent it from being propagated), it should return a true value. Otherwise, the exception will be processed normally upon exit from this method.

Note that **__exit__()** methods should not reraise the passed-in exception; this is the caller's responsibility.

See also

PEP 343 **[https://peps.python.org/pep-0343/]** **- The "with" statement**

The specification, background, and examples for the

Python `with` statement.

3.3.10. Customizing positional arguments in class pattern matching

When using a class name in a pattern, positional arguments in the pattern are not allowed by default, i.e. `case MyClass(x, y)` is typically invalid without special support in `MyClass`. To be able to use that kind of pattern, the class needs to define a *__match_args__* attribute.

object.__match_args__

> This class variable can be assigned a tuple of strings. When this class is used in a class pattern with positional arguments, each positional argument will be converted into a keyword argument, using the corresponding value in *__match_args__* as the keyword. The absence of this attribute is equivalent to setting it to `()`.

For example, if `MyClass.__match_args__` is `("left", "center", "right")` that means that `case MyClass(x, y)` is equivalent to `case MyClass(left=x, center=y)`. Note that the number of arguments in the pattern must be smaller than or equal to the number of elements in *__match_args__*; if it is larger, the pattern match attempt will raise a `TypeError`.

New in version 3.10.

See also

PEP 634 [https://peps.python.org/pep-0634/] - Structural Pattern Matching
> The specification for the Python `match` statement.

3.3.11. Special method lookup

For custom classes, implicit invocations of special methods are only guaranteed to work correctly if defined on an object's type, not in

the object's instance dictionary. That behaviour is the reason why the following code raises an exception:

```
>>> class C:
...     pass
...
>>> c = C()
>>> c.__len__ = lambda: 5
>>> len(c)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: object of type 'C' has no len()
```

The rationale behind this behaviour lies with a number of special methods such as **`__hash__()`** and **`__repr__()`** that are implemented by all objects, including type objects. If the implicit lookup of these methods used the conventional lookup process, they would fail when invoked on the type object itself:

```
>>> 1 .__hash__() == hash(1)
True
>>> int.__hash__() == hash(int)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: descriptor '__hash__' of 'int' object needs a
```

Incorrectly attempting to invoke an unbound method of a class in this way is sometimes referred to as 'metaclass confusion', and is avoided by bypassing the instance when looking up special methods:

```
>>> type(1).__hash__(1) == hash(1)
True
>>> type(int).__hash__(int) == hash(int)
True
```

In addition to bypassing any instance attributes in the interest of correctness, implicit special method lookup generally also bypasses the **`__getattribute__()`** method even of the object's metaclass:

```
>>> class Meta(type):
...     def __getattribute__(*args):
...         print("Metaclass getattribute invoked")
...         return type.__getattribute__(*args)
...
>>> class C(object, metaclass=Meta):
...     def __len__(self):
...         return 10
...     def __getattribute__(*args):
...         print("Class getattribute invoked")
...         return object.__getattribute__(*args)
...
>>> c = C()
>>> c.__len__()                 # Explicit lookup via in
Class getattribute invoked
10
>>> type(c).__len__(c)          # Explicit lookup via ty
Metaclass getattribute invoked
10
>>> len(c)                      # Implicit lookup
10
```

Bypassing the **`__getattribute__()`** machinery in this fashion provides significant scope for speed optimisations within the interpreter, at the cost of some flexibility in the handling of special methods (the special method *must* be set on the class object itself in order to be consistently invoked by the interpreter).

3.4. Coroutines

3.4.1. Awaitable Objects

An awaitable object generally implements an **`__await__()`** method. Coroutine objects returned from **`async def`** functions are awaitable.

Note

The generator iterator objects returned from generators decorated with **types.coroutine()** are also awaitable, but they do not implement **__await__()**.

object.__await__(*self*)

Must return an iterator. Should be used to implement awaitable objects. For instance, **asyncio.Future** implements this method to be compatible with the **await** expression.

New in version 3.5.

See also

PEP 492 [https://peps.python.org/pep-0492/] for additional information about awaitable objects.

3.4.2. Coroutine Objects

Coroutine objects are awaitable objects. A coroutine's execution can be controlled by calling **__await__()** and iterating over the result. When the coroutine has finished executing and returns, the iterator raises **StopIteration**, and the exception's **value** attribute holds the return value. If the coroutine raises an exception, it is propagated by the iterator. Coroutines should not directly raise unhandled **StopIteration** exceptions.

Coroutines also have the methods listed below, which are analogous to those of generators (see Generator-iterator methods). However, unlike generators, coroutines do not directly support iteration.

Changed in version 3.5.2: It is a **RuntimeError** to await on a coroutine more than once.

coroutine.send(*value*)

Starts or resumes execution of the coroutine. If *value* is `None`, this is equivalent to advancing the iterator returned by **__await__()**. If *value* is not `None`, this method delegates to

the **send()** method of the iterator that caused the coroutine to suspend. The result (return value, **StopIteration**, or other exception) is the same as when iterating over the **__await__()** return value, described above.

coroutine.throw(*value*)

coroutine.throw(*type*[, *value*[, *traceback*]])

Raises the specified exception in the coroutine. This method delegates to the **throw()** method of the iterator that caused the coroutine to suspend, if it has such a method. Otherwise, the exception is raised at the suspension point. The result (return value, **StopIteration**, or other exception) is the same as when iterating over the **__await__()** return value, described above. If the exception is not caught in the coroutine, it propagates back to the caller.

coroutine.close()

Causes the coroutine to clean itself up and exit. If the coroutine is suspended, this method first delegates to the **close()** method of the iterator that caused the coroutine to suspend, if it has such a method. Then it raises **GeneratorExit** at the suspension point, causing the coroutine to immediately clean itself up. Finally, the coroutine is marked as having finished executing, even if it was never started.

Coroutine objects are automatically closed using the above process when they are about to be destroyed.

3.4.3. Asynchronous Iterators

An *asynchronous iterator* can call asynchronous code in its `__anext__` method.

Asynchronous iterators can be used in an **async for** statement.

object.__aiter__(*self*)

Must return an *asynchronous iterator* object.

object._anext_(*self*)

Must return an *awaitable* resulting in a next value of the iterator. Should raise a **StopAsyncIteration** error when the iteration is over.

An example of an asynchronous iterable object:

```
class Reader:
    async def readline(self):
        ...

    def __aiter__(self):
        return self

    async def __anext__(self):
        val = await self.readline()
        if val == b'':
            raise StopAsyncIteration
        return val
```

New in version 3.5.

Changed in version 3.7: Prior to Python 3.7, **__aiter__()** could return an *awaitable* that would resolve to an asynchronous iterator.

Starting with Python 3.7, **__aiter__()** must return an asynchronous iterator object. Returning anything else will result in a **TypeError** error.

3.4.4. Asynchronous Context Managers

An *asynchronous context manager* is a *context manager* that is able to suspend execution in its `__aenter__` and `__aexit__` methods.

Asynchronous context managers can be used in an **async with** statement.

object._aenter_(*self*)

Semantically similar to **__enter__()**, the only difference

being that it must return an *awaitable*.

object.__aexit__(*self*, *exc_type*, *exc_value*, *traceback*)

Semantically similar to **__exit__()**, the only difference being that it must return an *awaitable*.

An example of an asynchronous context manager class:

```
class AsyncContextManager:
    async def __aenter__(self):
        await log('entering context')

    async def __aexit__(self, exc_type, exc, tb):
        await log('exiting context')
```

New in version 3.5.

Footnotes

1

It *is* possible in some cases to change an object's type, under certain controlled conditions. It generally isn't a good idea though, since it can lead to some very strange behaviour if it is handled incorrectly.

2

The **__hash__()**, **__iter__()**, **__reversed__()**, and **__contains__()** methods have special handling for this; others will still raise a **TypeError**, but may do so by relying on the behavior that `None` is not callable.

3

"Does not support" here means that the class has no such method, or the method returns `NotImplemented`. Do not set the method to `None` if you want to force fallback to the right operand's reflected method—that will instead have the opposite effect of explicitly *blocking* such fallback.

4

For operands of the same type, it is assumed that if the non-reflected method – such as `__add__()` – fails then the overall operation is not supported, which is why the reflected method is not called.

4. Execution model

4.1. Structure of a program

A Python program is constructed from code blocks. A *block* is a piece of Python program text that is executed as a unit. The following are blocks: a module, a function body, and a class definition. Each command typed interactively is a block. A script file (a file given as standard input to the interpreter or specified as a command line argument to the interpreter) is a code block. A script command (a command specified on the interpreter command line with the **`-c`** option) is a code block. A module run as a top level script (as module `__main__`) from the command line using a **`-m`** argument is also a code block. The string argument passed to the built-in functions **`eval()`** and **`exec()`** is a code block.

A code block is executed in an *execution frame*. A frame contains some administrative information (used for debugging) and determines where and how execution continues after the code block's execution has completed.

4.2. Naming and binding

4.2.1. Binding of names

Names refer to objects. Names are introduced by name binding operations.

The following constructs bind names:

- formal parameters to functions,
- class definitions,
- function definitions,
- assignment expressions,
- targets that are identifiers if occurring in an assignment:

    - **for** loop header,
    - after **as** in a **with** statement, **except** clause, **except*** clause, or in the as-pattern in structural pattern matching,
    - in a capture pattern in structural pattern matching
- **import** statements.

The **import** statement of the form `from ... import *` binds all names defined in the imported module, except those beginning with an underscore. This form may only be used at the module level.

A target occurring in a **del** statement is also considered bound for this purpose (though the actual semantics are to unbind the name).

Each assignment or import statement occurs within a block defined by a class or function definition or at the module level (the top-level code block).

If a name is bound in a block, it is a local variable of that block, unless declared as **nonlocal** or **global**. If a name is bound at the module level, it is a global variable. (The variables of the module code block are local and global.) If a variable is used in a code block but not defined there, it is a *free variable*.

Each occurrence of a name in the program text refers to the *binding* of that name established by the following name resolution rules.

4.2.2. Resolution of names

A *scope* defines the visibility of a name within a block. If a local variable is defined in a block, its scope includes that block. If the definition occurs in a function block, the scope extends to any blocks contained within the defining one, unless a contained block introduces a different binding for the name.

When a name is used in a code block, it is resolved using the nearest enclosing scope. The set of all such scopes visible to a code block is called the block's *environment*.

When a name is not found at all, a **NameError** exception is raised.

If the current scope is a function scope, and the name refers to a local variable that has not yet been bound to a value at the point where the name is used, an **UnboundLocalError** exception is raised. **UnboundLocalError** is a subclass of **NameError**.

If a name binding operation occurs anywhere within a code block, all uses of the name within the block are treated as references to the current block. This can lead to errors when a name is used within a block before it is bound. This rule is subtle. Python lacks declarations and allows name binding operations to occur anywhere within a code block. The local variables of a code block can be determined by scanning the entire text of the block for name binding operations.

If the **global** statement occurs within a block, all uses of the names specified in the statement refer to the bindings of those names in the top-level namespace. Names are resolved in the top-level namespace by searching the global namespace, i.e. the namespace of the module containing the code block, and the builtins namespace, the namespace of the module **builtins**. The global namespace is searched first. If the names are not found there, the builtins namespace is searched. The **global** statement must precede all uses of the listed names.

The **global** statement has the same scope as a name binding operation in the same block. If the nearest enclosing scope for a free variable contains a global statement, the free variable is treated as a global.

The **nonlocal** statement causes corresponding names to refer to previously bound variables in the nearest enclosing function scope. **SyntaxError** is raised at compile time if the given name does not exist in any enclosing function scope.

The namespace for a module is automatically created the first time a module is imported. The main module for a script is always called **__main__**.

Class definition blocks and arguments to **exec()** and **eval()** are special in the context of name resolution. A class definition is an executable statement that may use and define names. These

references follow the normal rules for name resolution with an exception that unbound local variables are looked up in the global namespace. The namespace of the class definition becomes the attribute dictionary of the class. The scope of names defined in a class block is limited to the class block; it does not extend to the code blocks of methods – this includes comprehensions and generator expressions since they are implemented using a function scope. This means that the following will fail:

```
class A:
    a = 42
    b = list(a + i for i in range(10))
```

4.2.3. Builtins and restricted execution

CPython implementation detail: Users should not touch `__builtins__`; it is strictly an implementation detail. Users wanting to override values in the builtins namespace should **`import`** the **`builtins`** module and modify its attributes appropriately.

The builtins namespace associated with the execution of a code block is actually found by looking up the name `__builtins__` in its global namespace; this should be a dictionary or a module (in the latter case the module's dictionary is used). By default, when in the **`__main__`** module, `__builtins__` is the built-in module **`builtins`**; when in any other module, `__builtins__` is an alias for the dictionary of the **`builtins`** module itself.

4.2.4. Interaction with dynamic features

Name resolution of free variables occurs at runtime, not at compile time. This means that the following code will print 42:

```
i = 10
def f():
    print(i)
i = 42
f()
```

The `eval()` and `exec()` functions do not have access to the full environment for resolving names. Names may be resolved in the local and global namespaces of the caller. Free variables are not resolved in the nearest enclosing namespace, but in the global namespace. 1 The `exec()` and `eval()` functions have optional arguments to override the global and local namespace. If only one namespace is specified, it is used for both.

4.3. Exceptions

Exceptions are a means of breaking out of the normal flow of control of a code block in order to handle errors or other exceptional conditions. An exception is *raised* at the point where the error is detected; it may be *handled* by the surrounding code block or by any code block that directly or indirectly invoked the code block where the error occurred.

The Python interpreter raises an exception when it detects a run-time error (such as division by zero). A Python program can also explicitly raise an exception with the `raise` statement. Exception handlers are specified with the `try` … `except` statement. The `finally` clause of such a statement can be used to specify cleanup code which does not handle the exception, but is executed whether an exception occurred or not in the preceding code.

Python uses the “termination” model of error handling: an exception handler can find out what happened and continue execution at an outer level, but it cannot repair the cause of the error and retry the failing operation (except by re-entering the offending piece of code from the top).

When an exception is not handled at all, the interpreter terminates execution of the program, or returns to its interactive main loop. In either case, it prints a stack traceback, except when the exception is `SystemExit`.

Exceptions are identified by class instances. The `except` clause is selected depending on the class of the instance: it must reference the class of the instance or a non-virtual base class thereof. The instance can be received by the handler and can carry additional

information about the exceptional condition.

Note

Exception messages are not part of the Python API. Their contents may change from one version of Python to the next without warning and should not be relied on by code which will run under multiple versions of the interpreter.

See also the description of the `try` statement in section The try statement and `raise` statement in section The raise statement.

Footnotes

1

This limitation occurs because the code that is executed by these operations is not available at the time the module is compiled.

5. The import system

Python code in one module gains access to the code in another module by the process of importing it. The `import` statement is the most common way of invoking the import machinery, but it is not the only way. Functions such as `importlib.import_module()` and built-in `__import__()` can also be used to invoke the import machinery.

The `import` statement combines two operations; it searches for the named module, then it binds the results of that search to a name in the local scope. The search operation of the `import` statement is defined as a call to the `__import__()` function, with the appropriate arguments. The return value of `__import__()` is used to perform the name binding operation of the `import` statement. See the `import` statement for the exact details of that name binding operation.

A direct call to `__import__()` performs only the module search and, if found, the module creation operation. While certain side-effects may occur, such as the importing of parent packages, and the updating of various caches (including `sys.modules`), only the `import` statement performs a name binding operation.

When an `import` statement is executed, the standard builtin `__import__()` function is called. Other mechanisms for invoking the import system (such as `importlib.import_module()`) may choose to bypass `__import__()` and use their own solutions to implement import semantics.

When a module is first imported, Python searches for the module and if found, it creates a module object 1, initializing it. If the named module cannot be found, a `ModuleNotFoundError` is raised. Python implements various strategies to search for the named module when the import machinery is invoked. These strategies can be modified and extended by using various hooks described in the sections below.

Changed in version 3.3: The import system has been updated to fully implement the second phase of **PEP 302** [https://peps.python.org/pep-0302/]. There is no longer any implicit import machinery - the full import system is exposed through **`sys.meta_path`**. In addition, native namespace package support has been implemented (see **PEP 420** [https://peps.python.org/pep-0420/]).

5.1. `importlib`

The **`importlib`** module provides a rich API for interacting with the import system. For example **`importlib.import_module()`** provides a recommended, simpler API than built-in **`__import__()`** for invoking the import machinery. Refer to the **`importlib`** library documentation for additional detail.

5.2. Packages

Python has only one type of module object, and all modules are of this type, regardless of whether the module is implemented in Python, C, or something else. To help organize modules and provide a naming hierarchy, Python has a concept of packages.

You can think of packages as the directories on a file system and modules as files within directories, but don't take this analogy too literally since packages and modules need not originate from the file system. For the purposes of this documentation, we'll use this convenient analogy of directories and files. Like file system directories, packages are organized hierarchically, and packages may themselves contain subpackages, as well as regular modules.

It's important to keep in mind that all packages are modules, but not all modules are packages. Or put another way, packages are just a special kind of module. Specifically, any module that contains a `__path__` attribute is considered a package.

All modules have a name. Subpackage names are separated from their parent package name by a dot, akin to Python's standard attribute access syntax. Thus you might have a package called **`email`**, which in turn has a subpackage called **`email.mime`** and a

module within that subpackage called **`email.mime.text`**.

5.2.1. Regular packages

Python defines two types of packages, regular packages and namespace packages. Regular packages are traditional packages as they existed in Python 3.2 and earlier. A regular package is typically implemented as a directory containing an `__init__.py` file. When a regular package is imported, this `__init__.py` file is implicitly executed, and the objects it defines are bound to names in the package's namespace. The `__init__.py` file can contain the same Python code that any other module can contain, and Python will add some additional attributes to the module when it is imported.

For example, the following file system layout defines a top level `parent` package with three subpackages:

```
parent/
    __init__.py
    one/
        __init__.py
    two/
        __init__.py
    three/
        __init__.py
```

Importing `parent.one` will implicitly execute `parent/__init__.py` and `parent/one/__init__.py`. Subsequent imports of `parent.two` or `parent.three` will execute `parent/two/__init__.py` and `parent/three/__init__.py` respectively.

5.2.2. Namespace packages

A namespace package is a composite of various portions, where each portion contributes a subpackage to the parent package. Portions may reside in different locations on the file system. Portions may also be found in zip files, on the network, or anywhere else that Python searches during import. Namespace

packages may or may not correspond directly to objects on the file system; they may be virtual modules that have no concrete representation.

Namespace packages do not use an ordinary list for their `__path__` attribute. They instead use a custom iterable type which will automatically perform a new search for package portions on the next import attempt within that package if the path of their parent package (or **`sys.path`** for a top level package) changes.

With namespace packages, there is no `parent/__init__.py` file. In fact, there may be multiple `parent` directories found during import search, where each one is provided by a different portion. Thus `parent/one` may not be physically located next to `parent/two`. In this case, Python will create a namespace package for the top-level `parent` package whenever it or one of its subpackages is imported.

See also **PEP 420** [https://peps.python.org/pep-0420/] for the namespace package specification.

5.3. Searching

To begin the search, Python needs the fully qualified name of the module (or package, but for the purposes of this discussion, the difference is immaterial) being imported. This name may come from various arguments to the **`import`** statement, or from the parameters to the **`importlib.import_module()`** or **`__import__()`** functions.

This name will be used in various phases of the import search, and it may be the dotted path to a submodule, e.g. `foo.bar.baz`. In this case, Python first tries to import `foo`, then `foo.bar`, and finally `foo.bar.baz`. If any of the intermediate imports fail, a **`ModuleNotFoundError`** is raised.

5.3.1. The module cache

The first place checked during import search is **`sys.modules`**. This mapping serves as a cache of all modules that have been

previously imported, including the intermediate paths. So if `foo.bar.baz` was previously imported, **`sys.modules`** will contain entries for `foo`, `foo.bar`, and `foo.bar.baz`. Each key will have as its value the corresponding module object.

During import, the module name is looked up in **`sys.modules`** and if present, the associated value is the module satisfying the import, and the process completes. However, if the value is `None`, then a **`ModuleNotFoundError`** is raised. If the module name is missing, Python will continue searching for the module.

`sys.modules` is writable. Deleting a key may not destroy the associated module (as other modules may hold references to it), but it will invalidate the cache entry for the named module, causing Python to search anew for the named module upon its next import. The key can also be assigned to `None`, forcing the next import of the module to result in a **`ModuleNotFoundError`**.

Beware though, as if you keep a reference to the module object, invalidate its cache entry in **`sys.modules`**, and then re-import the named module, the two module objects will *not* be the same. By contrast, **`importlib.reload()`** will reuse the *same* module object, and simply reinitialise the module contents by rerunning the module's code.

5.3.2. Finders and loaders

If the named module is not found in **`sys.modules`**, then Python's import protocol is invoked to find and load the module. This protocol consists of two conceptual objects, finders and loaders. A finder's job is to determine whether it can find the named module using whatever strategy it knows about. Objects that implement both of these interfaces are referred to as importers - they return themselves when they find that they can load the requested module.

Python includes a number of default finders and importers. The first one knows how to locate built-in modules, and the second knows how to locate frozen modules. A third default finder searches an import path for modules. The import path is a list of locations that may name file system paths or zip files. It can also be extended to search for any locatable resource, such as those identified by URLs.

The import machinery is extensible, so new finders can be added to extend the range and scope of module searching.

Finders do not actually load modules. If they can find the named module, they return a *module spec*, an encapsulation of the module's import-related information, which the import machinery then uses when loading the module.

The following sections describe the protocol for finders and loaders in more detail, including how you can create and register new ones to extend the import machinery.

Changed in version 3.4: In previous versions of Python, finders returned loaders directly, whereas now they return module specs which *contain* loaders. Loaders are still used during import but have fewer responsibilities.

5.3.3. Import hooks

The import machinery is designed to be extensible; the primary mechanism for this are the *import hooks*. There are two types of import hooks: *meta hooks* and *import path hooks*.

Meta hooks are called at the start of import processing, before any other import processing has occurred, other than **`sys.modules`** cache look up. This allows meta hooks to override **`sys.path`** processing, frozen modules, or even built-in modules. Meta hooks are registered by adding new finder objects to **`sys.meta_path`**, as described below.

Import path hooks are called as part of **`sys.path`** (or `package.__path__`) processing, at the point where their associated path item is encountered. Import path hooks are registered by adding new callables to **`sys.path_hooks`** as described below.

5.3.4. The meta path

When the named module is not found in **`sys.modules`**, Python next searches **`sys.meta_path`**, which contains a list of meta path finder objects. These finders are queried in order to see if they know

how to handle the named module. Meta path finders must implement a method called **`find_spec()`** which takes three arguments: a name, an import path, and (optionally) a target module. The meta path finder can use any strategy it wants to determine whether it can handle the named module or not.

If the meta path finder knows how to handle the named module, it returns a spec object. If it cannot handle the named module, it returns `None`. If **`sys.meta_path`** processing reaches the end of its list without returning a spec, then a **`ModuleNotFoundError`** is raised. Any other exceptions raised are simply propagated up, aborting the import process.

The **`find_spec()`** method of meta path finders is called with two or three arguments. The first is the fully qualified name of the module being imported, for example `foo.bar.baz`. The second argument is the path entries to use for the module search. For top-level modules, the second argument is `None`, but for submodules or subpackages, the second argument is the value of the parent package's `__path__` attribute. If the appropriate `__path__` attribute cannot be accessed, a **`ModuleNotFoundError`** is raised. The third argument is an existing module object that will be the target of loading later. The import system passes in a target module only during reload.

The meta path may be traversed multiple times for a single import request. For example, assuming none of the modules involved has already been cached, importing `foo.bar.baz` will first perform a top level import, calling `mpf.find_spec("foo", None, None)` on each meta path finder (`mpf`). After `foo` has been imported, `foo.bar` will be imported by traversing the meta path a second time, calling `mpf.find_spec("foo.bar", foo.__path__, None)`. Once `foo.bar` has been imported, the final traversal will call `mpf.find_spec("foo.bar.baz", foo.bar.__path__, None)`.

Some meta path finders only support top level imports. These importers will always return `None` when anything other than `None` is passed as the second argument.

Python's default **`sys.meta_path`** has three meta path finders, one

that knows how to import built-in modules, one that knows how to import frozen modules, and one that knows how to import modules from an import path (i.e. the path based finder).

Changed in version 3.4: The **find_spec()** method of meta path finders replaced **find_module()**, which is now deprecated. While it will continue to work without change, the import machinery will try it only if the finder does not implement `find_spec()`.

Changed in version 3.10: Use of **find_module()** by the import system now raises **ImportWarning**.

5.4. Loading

If and when a module spec is found, the import machinery will use it (and the loader it contains) when loading the module. Here is an approximation of what happens during the loading portion of import:

```
module = None
if spec.loader is not None and hasattr(spec.loader, 'cre
    # It is assumed 'exec_module' will also be defined o
    module = spec.loader.create_module(spec)
if module is None:
    module = ModuleType(spec.name)
# The import-related module attributes get set here:
_init_module_attrs(spec, module)

if spec.loader is None:
    # unsupported
    raise ImportError
if spec.origin is None and spec.submodule_search_locatio
    # namespace package
    sys.modules[spec.name] = module
elif not hasattr(spec.loader, 'exec_module'):
    module = spec.loader.load_module(spec.name)
    # Set __loader__ and __package__ if missing.
else:
    sys.modules[spec.name] = module
```

```
    try:
        spec.loader.exec_module(module)
    except BaseException:
        try:
            del sys.modules[spec.name]
        except KeyError:
            pass
        raise
return sys.modules[spec.name]
```

Note the following details:

- If there is an existing module object with the given name in **`sys.modules`**, import will have already returned it.
- The module will exist in **`sys.modules`** before the loader executes the module code. This is crucial because the module code may (directly or indirectly) import itself; adding it to **`sys.modules`** beforehand prevents unbounded recursion in the worst case and multiple loading in the best.
- If loading fails, the failing module – and only the failing module – gets removed from **`sys.modules`**. Any module already in the **`sys.modules`** cache, and any module that was successfully loaded as a side-effect, must remain in the cache. This contrasts with reloading where even the failing module is left in **`sys.modules`**.
- After the module is created but before execution, the import machinery sets the import-related module attributes ("_init_module_attrs" in the pseudo-code example above), as summarized in a later section.
- Module execution is the key moment of loading in which the module's namespace gets populated. Execution is entirely delegated to the loader, which gets to decide

what gets populated and how.
- The module created during loading and passed to exec_module() may not be the one returned at the end of import 2.

Changed in version 3.4: The import system has taken over the boilerplate responsibilities of loaders. These were previously performed by the **`importlib.abc.Loader.load_module()`** method.

5.4.1. Loaders

Module loaders provide the critical function of loading: module execution. The import machinery calls the **`importlib.abc.Loader.exec_module()`** method with a single argument, the module object to execute. Any value returned from **`exec_module()`** is ignored.

Loaders must satisfy the following requirements:

- If the module is a Python module (as opposed to a built-in module or a dynamically loaded extension), the loader should execute the module's code in the module's global name space (`module.__dict__`).
- If the loader cannot execute the module, it should raise an **`ImportError`**, although any other exception raised during **`exec_module()`** will be propagated.

In many cases, the finder and loader can be the same object; in such cases the **`find_spec()`** method would just return a spec with the loader set to `self`.

Module loaders may opt in to creating the module object during loading by implementing a **`create_module()`** method. It takes one argument, the module spec, and returns the new module object to use during loading. `create_module()` does not need to set any attributes on the module object. If the method returns `None`, the import machinery will create the new module itself.

New in version 3.4: The **`create_module()`** method of loaders.

Changed in version 3.4: The **`load_module()`** method was replaced by **`exec_module()`** and the import machinery assumed all the boilerplate responsibilities of loading.

For compatibility with existing loaders, the import machinery will use the `load_module()` method of loaders if it exists and the loader does not also implement `exec_module()`. However, `load_module()` has been deprecated and loaders should implement `exec_module()` instead.

The `load_module()` method must implement all the boilerplate loading functionality described above in addition to executing the module. All the same constraints apply, with some additional clarification:

- If there is an existing module object with the given name in **`sys.modules`**, the loader must use that existing module. (Otherwise, **`importlib.reload()`** will not work correctly.) If the named module does not exist in **`sys.modules`**, the loader must create a new module object and add it to **`sys.modules`**.
- The module *must* exist in **`sys.modules`** before the loader executes the module code, to prevent unbounded recursion or multiple loading.
- If loading fails, the loader must remove any modules it has inserted into **`sys.modules`**, but it must remove **only** the failing module(s), and only if the loader itself has loaded the module(s) explicitly.

Changed in version 3.5: A **`DeprecationWarning`** is raised when `exec_module()` is defined but `create_module()` is not.

Changed in version 3.6: An **`ImportError`** is raised when `exec_module()` is defined but `create_module()` is not.

Changed in version 3.10: Use of `load_module()` will raise **`ImportWarning`**.

5.4.2. Submodules

When a submodule is loaded using any mechanism (e.g. `importlib` APIs, the `import` or `import-from` statements, or built-in `__import__()`) a binding is placed in the parent module's namespace to the submodule object. For example, if package `spam` has a submodule `foo`, after importing `spam.foo`, `spam` will have an attribute `foo` which is bound to the submodule. Let's say you have the following directory structure:

```
spam/
    __init__.py
    foo.py
```

and `spam/__init__.py` has the following line in it:

```
from .foo import Foo
```

then executing the following puts name bindings for `foo` and `Foo` in the `spam` module:

```
>>> import spam
>>> spam.foo
<module 'spam.foo' from '/tmp/imports/spam/foo.py'>
>>> spam.Foo
<class 'spam.foo.Foo'>
```

Given Python's familiar name binding rules this might seem surprising, but it's actually a fundamental feature of the import system. The invariant holding is that if you have `sys.modules['spam']` and `sys.modules['spam.foo']` (as you would after the above import), the latter must appear as the `foo` attribute of the former.

5.4.3. Module spec

The import machinery uses a variety of information about each

module during import, especially before loading. Most of the information is common to all modules. The purpose of a module's spec is to encapsulate this import-related information on a per-module basis.

Using a spec during import allows state to be transferred between import system components, e.g. between the finder that creates the module spec and the loader that executes it. Most importantly, it allows the import machinery to perform the boilerplate operations of loading, whereas without a module spec the loader had that responsibility.

The module's spec is exposed as the `__spec__` attribute on a module object. See **`ModuleSpec`** for details on the contents of the module spec.

New in version 3.4.

5.4.4. Import-related module attributes

The import machinery fills in these attributes on each module object during loading, based on the module's spec, before the loader executes the module.

name

> The `__name__` attribute must be set to the fully qualified name of the module. This name is used to uniquely identify the module in the import system.

loader

> The `__loader__` attribute must be set to the loader object that the import machinery used when loading the module. This is mostly for introspection, but can be used for additional loader-specific functionality, for example getting data associated with a loader.

package

> The module's `__package__` attribute must be set. Its value must be a string, but it can be the same value as its `__name__`. When the module is a package, its

`__package__` value should be set to its `__name__`. When the module is not a package, `__package__` should be set to the empty string for top-level modules, or for submodules, to the parent package's name. See **PEP 366** [https://peps.python.org/pep-0366/] for further details.

This attribute is used instead of `__name__` to calculate explicit relative imports for main modules, as defined in **PEP 366** [https://peps.python.org/pep-0366/]. It is expected to have the same value as `__spec__.parent`.

Changed in version 3.6: The value of `__package__` is expected to be the same as `__spec__.parent`.

spec

The `__spec__` attribute must be set to the module spec that was used when importing the module. Setting `__spec__` appropriately applies equally to modules initialized during interpreter startup. The one exception is `__main__`, where `__spec__` is set to None in some cases.

When `__package__` is not defined, `__spec__.parent` is used as a fallback.

New in version 3.4.

Changed in version 3.6: `__spec__.parent` is used as a fallback when `__package__` is not defined.

path

If the module is a package (either regular or namespace), the module object's `__path__` attribute must be set. The value must be iterable, but may be empty if `__path__` has no further significance. If `__path__` is not empty, it must produce strings when iterated over. More details on the semantics of `__path__` are given below.

Non-package modules should not have a `__path__` attribute.

file

cached

__file__ is optional (if set, value must be a string). It indicates the pathname of the file from which the module was loaded (if loaded from a file), or the pathname of the shared library file for extension modules loaded dynamically from a shared library. It might be missing for certain types of modules, such as C modules that are statically linked into the interpreter, and the import system may opt to leave it unset if it has no semantic meaning (e.g. a module loaded from a database).

If __file__ is set then the __cached__ attribute might also be set, which is the path to any compiled version of the code (e.g. byte-compiled file). The file does not need to exist to set this attribute; the path can simply point to where the compiled file would exist (see **PEP 3147** [https://peps.python.org/pep-3147/]).

Note that __cached__ may be set even if __file__ is not set. However, that scenario is quite atypical. Ultimately, the loader is what makes use of the module spec provided by the finder (from which __file__ and __cached__ are derived). So if a loader can load from a cached module but otherwise does not load from a file, that atypical scenario may be appropriate.

5.4.5. module._path_

By definition, if a module has a __path__ attribute, it is a package.

A package's __path__ attribute is used during imports of its subpackages. Within the import machinery, it functions much the same as **sys.path**, i.e. providing a list of locations to search for modules during import. However, __path__ is typically much more constrained than **sys.path**.

__path__ must be an iterable of strings, but it may be empty. The

same rules used for **sys.path** also apply to a package's __path__, and **sys.path_hooks** (described below) are consulted when traversing a package's __path__.

A package's __init__.py file may set or alter the package's __path__ attribute, and this was typically the way namespace packages were implemented prior to **PEP 420** [https://peps.python.org/pep-0420/]. With the adoption of **PEP 420** [https://peps.python.org/pep-0420/], namespace packages no longer need to supply __init__.py files containing only __path__ manipulation code; the import machinery automatically sets __path__ correctly for the namespace package.

5.4.6. Module reprs

By default, all modules have a usable repr, however depending on the attributes set above, and in the module's spec, you can more explicitly control the repr of module objects.

If the module has a spec (__spec__), the import machinery will try to generate a repr from it. If that fails or there is no spec, the import system will craft a default repr using whatever information is available on the module. It will try to use the module.__name__, module.__file__, and module.__loader__ as input into the repr, with defaults for whatever information is missing.

Here are the exact rules used:

- If the module has a __spec__ attribute, the information in the spec is used to generate the repr. The "name", "loader", "origin", and "has_location" attributes are consulted.
- If the module has a __file__ attribute, this is used as part of the module's repr.
- If the module has no __file__ but does have a __loader__ that is not None, then the loader's repr is used as part of the module's repr.
- Otherwise, just use the module's __name__ in the repr.

Changed in version 3.4: Use of **loader.module_repr()** has been deprecated and the module spec is now used by the import machinery to generate a module repr.

For backward compatibility with Python 3.3, the module repr will be generated by calling the loader's **module_repr()** method, if defined, before trying either approach described above. However, the method is deprecated.

Changed in version 3.10: Calling **module_repr()** now occurs after trying to use a module's `__spec__` attribute but before falling back on `__file__`. Use of **module_repr()** is slated to stop in Python 3.12.

5.4.7. Cached bytecode invalidation

Before Python loads cached bytecode from a `.pyc` file, it checks whether the cache is up-to-date with the source `.py` file. By default, Python does this by storing the source's last-modified timestamp and size in the cache file when writing it. At runtime, the import system then validates the cache file by checking the stored metadata in the cache file against the source's metadata.

Python also supports "hash-based" cache files, which store a hash of the source file's contents rather than its metadata. There are two variants of hash-based `.pyc` files: checked and unchecked. For checked hash-based `.pyc` files, Python validates the cache file by hashing the source file and comparing the resulting hash with the hash in the cache file. If a checked hash-based cache file is found to be invalid, Python regenerates it and writes a new checked hash-based cache file. For unchecked hash-based `.pyc` files, Python simply assumes the cache file is valid if it exists. Hash-based `.pyc` files validation behavior may be overridden with the **--check-hash-based-pycs** flag.

Changed in version 3.7: Added hash-based `.pyc` files. Previously, Python only supported timestamp-based invalidation of bytecode caches.

5.5. The Path Based Finder

As mentioned previously, Python comes with several default meta path finders. One of these, called the path based finder (**`PathFinder`**), searches an import path, which contains a list of path entries. Each path entry names a location to search for modules.

The path based finder itself doesn't know how to import anything. Instead, it traverses the individual path entries, associating each of them with a path entry finder that knows how to handle that particular kind of path.

The default set of path entry finders implement all the semantics for finding modules on the file system, handling special file types such as Python source code (`.py` files), Python byte code (`.pyc` files) and shared libraries (e.g. `.so` files). When supported by the **`zipimport`** module in the standard library, the default path entry finders also handle loading all of these file types (other than shared libraries) from zipfiles.

Path entries need not be limited to file system locations. They can refer to URLs, database queries, or any other location that can be specified as a string.

The path based finder provides additional hooks and protocols so that you can extend and customize the types of searchable path entries. For example, if you wanted to support path entries as network URLs, you could write a hook that implements HTTP semantics to find modules on the web. This hook (a callable) would return a path entry finder supporting the protocol described below, which was then used to get a loader for the module from the web.

A word of warning: this section and the previous both use the term *finder*, distinguishing between them by using the terms meta path finder and path entry finder. These two types of finders are very similar, support similar protocols, and function in similar ways during the import process, but it's important to keep in mind that they are subtly different. In particular, meta path finders operate at the beginning of the import process, as keyed off the **`sys.meta_path`** traversal.

By contrast, path entry finders are in a sense an implementation

detail of the path based finder, and in fact, if the path based finder were to be removed from **sys.meta_path**, none of the path entry finder semantics would be invoked.

5.5.1. Path entry finders

The path based finder is responsible for finding and loading Python modules and packages whose location is specified with a string path entry. Most path entries name locations in the file system, but they need not be limited to this.

As a meta path finder, the path based finder implements the **find_spec()** protocol previously described, however it exposes additional hooks that can be used to customize how modules are found and loaded from the import path.

Three variables are used by the path based finder, **sys.path**, **sys.path_hooks** and **sys.path_importer_cache**. The `__path__` attributes on package objects are also used. These provide additional ways that the import machinery can be customized.

sys.path contains a list of strings providing search locations for modules and packages. It is initialized from the **PYTHONPATH** environment variable and various other installation- and implementation-specific defaults. Entries in **sys.path** can name directories on the file system, zip files, and potentially other "locations" (see the **site** module) that should be searched for modules, such as URLs, or database queries. Only strings should be present on **sys.path**; all other data types are ignored.

The path based finder is a meta path finder, so the import machinery begins the import path search by calling the path based finder's **find_spec()** method as described previously. When the `path` argument to **find_spec()** is given, it will be a list of string paths to traverse - typically a package's `__path__` attribute for an import within that package. If the `path` argument is `None`, this indicates a top level import and **sys.path** is used.

The path based finder iterates over every entry in the search path, and for each of these, looks for an appropriate path entry finder

(**PathEntryFinder**) for the path entry. Because this can be an expensive operation (e.g. there may be `stat()` call overheads for this search), the path based finder maintains a cache mapping path entries to path entry finders. This cache is maintained in **sys.path_importer_cache** (despite the name, this cache actually stores finder objects rather than being limited to importer objects). In this way, the expensive search for a particular path entry location's path entry finder need only be done once. User code is free to remove cache entries from **sys.path_importer_cache** forcing the path based finder to perform the path entry search again 3.

If the path entry is not present in the cache, the path based finder iterates over every callable in **sys.path_hooks**. Each of the path entry hooks in this list is called with a single argument, the path entry to be searched. This callable may either return a path entry finder that can handle the path entry, or it may raise **ImportError**. An **ImportError** is used by the path based finder to signal that the hook cannot find a path entry finder for that path entry. The exception is ignored and import path iteration continues. The hook should expect either a string or bytes object; the encoding of bytes objects is up to the hook (e.g. it may be a file system encoding, UTF-8, or something else), and if the hook cannot decode the argument, it should raise **ImportError**.

If **sys.path_hooks** iteration ends with no path entry finder being returned, then the path based finder's **find_spec()** method will store `None` in **sys.path_importer_cache** (to indicate that there is no finder for this path entry) and return `None`, indicating that this meta path finder could not find the module.

If a path entry finder *is* returned by one of the path entry hook callables on **sys.path_hooks**, then the following protocol is used to ask the finder for a module spec, which is then used when loading the module.

The current working directory – denoted by an empty string – is handled slightly differently from other entries on **sys.path**. First, if the current working directory is found to not exist, no value is stored in **sys.path_importer_cache**. Second, the value for the current working directory is looked up fresh for each module

lookup. Third, the path used for **sys.path_importer_cache** and returned by **importlib.machinery.PathFinder.find_spec()** will be the actual current working directory and not the empty string.

5.5.2. Path entry finder protocol

In order to support imports of modules and initialized packages and also to contribute portions to namespace packages, path entry finders must implement the **find_spec()** method.

find_spec() takes two arguments: the fully qualified name of the module being imported, and the (optional) target module. `find_spec()` returns a fully populated spec for the module. This spec will always have “loader” set (with one exception).

To indicate to the import machinery that the spec represents a namespace portion, the path entry finder sets “submodule_search_locations” to a list containing the portion.

Changed in version 3.4: **find_spec()** replaced **find_loader()** and **find_module()**, both of which are now deprecated, but will be used if `find_spec()` is not defined.

Older path entry finders may implement one of these two deprecated methods instead of `find_spec()`. The methods are still respected for the sake of backward compatibility. However, if `find_spec()` is implemented on the path entry finder, the legacy methods are ignored.

find_loader() takes one argument, the fully qualified name of the module being imported. `find_loader()` returns a 2-tuple where the first item is the loader and the second item is a namespace portion.

For backwards compatibility with other implementations of the import protocol, many path entry finders also support the same, traditional `find_module()` method that meta path finders support. However path entry finder `find_module()` methods are never called with a `path` argument (they are expected to record the appropriate path information from the initial call to the path

hook).

The `find_module()` method on path entry finders is deprecated, as it does not allow the path entry finder to contribute portions to namespace packages. If both `find_loader()` and `find_module()` exist on a path entry finder, the import system will always call `find_loader()` in preference to `find_module()`.

Changed in version 3.10: Calls to **`find_module()`** and **`find_loader()`** by the import system will raise **`ImportWarning`**.

5.6. Replacing the standard import system

The most reliable mechanism for replacing the entire import system is to delete the default contents of **`sys.meta_path`**, replacing them entirely with a custom meta path hook.

If it is acceptable to only alter the behaviour of import statements without affecting other APIs that access the import system, then replacing the builtin **`__import__()`** function may be sufficient. This technique may also be employed at the module level to only alter the behaviour of import statements within that module.

To selectively prevent the import of some modules from a hook early on the meta path (rather than disabling the standard import system entirely), it is sufficient to raise **`ModuleNotFoundError`** directly from **`find_spec()`** instead of returning `None`. The latter indicates that the meta path search should continue, while raising an exception terminates it immediately.

5.7. Package Relative Imports

Relative imports use leading dots. A single leading dot indicates a relative import, starting with the current package. Two or more leading dots indicate a relative import to the parent(s) of the current package, one level per dot after the first. For example, given

the following package layout:

```
package/
    __init__.py
    subpackage1/
        __init__.py
        moduleX.py
        moduleY.py
    subpackage2/
        __init__.py
        moduleZ.py
    moduleA.py
```

In either `subpackage1/moduleX.py` or `subpackage1/__init__.py`, the following are valid relative imports:

```
from .moduleY import spam
from .moduleY import spam as ham
from . import moduleY
from ..subpackage1 import moduleY
from ..subpackage2.moduleZ import eggs
from ..moduleA import foo
```

Absolute imports may use either the `import <>` or `from <> import <>` syntax, but relative imports may only use the second form; the reason for this is that:

```
import XXX.YYY.ZZZ
```

should expose `XXX.YYY.ZZZ` as a usable expression, but .moduleY is not a valid expression.

5.8. Special considerations for _main_

The **`__main__`** module is a special case relative to Python's import system. As noted elsewhere, the `__main__` module is directly initialized at interpreter startup, much like **`sys`** and **`builtins`**. However, unlike those two, it doesn't strictly qualify as a built-in module. This is because the manner in which `__main__` is initialized depends on the flags and other options with which the

interpreter is invoked.

5.8.1. _main_._spec_

Depending on how **__main__** is initialized, `__main__.__spec__` gets set appropriately or to `None`.

When Python is started with the **-m** option, `__spec__` is set to the module spec of the corresponding module or package. `__spec__` is also populated when the `__main__` module is loaded as part of executing a directory, zipfile or other **sys.path** entry.

In the remaining cases `__main__.__spec__` is set to `None`, as the code used to populate the **__main__** does not correspond directly with an importable module:

- interactive prompt
- **-c** option
- running from stdin
- running directly from a source or bytecode file

Note that `__main__.__spec__` is always `None` in the last case, *even if* the file could technically be imported directly as a module instead. Use the **-m** switch if valid module metadata is desired in **__main__**.

Note also that even when `__main__` corresponds with an importable module and `__main__.__spec__` is set accordingly, they're still considered *distinct* modules. This is due to the fact that blocks guarded by `if __name__ == "__main__":` checks only execute when the module is used to populate the `__main__` namespace, and not during normal import.

5.9. References

The import machinery has evolved considerably since Python's early days. The original specification for packages [https://www.python.org/doc/essays/packages/] is still available to read, although some details have changed since the writing of that document.

The original specification for **sys.meta_path** was **PEP 302** [https://peps.python.org/pep-0302/], with subsequent extension in **PEP 420** [https://peps.python.org/pep-0420/].

PEP 420 [https://peps.python.org/pep-0420/] introduced namespace packages for Python 3.3. **PEP 420** [https://peps.python.org/pep-0420/] also introduced the **find_loader()** protocol as an alternative to **find_module()**.

PEP 366 [https://peps.python.org/pep-0366/] describes the addition of the `__package__` attribute for explicit relative imports in main modules.

PEP 328 [https://peps.python.org/pep-0328/] introduced absolute and explicit relative imports and initially proposed `__name__` for semantics **PEP 366** [https://peps.python.org/pep-0366/] would eventually specify for `__package__`.

PEP 338 [https://peps.python.org/pep-0338/] defines executing modules as scripts.

PEP 451 [https://peps.python.org/pep-0451/] adds the encapsulation of per-module import state in spec objects. It also off-loads most of the boilerplate responsibilities of loaders back onto the import machinery. These changes allow the deprecation of several APIs in the import system and also addition of new methods to finders and loaders.

Footnotes

1

See **types.ModuleType**.

2

The importlib implementation avoids using the return value directly. Instead, it gets the module object by looking the module name up in **sys.modules**. The indirect effect of this is that an imported module may replace itself in **sys.modules**. This is implementation-specific behavior that is

not guaranteed to work in other Python implementations.

3

In legacy code, it is possible to find instances of **`imp.NullImporter`** in the **`sys.path_importer_cache`**. It is recommended that code be changed to use `None` instead. See Porting Python code for more details.

6. Expressions

This chapter explains the meaning of the elements of expressions in Python.

Syntax Notes: In this and the following chapters, extended BNF notation will be used to describe syntax, not lexical analysis. When (one alternative of) a syntax rule has the form

```
name ::=  othername
```

and no semantics are given, the semantics of this form of `name` are the same as for `othername`.

6.1. Arithmetic conversions

When a description of an arithmetic operator below uses the phrase “the numeric arguments are converted to a common type”, this means that the operator implementation for built-in types works as follows:

- If either argument is a complex number, the other is converted to complex;
- otherwise, if either argument is a floating point number, the other is converted to floating point;
- otherwise, both must be integers and no conversion is necessary.

Some additional rules apply for certain operators (e.g., a string as a left argument to the ‘%’ operator). Extensions must define their own conversion behavior.

6.2. Atoms

Atoms are the most basic elements of expressions. The simplest atoms are identifiers or literals. Forms enclosed in parentheses,

brackets or braces are also categorized syntactically as atoms. The syntax for atoms is:

```
atom      ::=  identifier | literal | enclosure
enclosure ::=  parenth_form | list_display | dict_displa
               | generator_expression | yield_atom
```

6.2.1. Identifiers (Names)

An identifier occurring as an atom is a name. See section Identifiers and keywords for lexical definition and section Naming and binding for documentation of naming and binding.

When the name is bound to an object, evaluation of the atom yields that object. When a name is not bound, an attempt to evaluate it raises a `NameError` exception.

Private name mangling: When an identifier that textually occurs in a class definition begins with two or more underscore characters and does not end in two or more underscores, it is considered a *private name* of that class. Private names are transformed to a longer form before code is generated for them. The transformation inserts the class name, with leading underscores removed and a single underscore inserted, in front of the name. For example, the identifier `__spam` occurring in a class named `Ham` will be transformed to `_Ham__spam`. This transformation is independent of the syntactical context in which the identifier is used. If the transformed name is extremely long (longer than 255 characters), implementation defined truncation may happen. If the class name consists only of underscores, no transformation is done.

6.2.2. Literals

Python supports string and bytes literals and various numeric literals:

```
literal ::=  stringliteral | bytesliteral
             | integer | floatnumber | imagnumber
```

Evaluation of a literal yields an object of the given type (string,

bytes, integer, floating point number, complex number) with the given value. The value may be approximated in the case of floating point and imaginary (complex) literals. See section Literals for details.

All literals correspond to immutable data types, and hence the object's identity is less important than its value. Multiple evaluations of literals with the same value (either the same occurrence in the program text or a different occurrence) may obtain the same object or a different object with the same value.

6.2.3. Parenthesized forms

A parenthesized form is an optional expression list enclosed in parentheses:

```
parenth_form ::=  "(" [starred_expression] ")"
```

A parenthesized expression list yields whatever that expression list yields: if the list contains at least one comma, it yields a tuple; otherwise, it yields the single expression that makes up the expression list.

An empty pair of parentheses yields an empty tuple object. Since tuples are immutable, the same rules as for literals apply (i.e., two occurrences of the empty tuple may or may not yield the same object).

Note that tuples are not formed by the parentheses, but rather by use of the comma. The exception is the empty tuple, for which parentheses *are* required — allowing unparenthesized "nothing" in expressions would cause ambiguities and allow common typos to pass uncaught.

6.2.4. Displays for lists, sets and dictionaries

For constructing a list, a set or a dictionary Python provides special syntax called "displays", each of them in two flavors:

- either the container contents are listed explicitly, or
- they are computed via a set of looping and filtering

instructions, called a *comprehension*.

Common syntax elements for comprehensions are:

```
comprehension ::=  assignment_expression comp_for
comp_for      ::=  ["async"] "for" target_list "in" or_t
comp_iter     ::=  comp_for | comp_if
comp_if       ::=  "if" or_test [comp_iter]
```

The comprehension consists of a single expression followed by at least one **`for`** clause and zero or more **`for`** or **`if`** clauses. In this case, the elements of the new container are those that would be produced by considering each of the **`for`** or **`if`** clauses a block, nesting from left to right, and evaluating the expression to produce an element each time the innermost block is reached.

However, aside from the iterable expression in the leftmost **`for`** clause, the comprehension is executed in a separate implicitly nested scope. This ensures that names assigned to in the target list don't "leak" into the enclosing scope.

The iterable expression in the leftmost **`for`** clause is evaluated directly in the enclosing scope and then passed as an argument to the implicitly nested scope. Subsequent **`for`** clauses and any filter condition in the leftmost **`for`** clause cannot be evaluated in the enclosing scope as they may depend on the values obtained from the leftmost iterable. For example: `[x*y for x in range(10) for y in range(x, x+10)]`.

To ensure the comprehension always results in a container of the appropriate type, `yield` and `yield from` expressions are prohibited in the implicitly nested scope.

Since Python 3.6, in an **`async def`** function, an **`async for`** clause may be used to iterate over a asynchronous iterator. A comprehension in an **`async def`** function may consist of either a **`for`** or **`async for`** clause following the leading expression, may contain additional **`for`** or **`async for`** clauses, and may also use **`await`** expressions. If a comprehension contains either **`async for`** clauses or **`await`** expressions or other asynchronous comprehensions it is called an *asynchronous comprehension*. An

asynchronous comprehension may suspend the execution of the coroutine function in which it appears. See also **PEP 530** [https://peps.python.org/pep-0530/].

New in version 3.6: Asynchronous comprehensions were introduced.

Changed in version 3.8: `yield` and `yield from` prohibited in the implicitly nested scope.

Changed in version 3.11: Asynchronous comprehensions are now allowed inside comprehensions in asynchronous functions. Outer comprehensions implicitly become asynchronous.

6.2.5. List displays

A list display is a possibly empty series of expressions enclosed in square brackets:

```
list_display ::=  "[" [starred_list | comprehension] "]"
```

A list display yields a new list object, the contents being specified by either a list of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and placed into the list object in that order. When a comprehension is supplied, the list is constructed from the elements resulting from the comprehension.

6.2.6. Set displays

A set display is denoted by curly braces and distinguishable from dictionary displays by the lack of colons separating keys and values:

```
set_display ::=  "{" (starred_list | comprehension) "}"
```

A set display yields a new mutable set object, the contents being specified by either a sequence of expressions or a comprehension. When a comma-separated list of expressions is supplied, its elements are evaluated from left to right and added to the set object. When a comprehension is supplied, the set is constructed from the elements resulting from the comprehension.

An empty set cannot be constructed with `{}`; this literal constructs an empty dictionary.

6.2.7. Dictionary displays

A dictionary display is a possibly empty series of key/datum pairs enclosed in curly braces:

```
dict_display       ::=  "{" [key_datum_list | dict_compr
key_datum_list     ::=  key_datum ("," key_datum)* [","]
key_datum          ::=  expression ":" expression | "**"
dict_comprehension ::=  expression ":" expression comp_f
```

A dictionary display yields a new dictionary object.

If a comma-separated sequence of key/datum pairs is given, they are evaluated from left to right to define the entries of the dictionary: each key object is used as a key into the dictionary to store the corresponding datum. This means that you can specify the same key multiple times in the key/datum list, and the final dictionary's value for that key will be the last one given.

A double asterisk `**` denotes *dictionary unpacking*. Its operand must be a mapping. Each mapping item is added to the new dictionary. Later values replace values already set by earlier key/datum pairs and earlier dictionary unpackings.

New in version 3.5: Unpacking into dictionary displays, originally proposed by **PEP 448** [https://peps.python.org/pep-0448/].

A dict comprehension, in contrast to list and set comprehensions, needs two expressions separated with a colon followed by the usual "for" and "if" clauses. When the comprehension is run, the resulting key and value elements are inserted in the new dictionary in the order they are produced.

Restrictions on the types of the key values are listed earlier in section The standard type hierarchy. (To summarize, the key type should be hashable, which excludes all mutable objects.) Clashes between duplicate keys are not detected; the last datum (textually rightmost in the display) stored for a given key value prevails.

Changed in version 3.8: Prior to Python 3.8, in dict comprehensions, the evaluation order of key and value was not well-defined. In CPython, the value was evaluated before the key. Starting with 3.8, the key is evaluated before the value, as proposed by **PEP 572** [https://peps.python.org/pep-0572/].

6.2.8. Generator expressions

A generator expression is a compact generator notation in parentheses:

```
generator_expression ::=  "(" expression comp_for ")"
```

A generator expression yields a new generator object. Its syntax is the same as for comprehensions, except that it is enclosed in parentheses instead of brackets or curly braces.

Variables used in the generator expression are evaluated lazily when the `__next__()` method is called for the generator object (in the same fashion as normal generators). However, the iterable expression in the leftmost **for** clause is immediately evaluated, so that an error produced by it will be emitted at the point where the generator expression is defined, rather than at the point where the first value is retrieved. Subsequent **for** clauses and any filter condition in the leftmost **for** clause cannot be evaluated in the enclosing scope as they may depend on the values obtained from the leftmost iterable. For example: `(x*y for x in range(10) for y in range(x, x+10))`.

The parentheses can be omitted on calls with only one argument. See section Calls for details.

To avoid interfering with the expected operation of the generator expression itself, `yield` and `yield from` expressions are prohibited in the implicitly defined generator.

If a generator expression contains either **async for** clauses or **await** expressions it is called an *asynchronous generator expression*. An asynchronous generator expression returns a new asynchronous generator object, which is an asynchronous iterator (see Asynchronous Iterators).

New in version 3.6: Asynchronous generator expressions were introduced.

Changed in version 3.7: Prior to Python 3.7, asynchronous generator expressions could only appear in `async def` coroutines. Starting with 3.7, any function can use asynchronous generator expressions.

Changed in version 3.8: `yield` and `yield from` prohibited in the implicitly nested scope.

6.2.9. Yield expressions

```
yield_atom       ::=  "(" yield_expression ")"
yield_expression ::=  "yield" [expression_list | "from"
```

The yield expression is used when defining a generator function or an asynchronous generator function and thus can only be used in the body of a function definition. Using a yield expression in a function's body causes that function to be a generator function, and using it in an `async def` function's body causes that coroutine function to be an asynchronous generator function. For example:

```
def gen():  # defines a generator function
    yield 123

async def agen(): # defines an asynchronous generator fu
    yield 123
```

Due to their side effects on the containing scope, `yield` expressions are not permitted as part of the implicitly defined scopes used to implement comprehensions and generator expressions.

Changed in version 3.8: Yield expressions prohibited in the implicitly nested scopes used to implement comprehensions and generator expressions.

Generator functions are described below, while asynchronous generator functions are described separately in section Asynchronous generator functions.

When a generator function is called, it returns an iterator known as a generator. That generator then controls the execution of the generator function. The execution starts when one of the generator's methods is called. At that time, the execution proceeds to the first yield expression, where it is suspended again, returning the value of **`expression_list`** to the generator's caller. By suspended, we mean that all local state is retained, including the current bindings of local variables, the instruction pointer, the internal evaluation stack, and the state of any exception handling. When the execution is resumed by calling one of the generator's methods, the function can proceed exactly as if the yield expression were just another external call. The value of the yield expression after resuming depends on the method which resumed the execution. If **`__next__()`** is used (typically via either a **`for`** or the **`next()`** builtin) then the result is **`None`**. Otherwise, if **`send()`** is used, then the result will be the value passed in to that method.

All of this makes generator functions quite similar to coroutines; they yield multiple times, they have more than one entry point and their execution can be suspended. The only difference is that a generator function cannot control where the execution should continue after it yields; the control is always transferred to the generator's caller.

Yield expressions are allowed anywhere in a **`try`** construct. If the generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), the generator-iterator's **`close()`** method will be called, allowing any pending **`finally`** clauses to execute.

When `yield from <expr>` is used, the supplied expression must be an iterable. The values produced by iterating that iterable are passed directly to the caller of the current generator's methods. Any values passed in with **`send()`** and any exceptions passed in with **`throw()`** are passed to the underlying iterator if it has the appropriate methods. If this is not the case, then **`send()`** will raise **`AttributeError`** or **`TypeError`**, while **`throw()`** will just raise the passed in exception immediately.

When the underlying iterator is complete, the **`value`** attribute of the raised **`StopIteration`** instance becomes the value of the

yield expression. It can be either set explicitly when raising **StopIteration**, or automatically when the subiterator is a generator (by returning a value from the subgenerator).

> *Changed in version 3.3:* Added `yield from <expr>` to delegate control flow to a subiterator.

The parentheses may be omitted when the yield expression is the sole expression on the right hand side of an assignment statement.

The proposal to enhance the API and syntax of generators, making them usable as simple coroutines.

PEP 380 [https://peps.python.org/pep-0380/] **- Syntax for Delegating to a Subgenerator**
The proposal to introduce the **yield_from** syntax, making delegation to subgenerators easy.

PEP 525 [https://peps.python.org/pep-0525/] **- Asynchronous Generators**
The proposal that expanded on **PEP 492** [https://peps.python.org/pep-0492/] by adding generator capabilities to coroutine functions.

6.2.9.1. Generator-iterator methods

This subsection describes the methods of a generator iterator. They can be used to control the execution of a generator function.

Note that calling any of the generator methods below when the generator is already executing raises a **ValueError** exception.

generator.__next__()

Starts the execution of a generator function or resumes it at the last executed yield expression. When a generator function is resumed with a `__next__()` method, the current yield expression always evaluates to `None`. The execution then continues to the next yield expression, where the generator is suspended again, and the value of the `expression_list` is returned to `__next__()`'s caller. If the generator exits without yielding another value, a `StopIteration` exception is raised.

This method is normally called implicitly, e.g. by a `for` loop, or by the built-in `next()` function.

generator.send(*value*)

Resumes the execution and "sends" a value into the generator function. The *value* argument becomes the result of the current yield expression. The `send()` method returns the next value yielded by the generator, or raises `StopIteration` if the generator exits without yielding another value. When `send()` is called to start the generator, it must be called with `None` as the argument, because there is no yield expression that could receive the value.

generator.throw(*value*)

generator.throw(*type*[, *value*[, *traceback*]])

Raises an exception at the point where the generator was paused, and returns the next value yielded by the generator function. If the generator exits without yielding another value, a `StopIteration` exception is raised. If the generator function does not catch the passed-in exception, or raises a different exception, then that exception propagates to the caller.

In typical use, this is called with a single exception instance similar to the way the `raise` keyword is used.

For backwards compatibility, however, the second signature is supported, following a convention from older versions of

Python. The *type* argument should be an exception class, and *value* should be an exception instance. If the *value* is not provided, the *type* constructor is called to get an instance. If *traceback* is provided, it is set on the exception, otherwise any existing **__traceback__** attribute stored in *value* may be cleared.

generator.close()

Raises a **GeneratorExit** at the point where the generator function was paused. If the generator function then exits gracefully, is already closed, or raises **GeneratorExit** (by not catching the exception), close returns to its caller. If the generator yields a value, a **RuntimeError** is raised. If the generator raises any other exception, it is propagated to the caller. **close()** does nothing if the generator has already exited due to an exception or normal exit.

6.2.9.2. Examples

Here is a simple example that demonstrates the behavior of generators and generator functions:

```
>>> def echo(value=None):
...     print("Execution starts when 'next()' is called
...     try:
...         while True:
...             try:
...                 value = (yield value)
...             except Exception as e:
...                 value = e
...     finally:
...         print("Don't forget to clean up when 'close(
...
>>> generator = echo(1)
>>> print(next(generator))
Execution starts when 'next()' is called for the first t
1
>>> print(next(generator))
None
```

```
>>> print(generator.send(2))
2
>>> generator.throw(TypeError, "spam")
TypeError('spam',)
>>> generator.close()
Don't forget to clean up when 'close()' is called.
```

For examples using `yield from`, see PEP 380: Syntax for Delegating to a Subgenerator in "What's New in Python."

6.2.9.3. Asynchronous generator functions

The presence of a yield expression in a function or method defined using **`async def`** further defines the function as an asynchronous generator function.

When an asynchronous generator function is called, it returns an asynchronous iterator known as an asynchronous generator object. That object then controls the execution of the generator function. An asynchronous generator object is typically used in an **`async for`** statement in a coroutine function analogously to how a generator object would be used in a **`for`** statement.

Calling one of the asynchronous generator's methods returns an awaitable object, and the execution starts when this object is awaited on. At that time, the execution proceeds to the first yield expression, where it is suspended again, returning the value of **`expression_list`** to the awaiting coroutine. As with a generator, suspension means that all local state is retained, including the current bindings of local variables, the instruction pointer, the internal evaluation stack, and the state of any exception handling. When the execution is resumed by awaiting on the next object returned by the asynchronous generator's methods, the function can proceed exactly as if the yield expression were just another external call. The value of the yield expression after resuming depends on the method which resumed the execution. If **`__anext__()`** is used then the result is **`None`**. Otherwise, if **`asend()`** is used, then the result will be the value passed in to that method.

If an asynchronous generator happens to exit early by **`break`**, the

caller task being cancelled, or other exceptions, the generator's async cleanup code will run and possibly raise exceptions or access context variables in an unexpected context–perhaps after the lifetime of tasks it depends, or during the event loop shutdown when the async-generator garbage collection hook is called. To prevent this, the caller must explicitly close the async generator by calling **`aclose()`** method to finalize the generator and ultimately detach it from the event loop.

In an asynchronous generator function, yield expressions are allowed anywhere in a **`try`** construct. However, if an asynchronous generator is not resumed before it is finalized (by reaching a zero reference count or by being garbage collected), then a yield expression within a **`try`** construct could result in a failure to execute pending **`finally`** clauses. In this case, it is the responsibility of the event loop or scheduler running the asynchronous generator to call the asynchronous generator-iterator's **`aclose()`** method and run the resulting coroutine object, thus allowing any pending **`finally`** clauses to execute.

To take care of finalization upon event loop termination, an event loop should define a *finalizer* function which takes an asynchronous generator-iterator and presumably calls **`aclose()`** and executes the coroutine. This *finalizer* may be registered by calling **`sys.set_asyncgen_hooks()`**. When first iterated over, an asynchronous generator-iterator will store the registered *finalizer* to be called upon finalization. For a reference example of a *finalizer* method see the implementation of `asyncio.Loop.shutdown_asyncgens` in Lib/asyncio/base_events.py [https://github.com/python/cpython/tree/3.11/Lib/asyncio/base_events.py].

The expression `yield from <expr>` is a syntax error when used in an asynchronous generator function.

6.2.9.4. Asynchronous generator-iterator methods

This subsection describes the methods of an asynchronous generator iterator, which are used to control the execution of a generator function.

coroutine agen._anext_()

Returns an awaitable which when run starts to execute the asynchronous generator or resumes it at the last executed yield expression. When an asynchronous generator function is resumed with an **`__anext__()`** method, the current yield expression always evaluates to **`None`** in the returned awaitable, which when run will continue to the next yield expression. The value of the **`expression_list`** of the yield expression is the value of the **`StopIteration`** exception raised by the completing coroutine. If the asynchronous generator exits without yielding another value, the awaitable instead raises a **`StopAsyncIteration`** exception, signalling that the asynchronous iteration has completed.

This method is normally called implicitly by a **`async for`** loop.

coroutine agen.asend(*value*)

Returns an awaitable which when run resumes the execution of the asynchronous generator. As with the **`send()`** method for a generator, this "sends" a value into the asynchronous generator function, and the *value* argument becomes the result of the current yield expression. The awaitable returned by the **`asend()`** method will return the next value yielded by the generator as the value of the raised **`StopIteration`**, or raises **`StopAsyncIteration`** if the asynchronous generator exits without yielding another value. When **`asend()`** is called to start the asynchronous generator, it must be called with **`None`** as the argument, because there is no yield expression that could receive the value.

coroutine agen.athrow(*type*[, *value*[, *traceback*]])

Returns an awaitable that raises an exception of type `type` at the point where the asynchronous generator was paused, and returns the next value yielded by the generator function as the value of the raised **`StopIteration`** exception. If the asynchronous generator exits without yielding another value, a **`StopAsyncIteration`** exception is raised by the

awaitable. If the generator function does not catch the passed-in exception, or raises a different exception, then when the awaitable is run that exception propagates to the caller of the awaitable.

coroutine agen.aclose()

Returns an awaitable that when run will throw a **GeneratorExit** into the asynchronous generator function at the point where it was paused. If the asynchronous generator function then exits gracefully, is already closed, or raises **GeneratorExit** (by not catching the exception), then the returned awaitable will raise a **StopIteration** exception. Any further awaitables returned by subsequent calls to the asynchronous generator will raise a **StopAsyncIteration** exception. If the asynchronous generator yields a value, a **RuntimeError** is raised by the awaitable. If the asynchronous generator raises any other exception, it is propagated to the caller of the awaitable. If the asynchronous generator has already exited due to an exception or normal exit, then further calls to **aclose()** will return an awaitable that does nothing.

6.3. Primaries

Primaries represent the most tightly bound operations of the language. Their syntax is:

primary ::= **atom** | **attributeref** | **subscription** | **slicin**

6.3.1. Attribute references

An attribute reference is a primary followed by a period and a name:

attributeref ::= **primary** "." **identifier**

The primary must evaluate to an object of a type that supports attribute references, which most objects do. This object is then asked to produce the attribute whose name is the identifier. This

production can be customized by overriding the **__getattr__()** method. If this attribute is not available, the exception **AttributeError** is raised. Otherwise, the type and value of the object produced is determined by the object. Multiple evaluations of the same attribute reference may yield different objects.

6.3.2. Subscriptions

The subscription of an instance of a container class will generally select an element from the container. The subscription of a generic class will generally return a GenericAlias object.

subscription ::= **primary** "[" **expression_list** "]"

When an object is subscripted, the interpreter will evaluate the primary and the expression list.

The primary must evaluate to an object that supports subscription. An object may support subscription through defining one or both of **__getitem__()** and **__class_getitem__()**. When the primary is subscripted, the evaluated result of the expression list will be passed to one of these methods. For more details on when `__class_getitem__` is called instead of `__getitem__`, see _class_getitem_ versus _getitem_.

If the expression list contains at least one comma, it will evaluate to a **tuple** containing the items of the expression list. Otherwise, the expression list will evaluate to the value of the list's sole member.

For built-in objects, there are two types of objects that support subscription via **__getitem__()**:

1. Mappings. If the primary is a mapping, the expression list must evaluate to an object whose value is one of the keys of the mapping, and the subscription selects the value in the mapping that corresponds to that key. An example of a builtin mapping class is the **dict** class.
2. Sequences. If the primary is a sequence, the expression list must evaluate to an **int** or a **slice** (as discussed in the following section). Examples of builtin sequence classes include the **str**, **list** and **tuple** classes.

The formal syntax makes no special provision for negative indices in sequences. However, built-in sequences all provide a `__getitem__()` method that interprets negative indices by adding the length of the sequence to the index so that, for example, `x[-1]` selects the last item of `x`. The resulting value must be a nonnegative integer less than the number of items in the sequence, and the subscription selects the item whose index is that value (counting from zero). Since the support for negative indices and slicing occurs in the object's `__getitem__()` method, subclasses overriding this method will need to explicitly add that support.

A `string` is a special kind of sequence whose items are *characters*. A character is not a separate data type but a string of exactly one character.

6.3.3. Slicings

A slicing selects a range of items in a sequence object (e.g., a string, tuple or list). Slicings may be used as expressions or as targets in assignment or `del` statements. The syntax for a slicing:

```
slicing      ::=  primary "[" slice_list "]"
slice_list   ::=  slice_item ("," slice_item)* [","]
slice_item   ::=  expression | proper_slice
proper_slice ::=  [lower_bound] ":" [upper_bound] [ ":"
lower_bound  ::=  expression
upper_bound  ::=  expression
stride       ::=  expression
```

There is ambiguity in the formal syntax here: anything that looks like an expression list also looks like a slice list, so any subscription can be interpreted as a slicing. Rather than further complicating the syntax, this is disambiguated by defining that in this case the interpretation as a subscription takes priority over the interpretation as a slicing (this is the case if the slice list contains no proper slice).

The semantics for a slicing are as follows. The primary is indexed (using the same `__getitem__()` method as normal subscription) with a key that is constructed from the slice list, as follows. If the

slice list contains at least one comma, the key is a tuple containing the conversion of the slice items; otherwise, the conversion of the lone slice item is the key. The conversion of a slice item that is an expression is that expression. The conversion of a proper slice is a slice object (see section The standard type hierarchy) whose **`start`**, **`stop`** and **`step`** attributes are the values of the expressions given as lower bound, upper bound and stride, respectively, substituting `None` for missing expressions.

6.3.4. Calls

A call calls a callable object (e.g., a function) with a possibly empty series of arguments:

```
call                 ::=  primary "(" [argument_list [",
argument_list        ::=  positional_arguments ["," star
                            ["," keywords_arguments]
                          | starred_and_keywords ["," ke
                          | keywords_arguments
positional_arguments ::=  positional_item ("," positiona
positional_item      ::=  assignment_expression | "*" ex
starred_and_keywords ::=  ("*" expression | keyword_item
                          ("," "*" expression | "," keyw
keywords_arguments   ::=  (keyword_item | "**" expressio
                          ("," keyword_item | "," "**" e
keyword_item         ::=  identifier "=" expression
```

An optional trailing comma may be present after the positional and keyword arguments but does not affect the semantics.

The primary must evaluate to a callable object (user-defined functions, built-in functions, methods of built-in objects, class objects, methods of class instances, and all objects having a **`__call__()`** method are callable). All argument expressions are evaluated before the call is attempted. Please refer to section Function definitions for the syntax of formal parameter lists.

If keyword arguments are present, they are first converted to positional arguments, as follows. First, a list of unfilled slots is created for the formal parameters. If there are N positional

arguments, they are placed in the first N slots. Next, for each keyword argument, the identifier is used to determine the corresponding slot (if the identifier is the same as the first formal parameter name, the first slot is used, and so on). If the slot is already filled, a **`TypeError`** exception is raised. Otherwise, the argument is placed in the slot, filling it (even if the expression is `None`, it fills the slot). When all arguments have been processed, the slots that are still unfilled are filled with the corresponding default value from the function definition. (Default values are calculated, once, when the function is defined; thus, a mutable object such as a list or dictionary used as default value will be shared by all calls that don't specify an argument value for the corresponding slot; this should usually be avoided.) If there are any unfilled slots for which no default value is specified, a **`TypeError`** exception is raised. Otherwise, the list of filled slots is used as the argument list for the call.

CPython implementation detail: An implementation may provide built-in functions whose positional parameters do not have names, even if they are 'named' for the purpose of documentation, and which therefore cannot be supplied by keyword. In CPython, this is the case for functions implemented in C that use **`PyArg_ParseTuple()`** to parse their arguments.

If there are more positional arguments than there are formal parameter slots, a **`TypeError`** exception is raised, unless a formal parameter using the syntax `*identifier` is present; in this case, that formal parameter receives a tuple containing the excess positional arguments (or an empty tuple if there were no excess positional arguments).

If any keyword argument does not correspond to a formal parameter name, a **`TypeError`** exception is raised, unless a formal parameter using the syntax `**identifier` is present; in this case, that formal parameter receives a dictionary containing the excess keyword arguments (using the keywords as keys and the argument values as corresponding values), or a (new) empty dictionary if there were no excess keyword arguments.

If the syntax `*expression` appears in the function call, `expression` must evaluate to an iterable. Elements from these

iterables are treated as if they were additional positional arguments. For the call `f(x1, x2, *y, x3, x4)`, if *y* evaluates to a sequence *y1*, …, *yM*, this is equivalent to a call with M+4 positional arguments *x1*, *x2*, *y1*, …, *yM*, *x3*, *x4*.

A consequence of this is that although the `*expression` syntax may appear *after* explicit keyword arguments, it is processed *before* the keyword arguments (and any `**expression` arguments – see below). So:

```
>>> def f(a, b):
...     print(a, b)
...
>>> f(b=1, *(2,))
2 1
>>> f(a=1, *(2,))
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: f() got multiple values for keyword argument
>>> f(1, *(2,))
1 2
```

It is unusual for both keyword arguments and the `*expression` syntax to be used in the same call, so in practice this confusion does not often arise.

If the syntax `**expression` appears in the function call, `expression` must evaluate to a mapping, the contents of which are treated as additional keyword arguments. If a parameter matching a key has already been given a value (by an explicit keyword argument, or from another unpacking), a **`TypeError`** exception is raised.

When `**expression` is used, each key in this mapping must be a string. Each value from the mapping is assigned to the first formal parameter eligible for keyword assignment whose name is equal to the key. A key need not be a Python identifier (e.g. `"max-temp °F"` is acceptable, although it will not match any formal parameter that could be declared). If there is no match to a formal parameter the key-value pair is collected by the `**` parameter, if there is one,

or if there is not, a **`TypeError`** exception is raised.

Formal parameters using the syntax `*identifier` or `**identifier` cannot be used as positional argument slots or as keyword argument names.

Changed in version 3.5: Function calls accept any number of `*` and `**` unpackings, positional arguments may follow iterable unpackings (`*`), and keyword arguments may follow dictionary unpackings (`**`). Originally proposed by **PEP 448** [https://peps.python.org/pep-0448/].

A call always returns some value, possibly `None`, unless it raises an exception. How this value is computed depends on the type of the callable object.

If it is—

a user-defined function:

> The code block for the function is executed, passing it the argument list. The first thing the code block will do is bind the formal parameters to the arguments; this is described in section Function definitions. When the code block executes a **`return`** statement, this specifies the return value of the function call.

a built-in function or method:

> The result is up to the interpreter; see Built-in Functions for the descriptions of built-in functions and methods.

a class object:

> A new instance of that class is returned.

a class instance method:

> The corresponding user-defined function is called, with an argument list that is one longer than the argument list of the call: the instance becomes the first argument.

a class instance:

> The class must define a **`__call__()`** method; the effect is

then the same as if that method was called.

6.4. Await expression

Suspend the execution of coroutine on an awaitable object. Can only be used inside a coroutine function.

```
await_expr ::=  "await" primary
```

New in version 3.5.

6.5. The power operator

The power operator binds more tightly than unary operators on its left; it binds less tightly than unary operators on its right. The syntax is:

```
power ::=  (await_expr | primary) ["**" u_expr]
```

Thus, in an unparenthesized sequence of power and unary operators, the operators are evaluated from right to left (this does not constrain the evaluation order for the operands): `-1**2` results in `-1`.

The power operator has the same semantics as the built-in **`pow()`** function, when called with two arguments: it yields its left argument raised to the power of its right argument. The numeric arguments are first converted to a common type, and the result is of that type.

For int operands, the result has the same type as the operands unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `10**2` returns `100`, but `10**-2` returns `0.01`.

Raising `0.0` to a negative power results in a **`ZeroDivisionError`**. Raising a negative number to a fractional power results in a **`complex`** number. (In earlier versions it raised a **`ValueError`**.)

This operation can be customized using the special **__pow__()** method.

6.6. Unary arithmetic and bitwise operations

All unary arithmetic and bitwise operations have the same priority:

```
u_expr ::=  power | "-" u_expr | "+" u_expr | "~" u_expr
```

The unary **-** (minus) operator yields the negation of its numeric argument; the operation can be overridden with the **__neg__()** special method.

The unary **+** (plus) operator yields its numeric argument unchanged; the operation can be overridden with the **__pos__()** special method.

The unary **~** (invert) operator yields the bitwise inversion of its integer argument. The bitwise inversion of `x` is defined as `-(x+1)`. It only applies to integral numbers or to custom objects that override the **__invert__()** special method.

In all three cases, if the argument does not have the proper type, a **TypeError** exception is raised.

6.7. Binary arithmetic operations

The binary arithmetic operations have the conventional priority levels. Note that some of these operations also apply to certain non-numeric types. Apart from the power operator, there are only two levels, one for multiplicative operators and one for additive operators:

```
m_expr ::=  u_expr | m_expr "*" u_expr | m_expr "@" m_ex
            m_expr "//" u_expr | m_expr "/" u_expr |
            m_expr "%" u_expr
a_expr ::=  m_expr | a_expr "+" m_expr | a_expr "-" m_ex
```

The `*` (multiplication) operator yields the product of its arguments. The arguments must either both be numbers, or one argument must be an integer and the other must be a sequence. In the former case, the numbers are converted to a common type and then multiplied together. In the latter case, sequence repetition is performed; a negative repetition factor yields an empty sequence.

This operation can be customized using the special **`__mul__()`** and **`__rmul__()`** methods.

The `@` (at) operator is intended to be used for matrix multiplication. No builtin Python types implement this operator.

New in version 3.5.

The `/` (division) and `//` (floor division) operators yield the quotient of their arguments. The numeric arguments are first converted to a common type. Division of integers yields a float, while floor division of integers results in an integer; the result is that of mathematical division with the 'floor' function applied to the result. Division by zero raises the **`ZeroDivisionError`** exception.

This operation can be customized using the special **`__truediv__()`** and **`__floordiv__()`** methods.

The `%` (modulo) operator yields the remainder from the division of the first argument by the second. The numeric arguments are first converted to a common type. A zero right argument raises the **`ZeroDivisionError`** exception. The arguments may be floating point numbers, e.g., `3.14%0.7` equals `0.34` (since `3.14` equals `4*0.7 + 0.34`.) The modulo operator always yields a result with the same sign as its second operand (or zero); the absolute value of the result is strictly smaller than the absolute value of the second operand [1].

The floor division and modulo operators are connected by the following identity: `x == (x//y)*y + (x%y)`. Floor division and modulo are also connected with the built-in function **`divmod()`**: `divmod(x, y) == (x//y, x%y)`. [2].

In addition to performing the modulo operation on numbers, the `%` operator is also overloaded by string objects to perform old-style string formatting (also known as interpolation). The syntax for string formatting is described in the Python Library Reference, section printf-style String Formatting.

The *modulo* operation can be customized using the special **`__mod__()`** method.

The floor division operator, the modulo operator, and the **`divmod()`** function are not defined for complex numbers. Instead, convert to a floating point number using the **`abs()`** function if appropriate.

The `+` (addition) operator yields the sum of its arguments. The arguments must either both be numbers or both be sequences of the same type. In the former case, the numbers are converted to a common type and then added together. In the latter case, the sequences are concatenated.

This operation can be customized using the special **`__add__()`** and **`__radd__()`** methods.

The `-` (subtraction) operator yields the difference of its arguments. The numeric arguments are first converted to a common type.

This operation can be customized using the special **`__sub__()`** method.

6.8. Shifting operations

The shifting operations have lower priority than the arithmetic operations:

```
shift_expr ::=  a_expr | shift_expr ("<<" | ">>") a_expr
```

These operators accept integers as arguments. They shift the first argument to the left or right by the number of bits given by the second argument.

This operation can be customized using the special **`__lshift__()`**

and **`__rshift__()`** methods.

A right shift by *n* bits is defined as floor division by `pow(2,n)`. A left shift by *n* bits is defined as multiplication with `pow(2,n)`.

6.9. Binary bitwise operations

Each of the three bitwise operations has a different priority level:

```
and_expr ::=  shift_expr | and_expr "&" shift_expr
xor_expr ::=  and_expr | xor_expr "^" and_expr
or_expr  ::=  xor_expr | or_expr "|" xor_expr
```

The `&` operator yields the bitwise AND of its arguments, which must be integers or one of them must be a custom object overriding **`__and__()`** or **`__rand__()`** special methods.

The `^` operator yields the bitwise XOR (exclusive OR) of its arguments, which must be integers or one of them must be a custom object overriding **`__xor__()`** or **`__rxor__()`** special methods.

The `|` operator yields the bitwise (inclusive) OR of its arguments, which must be integers or one of them must be a custom object overriding **`__or__()`** or **`__ror__()`** special methods.

6.10. Comparisons

Unlike C, all comparison operations in Python have the same priority, which is lower than that of any arithmetic, shifting or bitwise operation. Also unlike C, expressions like `a < b < c` have the interpretation that is conventional in mathematics:

```
comparison    ::=  or_expr (comp_operator or_expr)*
comp_operator ::=  "<" | ">" | "==" | ">=" | "<=" | "!="
                   | "is" ["not"] | ["not"] "in"
```

Comparisons yield boolean values: `True` or `False`. Custom *rich comparison methods* may return non-boolean values. In this case Python will call **`bool()`** on such value in boolean contexts.

Comparisons can be chained arbitrarily, e.g., `x < y <= z` is equivalent to `x < y and y <= z`, except that `y` is evaluated only once (but in both cases `z` is not evaluated at all when `x < y` is found to be false).

Formally, if *a*, *b*, *c*, ..., *y*, *z* are expressions and *op1*, *op2*, ..., *opN* are comparison operators, then `a op1 b op2 c ... y opN z` is equivalent to `a op1 b and b op2 c and ... y opN z`, except that each expression is evaluated at most once.

Note that `a op1 b op2 c` doesn't imply any kind of comparison between *a* and *c*, so that, e.g., `x < y > z` is perfectly legal (though perhaps not pretty).

6.10.1. Value comparisons

The operators `<`, `>`, `==`, `>=`, `<=`, and `!=` compare the values of two objects. The objects do not need to have the same type.

Chapter Objects, values and types states that objects have a value (in addition to type and identity). The value of an object is a rather abstract notion in Python: For example, there is no canonical access method for an object's value. Also, there is no requirement that the value of an object should be constructed in a particular way, e.g. comprised of all its data attributes. Comparison operators implement a particular notion of what the value of an object is. One can think of them as defining the value of an object indirectly, by means of their comparison implementation.

Because all types are (direct or indirect) subtypes of **`object`**, they inherit the default comparison behavior from **`object`**. Types can customize their comparison behavior by implementing *rich comparison methods* like **`__lt__()`**, described in Basic customization.

The default behavior for equality comparison (`==` and `!=`) is based on the identity of the objects. Hence, equality comparison of instances with the same identity results in equality, and equality comparison of instances with different identities results in inequality. A motivation for this default behavior is the desire that all objects should be reflexive (i.e. `x is y` implies `x == y`).

A default order comparison (`<`, `>`, `<=`, and `>=`) is not provided; an attempt raises **`TypeError`**. A motivation for this default behavior is the lack of a similar invariant as for equality.

The behavior of the default equality comparison, that instances with different identities are always unequal, may be in contrast to what types will need that have a sensible definition of object value and value-based equality. Such types will need to customize their comparison behavior, and in fact, a number of built-in types have done that.

The following list describes the comparison behavior of the most important built-in types.

- Numbers of built-in numeric types (Numeric Types — int, float, complex) and of the standard library types **`fractions.Fraction`** and **`decimal.Decimal`** can be compared within and across their types, with the restriction that complex numbers do not support order comparison. Within the limits of the types involved, they compare mathematically (algorithmically) correct without loss of precision.

  The not-a-number values `float('NaN')` and `decimal.Decimal('NaN')` are special. Any ordered comparison of a number to a not-a-number value is false. A counter-intuitive implication is that not-a-number values are not equal to themselves. For example, if `x = float('NaN')`, `3 < x`, `x < 3` and `x == x` are all false, while `x != x` is true. This behavior is compliant with IEEE 754.

- `None` and `NotImplemented` are singletons. **PEP 8** [https://peps.python.org/pep-0008/] advises that comparisons for singletons should always be done with `is` or `is not`, never the equality operators.

- Binary sequences (instances of **`bytes`** or **`bytearray`**) can be compared within and across their types. They compare lexicographically using the numeric values of their elements.

- Strings (instances of **`str`**) compare lexicographically using the numerical Unicode code points (the result of the built-in function **`ord()`**) of their characters. 3

  Strings and binary sequences cannot be directly compared.

- Sequences (instances of **`tuple`**, **`list`**, or **`range`**) can be compared only within each of their types, with the restriction that ranges do not support order comparison. Equality comparison across these types results in inequality, and ordering comparison across these types raises **`TypeError`**.

  Sequences compare lexicographically using comparison of corresponding elements. The built-in containers typically assume identical objects are equal to themselves. That lets them bypass equality tests for identical objects to improve performance and to maintain their internal invariants.

  Lexicographical comparison between built-in collections works as follows:

  - For two collections to compare equal, they must be of the same type, have the same length, and each pair of corresponding elements must compare equal (for example, `[1,2] == (1,2)` is false because the type is not the same).
  - Collections that support order comparison are ordered the same as their first unequal elements (for example, `[1,2,x] <= [1,2,y]` has the same value as `x <= y`). If a corresponding element does not exist, the shorter collection is ordered first (for example, `[1,2] < [1,2,3]` is true).

- Mappings (instances of **`dict`**) compare equal if and only if they have equal `(key, value)` pairs. Equality comparison of the keys and values enforces reflexivity.

  Order comparisons (`<`, `>`, `<=`, and `>=`) raise **`TypeError`**.

- Sets (instances of **`set`** or **`frozenset`**) can be compared within and across their types.

They define order comparison operators to mean subset and superset tests. Those relations do not define total orderings (for example, the two sets `{1,2}` and `{2,3}` are not equal, nor subsets of one another, nor supersets of one another). Accordingly, sets are not appropriate arguments for functions which depend on total ordering (for example, **`min()`**, **`max()`**, and **`sorted()`** produce undefined results given a list of sets as inputs).

Comparison of sets enforces reflexivity of its elements.

- Most other built-in types have no comparison methods implemented, so they inherit the default comparison behavior.

User-defined classes that customize their comparison behavior should follow some consistency rules, if possible:

- Equality comparison should be reflexive. In other words, identical objects should compare equal:

  `x is y` implies `x == y`

- Comparison should be symmetric. In other words, the following expressions should have the same result:

  `x == y` and `y == x`

  `x != y` and `y != x`

  `x < y` and `y > x`

  `x <= y` and `y >= x`

- Comparison should be transitive. The following (non-exhaustive) examples illustrate that:

  `x > y and y > z` implies `x > z`

  `x < y and y <= z` implies `x < z`

- Inverse comparison should result in the boolean negation. In

other words, the following expressions should have the same result:

`x == y` and `not x != y`

`x < y` and `not x >= y` (for total ordering)

`x > y` and `not x <= y` (for total ordering)

The last two expressions apply to totally ordered collections (e.g. to sequences, but not to sets or mappings). See also the **`total_ordering()`** decorator.

- The **`hash()`** result should be consistent with equality. Objects that are equal should either have the same hash value, or be marked as unhashable.

Python does not enforce these consistency rules. In fact, the not-a-number values are an example for not following these rules.

6.10.2. Membership test operations

The operators **`in`** and **`not in`** test for membership. `x in s` evaluates to `True` if *x* is a member of *s*, and `False` otherwise. `x not in s` returns the negation of `x in s`. All built-in sequences and set types support this as well as dictionary, for which **`in`** tests whether the dictionary has a given key. For container types such as list, tuple, set, frozenset, dict, or collections.deque, the expression `x in y` is equivalent to `any(x is e or x == e for e in y)`.

For the string and bytes types, `x in y` is `True` if and only if *x* is a substring of *y*. An equivalent test is `y.find(x) != -1`. Empty strings are always considered to be a substring of any other string, so `"" in "abc"` will return `True`.

For user-defined classes which define the **`__contains__()`** method, `x in y` returns `True` if `y.__contains__(x)` returns a true value, and `False` otherwise.

For user-defined classes which do not define **`__contains__()`**

but do define `__iter__()`, `x in y` is `True` if some value `z`, for which the expression `x is z or x == z` is true, is produced while iterating over `y`. If an exception is raised during the iteration, it is as if `in` raised that exception.

Lastly, the old-style iteration protocol is tried: if a class defines `__getitem__()`, `x in y` is `True` if and only if there is a non-negative integer index *i* such that `x is y[i] or x == y[i]`, and no lower integer index raises the `IndexError` exception. (If any other exception is raised, it is as if `in` raised that exception).

The operator `not in` is defined to have the inverse truth value of `in`.

6.10.3. Identity comparisons

The operators `is` and `is not` test for an object's identity: `x is y` is true if and only if *x* and *y* are the same object. An Object's identity is determined using the `id()` function. `x is not y` yields the inverse truth value. 4

6.11. Boolean operations

```
or_test  ::=  and_test | or_test "or" and_test
and_test ::=  not_test | and_test "and" not_test
not_test ::=  comparison | "not" not_test
```

In the context of Boolean operations, and also when expressions are used by control flow statements, the following values are interpreted as false: `False`, `None`, numeric zero of all types, and empty strings and containers (including strings, tuples, lists, dictionaries, sets and frozensets). All other values are interpreted as true. User-defined objects can customize their truth value by providing a `__bool__()` method.

The operator `not` yields `True` if its argument is false, `False` otherwise.

The expression `x and y` first evaluates *x*; if *x* is false, its value is returned; otherwise, *y* is evaluated and the resulting value is

returned.

The expression `x or y` first evaluates *x*; if *x* is true, its value is returned; otherwise, *y* is evaluated and the resulting value is returned.

Note that neither **`and`** nor **`or`** restrict the value and type they return to `False` and `True`, but rather return the last evaluated argument. This is sometimes useful, e.g., if `s` is a string that should be replaced by a default value if it is empty, the expression `s or 'foo'` yields the desired value. Because **`not`** has to create a new value, it returns a boolean value regardless of the type of its argument (for example, `not 'foo'` produces `False` rather than `''`.)

6.12. Assignment expressions

`assignment_expression` `::=` `[`**`identifier`** `":="]` **`expression`**

An assignment expression (sometimes also called a “named expression” or “walrus”) assigns an **`expression`** to an **`identifier`**, while also returning the value of the **`expression`**.

One common use case is when handling matched regular expressions:

```
if matching := pattern.search(data):
    do_something(matching)
```

Or, when processing a file stream in chunks:

```
while chunk := file.read(9000):
    process(chunk)
```

Assignment expressions must be surrounded by parentheses when used as sub-expressions in slicing, conditional, lambda, keyword-argument, and comprehension-if expressions and in `assert` and `with` statements. In all other places where they can be used, parentheses are not required, including in `if` and `while` statements.

New in version 3.8: See **PEP 572** [https://peps.python.org/pep-0572/] for more details about assignment expressions.

6.13. Conditional expressions

```
conditional_expression ::=  or_test ["if" or_test "else"
expression             ::=  conditional_expression | lam
```

Conditional expressions (sometimes called a “ternary operator”) have the lowest priority of all Python operations.

The expression `x if C else y` first evaluates the condition, *C* rather than *x*. If *C* is true, *x* is evaluated and its value is returned; otherwise, *y* is evaluated and its value is returned.

See **PEP 308** [https://peps.python.org/pep-0308/] for more details about conditional expressions.

6.14. Lambdas

```
lambda_expr ::=  "lambda" [parameter_list] ":" expressio
```

Lambda expressions (sometimes called lambda forms) are used to create anonymous functions. The expression `lambda parameters: expression` yields a function object. The unnamed object behaves like a function object defined with:

```
def <lambda>(parameters):
    return expression
```

See section Function definitions for the syntax of parameter lists. Note that functions created with lambda expressions cannot contain statements or annotations.

6.15. Expression lists

```
expression_list    ::=  expression ("," expression)* [",
starred_list       ::=  starred_item ("," starred_item)*
starred_expression ::=  expression | (starred_item ",")*
```

```
starred_item       ::=  assignment_expression | "*" or_e
```

Except when part of a list or set display, an expression list containing at least one comma yields a tuple. The length of the tuple is the number of expressions in the list. The expressions are evaluated from left to right.

An asterisk `*` denotes *iterable unpacking*. Its operand must be an iterable. The iterable is expanded into a sequence of items, which are included in the new tuple, list, or set, at the site of the unpacking.

New in version 3.5: Iterable unpacking in expression lists, originally proposed by **PEP 448** [https://peps.python.org/pep-0448/].

The trailing comma is required only to create a single tuple (a.k.a. a *singleton*); it is optional in all other cases. A single expression without a trailing comma doesn't create a tuple, but rather yields the value of that expression. (To create an empty tuple, use an empty pair of parentheses: `()`.)

6.16. Evaluation order

Python evaluates expressions from left to right. Notice that while evaluating an assignment, the right-hand side is evaluated before the left-hand side.

In the following lines, expressions will be evaluated in the arithmetic order of their suffixes:

```
expr1, expr2, expr3, expr4
(expr1, expr2, expr3, expr4)
{expr1: expr2, expr3: expr4}
expr1 + expr2 * (expr3 - expr4)
expr1(expr2, expr3, *expr4, **expr5)
expr3, expr4 = expr1, expr2
```

6.17. Operator precedence

The following table summarizes the operator precedence in Python,

from highest precedence (most binding) to lowest precedence (least binding). Operators in the same box have the same precedence. Unless the syntax is explicitly given, operators are binary. Operators in the same box group left to right (except for exponentiation and conditional expressions, which group from right to left).

Note that comparisons, membership tests, and identity tests, all have the same precedence and have a left-to-right chaining feature as described in the Comparisons section.

Operator	Description
`(expressions...)`, `[expressions...]`, `{key: value...}`, `{expressions...}`	Binding or parenthesized expression, list display, dictionary display, set display
`x[index]`, `x[index:index]`, `x(arguments...)`, `x.attribute`	Subscription, slicing, call, attribute reference
`await x`	Await expression
`**`	Exponentiation [5]
`+x`, `-x`, `~x`	Positive, negative, bitwise NOT
`*`, `@`, `/`, `//`, `%`	Multiplication, matrix multiplication, division, floor division, remainder [6]
`+`, `-`	Addition and subtraction
`<<`, `>>`	Shifts
`&`	Bitwise AND
`^`	Bitwise XOR
`|`	Bitwise OR
`in`, `not in`, `is`, `is not`, `<`, `<=`, `>`, `>=`, `!=`, `==`	Comparisons, including membership tests and identity tests
`not x`	Boolean NOT
`and`	Boolean AND
`or`	Boolean OR
`if – else`	Conditional expression
`lambda`	Lambda expression
`:=`	Assignment expression

Footnotes

[1]

While `abs(x%y) < abs(y)` is true mathematically, for floats it may not be true numerically due to roundoff. For example,

and assuming a platform on which a Python float is an IEEE 754 double-precision number, in order that `-1e-100 % 1e100` have the same sign as `1e100`, the computed result is `-1e-100 + 1e100`, which is numerically exactly equal to `1e100`. The function **`math.fmod()`** returns a result whose sign matches the sign of the first argument instead, and so returns `-1e-100` in this case. Which approach is more appropriate depends on the application.

2

If x is very close to an exact integer multiple of y, it's possible for `x//y` to be one larger than `(x-x%y)//y` due to rounding. In such cases, Python returns the latter result, in order to preserve that `divmod(x,y)[0] * y + x % y` be very close to `x`.

3

The Unicode standard distinguishes between *code points* (e.g. U+0041) and *abstract characters* (e.g. "LATIN CAPITAL LETTER A"). While most abstract characters in Unicode are only represented using one code point, there is a number of abstract characters that can in addition be represented using a sequence of more than one code point. For example, the abstract character "LATIN CAPITAL LETTER C WITH CEDILLA" can be represented as a single *precomposed character* at code position U+00C7, or as a sequence of a *base character* at code position U+0043 (LATIN CAPITAL LETTER C), followed by a *combining character* at code position U+0327 (COMBINING CEDILLA).

The comparison operators on strings compare at the level of Unicode code points. This may be counter-intuitive to humans. For example, `"\u00C7" == "\u0043\u0327"` is `False`, even though both strings represent the same abstract character "LATIN CAPITAL LETTER C WITH CEDILLA".

To compare strings at the level of abstract characters (that is, in a way intuitive to humans), use **`unicodedata.normalize()`**.

4

Due to automatic garbage-collection, free lists, and the dynamic nature of descriptors, you may notice seemingly unusual behaviour in certain uses of the `is` operator, like those involving comparisons between instance methods, or constants. Check their documentation for more info.

5

The power operator `**` binds less tightly than an arithmetic or bitwise unary operator on its right, that is, `2**-1` is `0.5`.

6

The `%` operator is also used for string formatting; the same precedence applies.

7. Simple statements

A simple statement is comprised within a single logical line. Several simple statements may occur on a single line separated by semicolons. The syntax for simple statements is:

```
simple_stmt ::=  expression_stmt
                 | assert_stmt
                 | assignment_stmt
                 | augmented_assignment_stmt
                 | annotated_assignment_stmt
                 | pass_stmt
                 | del_stmt
                 | return_stmt
                 | yield_stmt
                 | raise_stmt
                 | break_stmt
                 | continue_stmt
                 | import_stmt
                 | future_stmt
                 | global_stmt
                 | nonlocal_stmt
```

7.1. Expression statements

Expression statements are used (mostly interactively) to compute and write a value, or (usually) to call a procedure (a function that returns no meaningful result; in Python, procedures return the value `None`). Other uses of expression statements are allowed and occasionally useful. The syntax for an expression statement is:

```
expression_stmt ::=  starred_expression
```

An expression statement evaluates the expression list (which may be a single expression).

In interactive mode, if the value is not `None`, it is converted to a string using the built-in **`repr()`** function and the resulting string is written to standard output on a line by itself (except if the result is `None`, so that procedure calls do not cause any output.)

7.2. Assignment statements

Assignment statements are used to (re)bind names to values and to modify attributes or items of mutable objects:

```
assignment_stmt ::=  (target_list "=")+ (starred_express
target_list     ::=  target ("," target)* [","]
target          ::=  identifier
                     | "(" [target_list] ")"
                     | "[" [target_list] "]"
                     | attributeref
                     | subscription
                     | slicing
                     | "*" target
```

(See section Primaries for the syntax definitions for *attributeref*, *subscription*, and *slicing*.)

An assignment statement evaluates the expression list (remember that this can be a single expression or a comma-separated list, the latter yielding a tuple) and assigns the single resulting object to each of the target lists, from left to right.

Assignment is defined recursively depending on the form of the target (list). When a target is part of a mutable object (an attribute reference, subscription or slicing), the mutable object must ultimately perform the assignment and decide about its validity, and may raise an exception if the assignment is unacceptable. The rules observed by various types and the exceptions raised are given with the definition of the object types (see section The standard type hierarchy).

Assignment of an object to a target list, optionally enclosed in parentheses or square brackets, is recursively defined as follows.

- If the target list is a single target with no trailing comma, optionally in parentheses, the object is assigned to that target.
- Else:
    - If the target list contains one target prefixed with an asterisk, called a “starred” target: The object must be an iterable with at least as many items as there are targets in the target list, minus one. The first items of the iterable are assigned, from left to right, to the targets before the starred target. The final items of the iterable are assigned to the targets after the starred target. A list of the remaining items in the iterable is then assigned to the starred target (the list can be empty).
    - Else: The object must be an iterable with the same number of items as there are targets in the target list, and the items are assigned, from left to right, to the corresponding targets.

Assignment of an object to a single target is recursively defined as follows.

- If the target is an identifier (name):

    - If the name does not occur in a **`global`** or **`nonlocal`** statement in the current code block: the name is bound to the object in the current local namespace.
    - Otherwise: the name is bound to the object in the global namespace or the outer namespace determined by **`nonlocal`**, respectively.

    The name is rebound if it was already bound. This may cause the reference count for the object previously bound to the name to reach zero, causing the object to be deallocated and its destructor (if it has one) to be called.

- If the target is an attribute reference: The primary expression in the reference is evaluated. It should yield an object with assignable attributes; if this is not the case, **`TypeError`** is raised. That object is then asked to assign the assigned object to the given attribute; if it cannot perform the assignment, it raises an exception (usually but not necessarily **`AttributeError`**).

Note: If the object is a class instance and the attribute reference occurs on both sides of the assignment operator, the right-hand side expression, `a.x` can access either an instance attribute or (if no instance attribute exists) a class attribute. The left-hand side target `a.x` is always set as an instance attribute, creating it if necessary. Thus, the two occurrences of `a.x` do not necessarily refer to the same attribute: if the right-hand side expression refers to a class attribute, the left-hand side creates a new instance attribute as the target of the assignment:

```
class Cls:
    x = 3              # class variable
inst = Cls()
inst.x = inst.x + 1    # writes inst.x as 4 leaving
```

This description does not necessarily apply to descriptor attributes, such as properties created with **`property()`**.

- If the target is a subscription: The primary expression in the reference is evaluated. It should yield either a mutable sequence object (such as a list) or a mapping object (such as a dictionary). Next, the subscript expression is evaluated.

  If the primary is a mutable sequence object (such as a list), the subscript must yield an integer. If it is negative, the sequence's length is added to it. The resulting value must be a nonnegative integer less than the sequence's length, and the sequence is asked to assign the assigned object to its item with that index. If the index is out of range, **`IndexError`** is raised (assignment to a subscripted sequence cannot add new items to a list).

  If the primary is a mapping object (such as a dictionary), the subscript must have a type compatible with the mapping's key type, and the mapping is then asked to create a key/datum pair which maps the subscript to the assigned object. This can either replace an existing key/value pair with the same key value, or insert a new key/value pair (if no key with the same value existed).

For user-defined objects, the **`__setitem__()`** method is called with appropriate arguments.

- If the target is a slicing: The primary expression in the reference is evaluated. It should yield a mutable sequence object (such as a list). The assigned object should be a sequence object of the same type. Next, the lower and upper bound expressions are evaluated, insofar they are present; defaults are zero and the sequence's length. The bounds should evaluate to integers. If either bound is negative, the sequence's length is added to it. The resulting bounds are clipped to lie between zero and the sequence's length, inclusive. Finally, the sequence object is asked to replace the slice with the items of the assigned sequence. The length of the slice may be different from the length of the assigned sequence, thus changing the length of the target sequence, if the target sequence allows it.

CPython implementation detail: In the current implementation, the syntax for targets is taken to be the same as for expressions, and invalid syntax is rejected during the code generation phase, causing less detailed error messages.

Although the definition of assignment implies that overlaps between the left-hand side and the right-hand side are 'simultaneous' (for example `a, b = b, a` swaps two variables), overlaps *within* the collection of assigned-to variables occur left-to-right, sometimes resulting in confusion. For instance, the following program prints `[0, 2]`:

```
x = [0, 1]
i = 0
i, x[i] = 1, 2          # i is updated, then x[i] is upda
print(x)
```

PEP 3132 **[https://peps.python.org/pep-3132/]** **- Extended Iterable Unpacking**

The specification for the `*target` feature.

7.2.1. Augmented assignment statements

Augmented assignment is the combination, in a single statement, of a binary operation and an assignment statement:

```
augmented_assignment_stmt ::=  augtarget augop (expressi
augtarget                 ::=  identifier | attributeref
augop                     ::=  "+=" | "-=" | "*=" | "@="
                               | ">>=" | "<<=" | "&=" |
```

(See section Primaries for the syntax definitions of the last three symbols.)

An augmented assignment evaluates the target (which, unlike normal assignment statements, cannot be an unpacking) and the expression list, performs the binary operation specific to the type of assignment on the two operands, and assigns the result to the original target. The target is only evaluated once.

An augmented assignment expression like `x += 1` can be rewritten as `x = x + 1` to achieve a similar, but not exactly equal effect. In the augmented version, `x` is only evaluated once. Also, when possible, the actual operation is performed *in-place*, meaning that rather than creating a new object and assigning that to the target, the old object is modified instead.

Unlike normal assignments, augmented assignments evaluate the left-hand side *before* evaluating the right-hand side. For example, `a[i] += f(x)` first looks-up `a[i]`, then it evaluates `f(x)` and performs the addition, and lastly, it writes the result back to `a[i]`.

With the exception of assigning to tuples and multiple targets in a single statement, the assignment done by augmented assignment statements is handled the same way as normal assignments. Similarly, with the exception of the possible *in-place* behavior, the binary operation performed by augmented assignment is the same as the normal binary operations.

For targets which are attribute references, the same caveat about class and instance attributes applies as for regular assignments.

7.2.2. Annotated assignment statements

Annotation assignment is the combination, in a single statement, of a variable or attribute annotation and an optional assignment statement:

```
annotated_assignment_stmt ::=  augtarget ":" expression
                               ["="  (starred_expression
```

The difference from normal Assignment statements is that only a single target is allowed.

For simple names as assignment targets, if in class or module scope, the annotations are evaluated and stored in a special class or module attribute **`__annotations__`** that is a dictionary mapping from variable names (mangled if private) to evaluated annotations. This attribute is writable and is automatically created at the start of class or module body execution, if annotations are found statically.

For expressions as assignment targets, the annotations are evaluated if in class or module scope, but not stored.

If a name is annotated in a function scope, then this name is local for that scope. Annotations are never evaluated and stored in function scopes.

If the right hand side is present, an annotated assignment performs the actual assignment before evaluating annotations (where applicable). If the right hand side is not present for an expression target, then the interpreter evaluates the target except for the last **`__setitem__()`** or **`__setattr__()`** call.

PEP 526 **[https://peps.python.org/pep-0526/]** **- Syntax for Variable Annotations**

The proposal that added syntax for annotating the types of variables (including class variables and instance variables), instead of expressing them through comments.

PEP 484 **[https://peps.python.org/pep-0484/]** **- Type hints**

The proposal that added the **typing** module to provide a standard syntax for type annotations that can be used in static analysis tools and IDEs.

Changed in version 3.8: Now annotated assignments allow the same expressions in the right hand side as regular assignments. Previously, some expressions (like un-parenthesized tuple expressions) caused a syntax error.

7.3. The `assert` statement

Assert statements are a convenient way to insert debugging assertions into a program:

assert_stmt ::= "assert" **expression** ["," **expression**]

The simple form, `assert expression`, is equivalent to

```
if __debug__:
    if not expression: raise AssertionError
```

The extended form, `assert expression1, expression2`, is equivalent to

```
if __debug__:
    if not expression1: raise AssertionError(expression2
```

These equivalences assume that **__debug__** and **AssertionError** refer to the built-in variables with those names. In the current implementation, the built-in variable **__debug__** is `True` under normal circumstances, `False` when optimization is requested (command line option **-O**). The current code generator emits no code for an assert statement when optimization is requested at compile time. Note that it is unnecessary to include the source code for the expression that failed in the error message; it will be displayed as part of the stack trace.

Assignments to **__debug__** are illegal. The value for the built-in variable is determined when the interpreter starts.

7.4. The `pass` statement

```
pass_stmt ::=  "pass"
```

`pass` is a null operation — when it is executed, nothing happens. It is useful as a placeholder when a statement is required syntactically, but no code needs to be executed, for example:

```
def f(arg): pass    # a function that does nothing (yet)

class C: pass       # a class with no methods (yet)
```

7.5. The `del` statement

```
del_stmt ::=  "del" target_list
```

Deletion is recursively defined very similar to the way assignment is defined. Rather than spelling it out in full details, here are some hints.

Deletion of a target list recursively deletes each target, from left to right.

Deletion of a name removes the binding of that name from the local or global namespace, depending on whether the name occurs in a `global` statement in the same code block. If the name is unbound, a `NameError` exception will be raised.

Deletion of attribute references, subscriptions and slicings is passed to the primary object involved; deletion of a slicing is in general equivalent to assignment of an empty slice of the right type (but even this is determined by the sliced object).

Changed in version 3.2: Previously it was illegal to delete a name from the local namespace if it occurs as a free variable in a nested block.

7.6. The `return` statement

return_stmt ::= "return" [**expression_list**]

return may only occur syntactically nested in a function definition, not within a nested class definition.

If an expression list is present, it is evaluated, else `None` is substituted.

return leaves the current function call with the expression list (or `None`) as return value.

When **return** passes control out of a **try** statement with a **finally** clause, that **finally** clause is executed before really leaving the function.

In a generator function, the **return** statement indicates that the generator is done and will cause **StopIteration** to be raised. The returned value (if any) is used as an argument to construct **StopIteration** and becomes the **StopIteration.value** attribute.

In an asynchronous generator function, an empty **return** statement indicates that the asynchronous generator is done and will cause **StopAsyncIteration** to be raised. A non-empty **return** statement is a syntax error in an asynchronous generator function.

7.7. The `yield` statement

yield_stmt ::= **yield_expression**

A **yield** statement is semantically equivalent to a yield expression. The yield statement can be used to omit the parentheses that would otherwise be required in the equivalent yield expression statement. For example, the yield statements

```
yield <expr>
yield from <expr>
```

are equivalent to the yield expression statements

```
(yield <expr>)
(yield from <expr>)
```

Yield expressions and statements are only used when defining a generator function, and are only used in the body of the generator function. Using yield in a function definition is sufficient to cause that definition to create a generator function instead of a normal function.

For full details of **`yield`** semantics, refer to the Yield expressions section.

7.8. The **`raise`** statement

`raise_stmt` `::=` `"raise"` [**`expression`** `["from"` **`expression`**`]]`

If no expressions are present, **`raise`** re-raises the exception that is currently being handled, which is also known as the *active exception*. If there isn't currently an active exception, a **`RuntimeError`** exception is raised indicating that this is an error.

Otherwise, **`raise`** evaluates the first expression as the exception object. It must be either a subclass or an instance of **`BaseException`**. If it is a class, the exception instance will be obtained when needed by instantiating the class with no arguments.

The *type* of the exception is the exception instance's class, the *value* is the instance itself.

A traceback object is normally created automatically when an exception is raised and attached to it as the **`__traceback__`** attribute, which is writable. You can create an exception and set your own traceback in one step using the **`with_traceback()`** exception method (which returns the same exception instance, with its traceback set to its argument), like so:

```
raise Exception("foo occurred").with_traceback(traceback
```

The `from` clause is used for exception chaining: if given, the second *expression* must be another exception class or instance. If the second expression is an exception instance, it will be attached to the

raised exception as the **__cause__** attribute (which is writable). If the expression is an exception class, the class will be instantiated and the resulting exception instance will be attached to the raised exception as the **__cause__** attribute. If the raised exception is not handled, both exceptions will be printed:

```
>>> try:
...     print(1 / 0)
... except Exception as exc:
...     raise RuntimeError("Something bad happened") fro
...
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: division by zero

The above exception was the direct cause of the followin

Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
```

A similar mechanism works implicitly if a new exception is raised when an exception is already being handled. An exception may be handled when an **except** or **finally** clause, or a **with** statement, is used. The previous exception is then attached as the new exception's **__context__** attribute:

```
>>> try:
...     print(1 / 0)
... except:
...     raise RuntimeError("Something bad happened")
...
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
ZeroDivisionError: division by zero

During handling of the above exception, another exceptio

Traceback (most recent call last):
```

```
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
```

Exception chaining can be explicitly suppressed by specifying **None** in the `from` clause:

```
>>> try:
...     print(1 / 0)
... except:
...     raise RuntimeError("Something bad happened") fro
...
Traceback (most recent call last):
  File "<stdin>", line 4, in <module>
RuntimeError: Something bad happened
```

Additional information on exceptions can be found in section Exceptions, and information about handling exceptions is in section The try statement.

Changed in version 3.3: **None** is now permitted as `Y` in `raise X from Y`.

New in version 3.3: The `__suppress_context__` attribute to suppress automatic display of the exception context.

Changed in version 3.11: If the traceback of the active exception is modified in an **except** clause, a subsequent `raise` statement re-raises the exception with the modified traceback. Previously, the exception was re-raised with the traceback it had when it was caught.

7.9. The **break** statement

break_stmt ::= "break"

break may only occur syntactically nested in a **for** or **while** loop, but not nested in a function or class definition within that loop.

It terminates the nearest enclosing loop, skipping the optional

else clause if the loop has one.

If a **for** loop is terminated by **break**, the loop control target keeps its current value.

When **break** passes control out of a **try** statement with a **finally** clause, that **finally** clause is executed before really leaving the loop.

7.10. The `continue` statement

```
continue_stmt ::=  "continue"
```

continue may only occur syntactically nested in a **for** or **while** loop, but not nested in a function or class definition within that loop. It continues with the next cycle of the nearest enclosing loop.

When **continue** passes control out of a **try** statement with a **finally** clause, that **finally** clause is executed before really starting the next loop cycle.

7.11. The `import` statement

```
import_stmt     ::=  "import" module ["as" identifier] (
                   | "from" relative_module "import" i
                   ("," identifier ["as" identifier])*
                   | "from" relative_module "import" "
                   ("," identifier ["as" identifier])*
                   | "from" relative_module "import" "
module          ::=  (identifier ".")* identifier
relative_module ::=  "."* module | "."+
```

The basic import statement (no **from** clause) is executed in two steps:

1. find a module, loading and initializing it if necessary
2. define a name or names in the local namespace for the scope where the **import** statement occurs.

When the statement contains multiple clauses (separated by

commas) the two steps are carried out separately for each clause, just as though the clauses had been separated out into individual import statements.

The details of the first step, finding and loading modules, are described in greater detail in the section on the import system, which also describes the various types of packages and modules that can be imported, as well as all the hooks that can be used to customize the import system. Note that failures in this step may indicate either that the module could not be located, *or* that an error occurred while initializing the module, which includes execution of the module's code.

If the requested module is retrieved successfully, it will be made available in the local namespace in one of three ways:

- If the module name is followed by **`as`**, then the name following **`as`** is bound directly to the imported module.
- If no other name is specified, and the module being imported is a top level module, the module's name is bound in the local namespace as a reference to the imported module
- If the module being imported is *not* a top level module, then the name of the top level package that contains the module is bound in the local namespace as a reference to the top level package. The imported module must be accessed using its full qualified name rather than directly

The **`from`** form uses a slightly more complex process:

1. find the module specified in the **`from`** clause, loading and initializing it if necessary;
2. for each of the identifiers specified in the **`import`** clauses:
    1. check if the imported module has an attribute by that name
    2. if not, attempt to import a submodule with that name and then check the imported module again for that attribute
    3. if the attribute is not found, **`ImportError`** is raised.
    4. otherwise, a reference to that value is stored in the local namespace, using the name in the **`as`** clause if it is present, otherwise using the attribute name

Examples:

```
import foo                   # foo imported and bound loca
import foo.bar.baz           # foo, foo.bar, and foo.bar.b
import foo.bar.baz as fbb    # foo, foo.bar, and foo.bar.b
from foo.bar import baz      # foo, foo.bar, and foo.bar.b
from foo import attr         # foo imported and foo.attr b
```

If the list of identifiers is replaced by a star (`'*'`), all public names defined in the module are bound in the local namespace for the scope where the **`import`** statement occurs.

The *public names* defined by a module are determined by checking the module's namespace for a variable named `__all__`; if defined, it must be a sequence of strings which are names defined or imported by that module. The names given in `__all__` are all considered public and are required to exist. If `__all__` is not defined, the set of public names includes all names found in the module's namespace which do not begin with an underscore character (`'_'`). `__all__` should contain the entire public API. It is intended to avoid accidentally exporting items that are not part of the API (such as library modules which were imported and used within the module).

The wild card form of import — `from module import *` — is only allowed at the module level. Attempting to use it in class or function definitions will raise a **`SyntaxError`**.

When specifying what module to import you do not have to specify the absolute name of the module. When a module or package is contained within another package it is possible to make a relative import within the same top package without having to mention the package name. By using leading dots in the specified module or package after **`from`** you can specify how high to traverse up the current package hierarchy without specifying exact names. One leading dot means the current package where the module making the import exists. Two dots means up one package level. Three dots is up two levels, etc. So if you execute `from . import mod` from a module in the `pkg` package then you will end up importing `pkg.mod`. If you execute `from ..subpkg2 import mod` from within `pkg.subpkg1` you will import `pkg.subpkg2.mod`. The

specification for relative imports is contained in the Package Relative Imports section.

`importlib.import_module()` is provided to support applications that determine dynamically the modules to be loaded.

Raises an auditing event `import` with arguments `module`, `filename`, `sys.path`, `sys.meta_path`, `sys.path_hooks`.

7.11.1. Future statements

A *future statement* is a directive to the compiler that a particular module should be compiled using syntax or semantics that will be available in a specified future release of Python where the feature becomes standard.

The future statement is intended to ease migration to future versions of Python that introduce incompatible changes to the language. It allows use of the new features on a per-module basis before the release in which the feature becomes standard.

```
future_stmt ::=  "from" "__future__" "import" feature ["
                 ("," feature ["as" identifier])*
                 | "from" "__future__" "import" "(" feat
                 ("," feature ["as" identifier])* [","]
feature     ::=  identifier
```

A future statement must appear near the top of the module. The only lines that can appear before a future statement are:

- the module docstring (if any),
- comments,
- blank lines, and
- other future statements.

The only feature that requires using the future statement is `annotations` (see **PEP 563** [https://peps.python.org/pep-0563/]).

All historical features enabled by the future statement are still recognized by Python 3. The list includes `absolute_import`, `division`, `generators`, `generator_stop`,

`unicode_literals`, `print_function`, `nested_scopes` and `with_statement`. They are all redundant because they are always enabled, and only kept for backwards compatibility.

A future statement is recognized and treated specially at compile time: Changes to the semantics of core constructs are often implemented by generating different code. It may even be the case that a new feature introduces new incompatible syntax (such as a new reserved word), in which case the compiler may need to parse the module differently. Such decisions cannot be pushed off until runtime.

For any given release, the compiler knows which feature names have been defined, and raises a compile-time error if a future statement contains a feature not known to it.

The direct runtime semantics are the same as for any import statement: there is a standard module **`__future__`**, described later, and it will be imported in the usual way at the time the future statement is executed.

The interesting runtime semantics depend on the specific feature enabled by the future statement.

Note that there is nothing special about the statement:

```
import __future__ [as name]
```

That is not a future statement; it's an ordinary import statement with no special semantics or syntax restrictions.

Code compiled by calls to the built-in functions **`exec()`** and **`compile()`** that occur in a module **`M`** containing a future statement will, by default, use the new syntax or semantics associated with the future statement. This can be controlled by optional arguments to **`compile()`** — see the documentation of that function for details.

A future statement typed at an interactive interpreter prompt will take effect for the rest of the interpreter session. If an interpreter is started with the **`-i`** option, is passed a script name to execute, and

the script includes a future statement, it will be in effect in the interactive session started after the script is executed.

PEP 236 [https://peps.python.org/pep-0236/] **- Back to the _future_**
The original proposal for the _future_ mechanism.

7.12. The `global` statement

```
global_stmt ::=  "global" identifier ("," identifier)*
```

The `global` statement is a declaration which holds for the entire current code block. It means that the listed identifiers are to be interpreted as globals. It would be impossible to assign to a global variable without `global`, although free variables may refer to globals without being declared global.

Names listed in a `global` statement must not be used in the same code block textually preceding that `global` statement.

Names listed in a `global` statement must not be defined as formal parameters, or as targets in `with` statements or `except` clauses, or in a `for` target list, `class` definition, function definition, `import` statement, or variable annotation.

CPython implementation detail: The current implementation does not enforce some of these restrictions, but programs should not abuse this freedom, as future implementations may enforce them or silently change the meaning of the program.

Programmer's note: `global` is a directive to the parser. It applies only to code parsed at the same time as the `global` statement. In particular, a `global` statement contained in a string or code object supplied to the built-in `exec()` function does not affect the code block *containing* the function call, and code contained in such a string is unaffected by `global` statements in the code containing the function call. The same applies to the `eval()` and

`compile()` functions.

7.13. The `nonlocal` statement

```
nonlocal_stmt ::=  "nonlocal" identifier ("," identifier
```

The `nonlocal` statement causes the listed identifiers to refer to previously bound variables in the nearest enclosing scope excluding globals. This is important because the default behavior for binding is to search the local namespace first. The statement allows encapsulated code to rebind variables outside of the local scope besides the global (module) scope.

Names listed in a `nonlocal` statement, unlike those listed in a `global` statement, must refer to pre-existing bindings in an enclosing scope (the scope in which a new binding should be created cannot be determined unambiguously).

Names listed in a `nonlocal` statement must not collide with pre-existing bindings in the local scope.

See also

PEP 3104 [https://peps.python.org/pep-3104/] **- Access to Names in Outer Scopes**
The specification for the `nonlocal` statement.

8. Compound statements

Compound statements contain (groups of) other statements; they affect or control the execution of those other statements in some way. In general, compound statements span multiple lines, although in simple incarnations a whole compound statement may be contained in one line.

The **`if`**, **`while`** and **`for`** statements implement traditional control flow constructs. **`try`** specifies exception handlers and/or cleanup code for a group of statements, while the **`with`** statement allows the execution of initialization and finalization code around a block of code. Function and class definitions are also syntactically compound statements.

A compound statement consists of one or more 'clauses.' A clause consists of a header and a 'suite.' The clause headers of a particular compound statement are all at the same indentation level. Each clause header begins with a uniquely identifying keyword and ends with a colon. A suite is a group of statements controlled by a clause. A suite can be one or more semicolon-separated simple statements on the same line as the header, following the header's colon, or it can be one or more indented statements on subsequent lines. Only the latter form of a suite can contain nested compound statements; the following is illegal, mostly because it wouldn't be clear to which **`if`** clause a following **`else`** clause would belong:

```
if test1: if test2: print(x)
```

Also note that the semicolon binds tighter than the colon in this context, so that in the following example, either all or none of the **`print()`** calls are executed:

```
if x < y < z: print(x); print(y); print(z)
```

Summarizing:

```
compound_stmt ::=  if_stmt
                   | while_stmt
                   | for_stmt
                   | try_stmt
                   | with_stmt
                   | match_stmt
                   | funcdef
                   | classdef
                   | async_with_stmt
                   | async_for_stmt
                   | async_funcdef
suite         ::=  stmt_list NEWLINE | NEWLINE INDENT st
statement     ::=  stmt_list NEWLINE | compound_stmt
stmt_list     ::=  simple_stmt (";" simple_stmt)* [";"]
```

Note that statements always end in a `NEWLINE` possibly followed by a `DEDENT`. Also note that optional continuation clauses always begin with a keyword that cannot start a statement, thus there are no ambiguities (the 'dangling **`else`**' problem is solved in Python by requiring nested **`if`** statements to be indented).

The formatting of the grammar rules in the following sections places each clause on a separate line for clarity.

8.1. The **`if`** statement

The **`if`** statement is used for conditional execution:

```
if_stmt ::=  "if" assignment_expression ":" suite
             ("elif" assignment_expression ":" suite)*
             ["else" ":" suite]
```

It selects exactly one of the suites by evaluating the expressions one by one until one is found to be true (see section Boolean operations for the definition of true and false); then that suite is executed (and no other part of the **`if`** statement is executed or evaluated). If all expressions are false, the suite of the **`else`** clause, if present, is executed.

8.2. The `while` statement

The `while` statement is used for repeated execution as long as an expression is true:

```
while_stmt ::=  "while" assignment_expression ":" suite
                ["else" ":" suite]
```

This repeatedly tests the expression and, if it is true, executes the first suite; if the expression is false (which may be the first time it is tested) the suite of the `else` clause, if present, is executed and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and goes back to testing the expression.

8.3. The `for` statement

The `for` statement is used to iterate over the elements of a sequence (such as a string, tuple or list) or other iterable object:

```
for_stmt ::=  "for" target_list "in" starred_list ":" su
              ["else" ":" suite]
```

The `starred_list` expression is evaluated once; it should yield an iterable object. An iterator is created for that iterable. The first item provided by the iterator is then assigned to the target list using the standard rules for assignments (see Assignment statements), and the suite is executed. This repeats for each item provided by the iterator. When the iterator is exhausted, the suite in the `else` clause, if present, is executed, and the loop terminates.

A `break` statement executed in the first suite terminates the loop without executing the `else` clause's suite. A `continue` statement executed in the first suite skips the rest of the suite and continues with the next item, or with the `else` clause if there is no next item.

The for-loop makes assignments to the variables in the target list.

This overwrites all previous assignments to those variables including those made in the suite of the for-loop:

```
for i in range(10):
    print(i)
    i = 5             # this will not affect the for-loo
                      # because i will be overwritten wi
                      # index in the range
```

Names in the target list are not deleted when the loop is finished, but if the sequence is empty, they will not have been assigned to at all by the loop. Hint: the built-in function **`range()`** returns an iterator of integers suitable to emulate the effect of Pascal's `for i := a to b do`; e.g., `list(range(3))` returns the list `[0, 1, 2]`.

Changed in version 3.11: Starred elements are now allowed in the expression list.

8.4. The `try` statement

The **`try`** statement specifies exception handlers and/or cleanup code for a group of statements:

```
try_stmt   ::=  try1_stmt | try2_stmt | try3_stmt
try1_stmt  ::=  "try" ":" suite
                ("except" [expression ["as" identifier]]
                ["else" ":" suite]
                ["finally" ":" suite]
try2_stmt  ::=  "try" ":" suite
                ("except" "*" expression ["as" identifier
                ["else" ":" suite]
                ["finally" ":" suite]
try3_stmt  ::=  "try" ":" suite
                "finally" ":" suite
```

Additional information on exceptions can be found in section Exceptions, and information on using the **`raise`** statement to generate exceptions may be found in section The raise statement.

8.4.1. `except` clause

The **`except`** clause(s) specify one or more exception handlers. When no exception occurs in the **`try`** clause, no exception handler is executed. When an exception occurs in the **`try`** suite, a search for an exception handler is started. This search inspects the **`except`** clauses in turn until one is found that matches the exception. An expression-less **`except`** clause, if present, must be last; it matches any exception. For an **`except`** clause with an expression, that expression is evaluated, and the clause matches the exception if the resulting object is "compatible" with the exception. An object is compatible with an exception if the object is the class or a non-virtual base class of the exception object, or a tuple containing an item that is the class or a non-virtual base class of the exception object.

If no **`except`** clause matches the exception, the search for an exception handler continues in the surrounding code and on the invocation stack. 1

If the evaluation of an expression in the header of an **`except`** clause raises an exception, the original search for a handler is canceled and a search starts for the new exception in the surrounding code and on the call stack (it is treated as if the entire **`try`** statement raised the exception).

When a matching **`except`** clause is found, the exception is assigned to the target specified after the **`as`** keyword in that **`except`** clause, if present, and the **`except`** clause's suite is executed. All **`except`** clauses must have an executable block. When the end of this block is reached, execution continues normally after the entire **`try`** statement. (This means that if two nested handlers exist for the same exception, and the exception occurs in the **`try`** clause of the inner handler, the outer handler will not handle the exception.)

When an exception has been assigned using `as target`, it is cleared at the end of the **`except`** clause. This is as if

```
except E as N:
    foo
```

was translated to

```
except E as N:
    try:
        foo
    finally:
        del N
```

This means the exception must be assigned to a different name to be able to refer to it after the **except** clause. Exceptions are cleared because with the traceback attached to them, they form a reference cycle with the stack frame, keeping all locals in that frame alive until the next garbage collection occurs.

Before an **except** clause's suite is executed, details about the exception are stored in the **sys** module and can be accessed via **sys.exc_info()**. **sys.exc_info()** returns a 3-tuple consisting of the exception class, the exception instance and a traceback object (see section The standard type hierarchy) identifying the point in the program where the exception occurred. The details about the exception accessed via **sys.exc_info()** are restored to their previous values when leaving an exception handler:

```
>>> print(sys.exc_info())
(None, None, None)
>>> try:
...     raise TypeError
... except:
...     print(sys.exc_info())
...     try:
...          raise ValueError
...     except:
...         print(sys.exc_info())
...     print(sys.exc_info())
...
(<class 'TypeError'>, TypeError(), <traceback object at
(<class 'ValueError'>, ValueError(), <traceback object a
(<class 'TypeError'>, TypeError(), <traceback object at
>>> print(sys.exc_info())
(None, None, None)
```

8.4.2. `except*` clause

The **`except*`** clause(s) are used for handling **`ExceptionGroup`**s. The exception type for matching is interpreted as in the case of **`except`**, but in the case of exception groups we can have partial matches when the type matches some of the exceptions in the group. This means that multiple **`except*`** clauses can execute, each handling part of the exception group. Each clause executes at most once and handles an exception group of all matching exceptions. Each exception in the group is handled by at most one **`except*`** clause, the first that matches it.

```
>>> try:
...     raise ExceptionGroup("eg",
...         [ValueError(1), TypeError(2), OSError(3), OS
... except* TypeError as e:
...     print(f'caught {type(e)} with nested {e.exceptio
... except* OSError as e:
...     print(f'caught {type(e)} with nested {e.exceptio
...
caught <class 'ExceptionGroup'> with nested (TypeError(2
caught <class 'ExceptionGroup'> with nested (OSError(3),
  + Exception Group Traceback (most recent call last):
  |   File "<stdin>", line 2, in <module>
  | ExceptionGroup: eg
  +-+---------------- 1 ----------------
    | ValueError: 1
    +------------------------------------
```

Any remaining exceptions that were not handled by any **`except*`** clause are re-raised at the end, combined into an exception group along with all exceptions that were raised from within **`except*`** clauses.

If the raised exception is not an exception group and its type matches one of the **`except*`** clauses, it is caught and wrapped by an exception group with an empty message string.

```
>>> try:
...     raise BlockingIOError
```

```
... except* BlockingIOError as e:
...     print(repr(e))
...
ExceptionGroup('', (BlockingIOError()))
```

An **except*** clause must have a matching type, and this type cannot be a subclass of **BaseExceptionGroup**. It is not possible to mix **except** and **except*** in the same **try**. **break**, **continue** and **return** cannot appear in an **except*** clause.

8.4.3. `else` clause

The optional **else** clause is executed if the control flow leaves the **try** suite, no exception was raised, and no **return**, **continue**, or **break** statement was executed. Exceptions in the **else** clause are not handled by the preceding **except** clauses.

8.4.4. `finally` clause

If **finally** is present, it specifies a 'cleanup' handler. The **try** clause is executed, including any **except** and **else** clauses. If an exception occurs in any of the clauses and is not handled, the exception is temporarily saved. The **finally** clause is executed. If there is a saved exception it is re-raised at the end of the **finally** clause. If the **finally** clause raises another exception, the saved exception is set as the context of the new exception. If the **finally** clause executes a **return**, **break** or **continue** statement, the saved exception is discarded:

```
>>> def f():
...     try:
...         1/0
...     finally:
...         return 42
...
>>> f()
42
```

The exception information is not available to the program during execution of the **finally** clause.

When a **return**, **break** or **continue** statement is executed in the **try** suite of a **try**…**finally** statement, the **finally** clause is also executed 'on the way out.'

The return value of a function is determined by the last **return** statement executed. Since the **finally** clause always executes, a **return** statement executed in the **finally** clause will always be the last one executed:

```
>>> def foo():
...     try:
...         return 'try'
...     finally:
...         return 'finally'
...
>>> foo()
'finally'
```

Changed in version 3.8: Prior to Python 3.8, a **continue** statement was illegal in the **finally** clause due to a problem with the implementation.

8.5. The **with** statement

The **with** statement is used to wrap the execution of a block with methods defined by a context manager (see section With Statement Context Managers). This allows common **try**…**except**…**finally** usage patterns to be encapsulated for convenient reuse.

```
with_stmt          ::=  "with" ( "(" with_stmt_contents
with_stmt_contents ::=  with_item ("," with_item)*
with_item          ::=  expression ["as" target]
```

The execution of the **with** statement with one "item" proceeds as follows:

1. The context expression (the expression given in the **with_item**) is evaluated to obtain a context manager.

2. The context manager's **__enter__()** is loaded for later use.

3. The context manager's **`__exit__()`** is loaded for later use.

4. The context manager's **`__enter__()`** method is invoked.

5. If a target was included in the **`with`** statement, the return value from **`__enter__()`** is assigned to it.

   Note

   The **`with`** statement guarantees that if the **`__enter__()`** method returns without an error, then **`__exit__()`** will always be called. Thus, if an error occurs during the assignment to the target list, it will be treated the same as an error occurring within the suite would be. See step 6 below.

6. The suite is executed.

7. The context manager's **`__exit__()`** method is invoked. If an exception caused the suite to be exited, its type, value, and traceback are passed as arguments to **`__exit__()`**. Otherwise, three **`None`** arguments are supplied.

   If the suite was exited due to an exception, and the return value from the **`__exit__()`** method was false, the exception is reraised. If the return value was true, the exception is suppressed, and execution continues with the statement following the **`with`** statement.

   If the suite was exited for any reason other than an exception, the return value from **`__exit__()`** is ignored, and execution proceeds at the normal location for the kind of exit that was taken.

The following code:

```
with EXPRESSION as TARGET:
    SUITE
```

is semantically equivalent to:

```
manager = (EXPRESSION)
enter = type(manager).__enter__
exit = type(manager).__exit__
value = enter(manager)
hit_except = False

try:
    TARGET = value
    SUITE
except:
    hit_except = True
    if not exit(manager, *sys.exc_info()):
        raise
finally:
    if not hit_except:
        exit(manager, None, None, None)
```

With more than one item, the context managers are processed as if multiple **`with`** statements were nested:

```
with A() as a, B() as b:
    SUITE
```

is semantically equivalent to:

```
with A() as a:
    with B() as b:
        SUITE
```

You can also write multi-item context managers in multiple lines if the items are surrounded by parentheses. For example:

```
with (
    A() as a,
    B() as b,
):
    SUITE
```

Changed in version 3.1: Support for multiple context expressions.

Changed in version 3.10: Support for using grouping parentheses to break the statement in multiple lines.

See also

PEP 343 [https://peps.python.org/pep-0343/] - The "with" statement
The specification, background, and examples for the Python `with` statement.

8.6. The `match` statement

New in version 3.10.

The match statement is used for pattern matching. Syntax:

```
match_stmt   ::=  'match' subject_expr ":" NEWLINE INDEN
subject_expr ::=  star_named_expression "," star_named_e
                  | named_expression
case_block   ::=  'case' patterns [guard] ":" block
```

Note

This section uses single quotes to denote soft keywords.

Pattern matching takes a pattern as input (following `case`) and a subject value (following `match`). The pattern (which may contain subpatterns) is matched against the subject value. The outcomes are:

- A match success or failure (also termed a pattern success or failure).
- Possible binding of matched values to a name. The prerequisites for this are further discussed below.

The `match` and `case` keywords are soft keywords.

See also

- **PEP 634** [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification
- **PEP 636** [https://peps.python.org/pep-0636/] – Structural Pattern Matching: Tutorial

8.6.1. Overview

Here's an overview of the logical flow of a match statement:

1. The subject expression `subject_expr` is evaluated and a resulting subject value obtained. If the subject expression contains a comma, a tuple is constructed using the standard rules.

2. Each pattern in a `case_block` is attempted to match with the subject value. The specific rules for success or failure are described below. The match attempt can also bind some or all of the standalone names within the pattern. The precise pattern binding rules vary per pattern type and are specified below. **Name bindings made during a successful pattern match outlive the executed block and can be used after the match statement**.

   > **Note**
   >
   > During failed pattern matches, some subpatterns may succeed. Do not rely on bindings being made for a failed match. Conversely, do not rely on variables remaining unchanged after a failed match. The exact behavior is dependent on implementation and may vary. This is an intentional decision made to allow different implementations to add optimizations.

3. If the pattern succeeds, the corresponding guard (if present) is

evaluated. In this case all name bindings are guaranteed to have happened.

- If the guard evaluates as true or is missing, the `block` inside `case_block` is executed.
- Otherwise, the next `case_block` is attempted as described above.
- If there are no further case blocks, the match statement is completed.

Note

Users should generally never rely on a pattern being evaluated. Depending on implementation, the interpreter may cache values or use other optimizations which skip repeated evaluations.

A sample match statement:

```
>>> flag = False
>>> match (100, 200):
...     case (100, 300):  # Mismatch: 200 != 300
...         print('Case 1')
...     case (100, 200) if flag:  # Successful match, but
...         print('Case 2')
...     case (100, y):  # Matches and binds y to 200
...         print(f'Case 3, y: {y}')
...     case _:  # Pattern not attempted
...         print('Case 4, I match anything!')
...
Case 3, y: 200
```

In this case, `if flag` is a guard. Read more about that in the next section.

8.6.2. Guards

`guard ::=  "if" named_expression`

A `guard` (which is part of the `case`) must succeed for code inside

the `case` block to execute. It takes the form: **`if`** followed by an expression.

The logical flow of a `case` block with a `guard` follows:

1. Check that the pattern in the `case` block succeeded. If the pattern failed, the `guard` is not evaluated and the next `case` block is checked.
2. If the pattern succeeded, evaluate the `guard`.
    - If the `guard` condition evaluates as true, the case block is selected.
    - If the `guard` condition evaluates as false, the case block is not selected.
    - If the `guard` raises an exception during evaluation, the exception bubbles up.

Guards are allowed to have side effects as they are expressions. Guard evaluation must proceed from the first to the last case block, one at a time, skipping case blocks whose pattern(s) don't all succeed. (I.e., guard evaluation must happen in order.) Guard evaluation must stop once a case block is selected.

8.6.3. Irrefutable Case Blocks

An irrefutable case block is a match-all case block. A match statement may have at most one irrefutable case block, and it must be last.

A case block is considered irrefutable if it has no guard and its pattern is irrefutable. A pattern is considered irrefutable if we can prove from its syntax alone that it will always succeed. Only the following patterns are irrefutable:

- AS Patterns whose left-hand side is irrefutable
- OR Patterns containing at least one irrefutable pattern
- Capture Patterns
- Wildcard Patterns
- parenthesized irrefutable patterns

8.6.4. Patterns

Note

This section uses grammar notations beyond standard EBNF:

- the notation `SEP.RULE+` is shorthand for `RULE (SEP RULE)*`
- the notation `!RULE` is shorthand for a negative lookahead assertion

The top-level syntax for `patterns` is:

```
patterns        ::=  open_sequence_pattern | pattern
pattern         ::=  as_pattern | or_pattern
closed_pattern  ::=  | literal_pattern
                     | capture_pattern
                     | wildcard_pattern
                     | value_pattern
                     | group_pattern
                     | sequence_pattern
                     | mapping_pattern
                     | class_pattern
```

The descriptions below will include a description “in simple terms” of what a pattern does for illustration purposes (credits to Raymond Hettinger for a document that inspired most of the descriptions). Note that these descriptions are purely for illustration purposes and **may not** reflect the underlying implementation. Furthermore, they do not cover all valid forms.

8.6.4.1. OR Patterns

An OR pattern is two or more patterns separated by vertical bars `|`. Syntax:

```
or_pattern ::=  "|".closed_pattern+
```

Only the final subpattern may be irrefutable, and each subpattern must bind the same set of names to avoid ambiguity.

An OR pattern matches each of its subpatterns in turn to the subject

value, until one succeeds. The OR pattern is then considered successful. Otherwise, if none of the subpatterns succeed, the OR pattern fails.

In simple terms, `P1 | P2 | ...` will try to match `P1`, if it fails it will try to match `P2`, succeeding immediately if any succeeds, failing otherwise.

8.6.4.2. AS Patterns

An AS pattern matches an OR pattern on the left of the **`as`** keyword against a subject. Syntax:

```
as_pattern ::=  or_pattern "as" capture_pattern
```

If the OR pattern fails, the AS pattern fails. Otherwise, the AS pattern binds the subject to the name on the right of the as keyword and succeeds. `capture_pattern` cannot be a a `_`.

In simple terms `P as NAME` will match with `P`, and on success it will set `NAME = <subject>`.

8.6.4.3. Literal Patterns

A literal pattern corresponds to most literals in Python. Syntax:

```
literal_pattern ::=  signed_number
                   | signed_number "+" NUMBER
                   | signed_number "-" NUMBER
                   | strings
                   | "None"
                   | "True"
                   | "False"
                   | signed_number: NUMBER | "-" NUMBE
```

The rule `strings` and the token `NUMBER` are defined in the standard Python grammar. Triple-quoted strings are supported. Raw strings and byte strings are supported. Formatted string literals are not supported.

The forms `signed_number '+' NUMBER` and `signed_number '-' NUMBER` are for expressing complex numbers; they require a real number on the left and an imaginary number on the right. E.g. `3 + 4j`.

In simple terms, `LITERAL` will succeed only if `<subject> == LITERAL`. For the singletons `None`, `True` and `False`, the **`is`** operator is used.

8.6.4.4. Capture Patterns

A capture pattern binds the subject value to a name. Syntax:

`capture_pattern` `::=  !'_' NAME`

A single underscore `_` is not a capture pattern (this is what `!'_'` expresses). It is instead treated as a **`wildcard_pattern`**.

In a given pattern, a given name can only be bound once. E.g. `case x, x: ...` is invalid while `case [x] | x: ...` is allowed.

Capture patterns always succeed. The binding follows scoping rules established by the assignment expression operator in **PEP 572** [https://peps.python.org/pep-0572/]; the name becomes a local variable in the closest containing function scope unless there's an applicable **`global`** or **`nonlocal`** statement.

In simple terms `NAME` will always succeed and it will set `NAME = <subject>`.

8.6.4.5. Wildcard Patterns

A wildcard pattern always succeeds (matches anything) and binds no name. Syntax:

`wildcard_pattern` `::=  '_'`

`_` is a soft keyword within any pattern, but only within patterns. It is an identifier, as usual, even within `match` subject expressions, `guard`s, and `case` blocks.

In simple terms, `_` will always succeed.

8.6.4.6. Value Patterns

A value pattern represents a named value in Python. Syntax:

```
value_pattern ::=  attr
attr          ::=  name_or_attr "." NAME
name_or_attr  ::=  attr | NAME
```

The dotted name in the pattern is looked up using standard Python name resolution rules. The pattern succeeds if the value found compares equal to the subject value (using the `==` equality operator).

In simple terms `NAME1.NAME2` will succeed only if `<subject> == NAME1.NAME2`

Note

If the same value occurs multiple times in the same match statement, the interpreter may cache the first value found and reuse it rather than repeat the same lookup. This cache is strictly tied to a given execution of a given match statement.

8.6.4.7. Group Patterns

A group pattern allows users to add parentheses around patterns to emphasize the intended grouping. Otherwise, it has no additional syntax. Syntax:

```
group_pattern ::=  "(" pattern ")"
```

In simple terms `(P)` has the same effect as `P`.

8.6.4.8. Sequence Patterns

A sequence pattern contains several subpatterns to be matched against sequence elements. The syntax is similar to the unpacking of

a list or tuple.

```
sequence_pattern         ::=  "[" [maybe_sequence_pattern]
                              | "(" [open_sequence_pattern
open_sequence_pattern    ::=  maybe_star_pattern "," [mayb
maybe_sequence_pattern   ::=  ",".maybe_star_pattern+ ","?
maybe_star_pattern       ::=  star_pattern | pattern
star_pattern             ::=  "*" (capture_pattern | wildc
```

There is no difference if parentheses or square brackets are used for sequence patterns (i.e. `(...)` vs `[...]`).

Note

A single pattern enclosed in parentheses without a trailing comma (e.g. `(3 | 4)`) is a group pattern. While a single pattern enclosed in square brackets (e.g. `[3 | 4]`) is still a sequence pattern.

At most one star subpattern may be in a sequence pattern. The star subpattern may occur in any position. If no star subpattern is present, the sequence pattern is a fixed-length sequence pattern; otherwise it is a variable-length sequence pattern.

The following is the logical flow for matching a sequence pattern against a subject value:

1. If the subject value is not a sequence 2, the sequence pattern fails.

2. If the subject value is an instance of `str`, `bytes` or `bytearray` the sequence pattern fails.

3. The subsequent steps depend on whether the sequence pattern is fixed or variable-length.

   If the sequence pattern is fixed-length:

   1. If the length of the subject sequence is not equal to the number of subpatterns, the sequence pattern fails

2. Subpatterns in the sequence pattern are matched to their corresponding items in the subject sequence from left to right. Matching stops as soon as a subpattern fails. If all subpatterns succeed in matching their corresponding item, the sequence pattern succeeds.

Otherwise, if the sequence pattern is variable-length:

1. If the length of the subject sequence is less than the number of non-star subpatterns, the sequence pattern fails.
2. The leading non-star subpatterns are matched to their corresponding items as for fixed-length sequences.
3. If the previous step succeeds, the star subpattern matches a list formed of the remaining subject items, excluding the remaining items corresponding to non-star subpatterns following the star subpattern.
4. Remaining non-star subpatterns are matched to their corresponding subject items, as for a fixed-length sequence.

Note

The length of the subject sequence is obtained via **`len()`** (i.e. via the **`__len__()`** protocol). This length may be cached by the interpreter in a similar manner as value patterns.

In simple terms `[P1, P2, P3, … , P<N>]` matches only if all the following happens:

- check `<subject>` is a sequence
- `len(subject) == <N>`
- `P1` matches `<subject>[0]` (note that this match can also bind names)
- `P2` matches `<subject>[1]` (note that this match can also bind names)
- … and so on for the corresponding pattern/element.

8.6.4.9. Mapping Patterns

A mapping pattern contains one or more key-value patterns. The syntax is similar to the construction of a dictionary. Syntax:

```
mapping_pattern      ::=  "{" [items_pattern] "}"
items_pattern        ::=  ",".key_value_pattern+ ","?
key_value_pattern    ::=  (literal_pattern | value_patter
                          | double_star_pattern
double_star_pattern  ::=  "**" capture_pattern
```

At most one double star pattern may be in a mapping pattern. The double star pattern must be the last subpattern in the mapping pattern.

Duplicate keys in mapping patterns are disallowed. Duplicate literal keys will raise a **SyntaxError**. Two keys that otherwise have the same value will raise a **ValueError** at runtime.

The following is the logical flow for matching a mapping pattern against a subject value:

1. If the subject value is not a mapping 3,the mapping pattern fails.
2. If every key given in the mapping pattern is present in the subject mapping, and the pattern for each key matches the corresponding item of the subject mapping, the mapping pattern succeeds.
3. If duplicate keys are detected in the mapping pattern, the pattern is considered invalid. A **SyntaxError** is raised for duplicate literal values; or a **ValueError** for named keys of the same value.

Note

Key-value pairs are matched using the two-argument form of the mapping subject's `get()` method. Matched key-value pairs must already be present in the mapping, and not created on-the-fly via **__missing__()** or **__getitem__()**.

In simple terms `{KEY1: P1, KEY2: P2, ... }` matches only if all the following happens:

- check `<subject>` is a mapping
- `KEY1 in <subject>`
- `P1` matches `<subject>[KEY1]`
- … and so on for the corresponding KEY/pattern pair.

8.6.4.10. Class Patterns

A class pattern represents a class and its positional and keyword arguments (if any). Syntax:

```
class_pattern       ::=  name_or_attr "(" [pattern_argum
pattern_arguments   ::=  positional_patterns ["," keywor
                         | keyword_patterns
positional_patterns ::=  ",".pattern+
keyword_patterns    ::=  ",".keyword_pattern+
keyword_pattern     ::=  NAME "=" pattern
```

The same keyword should not be repeated in class patterns.

The following is the logical flow for matching a class pattern against a subject value:

1. If `name_or_attr` is not an instance of the builtin **`type`**, raise **`TypeError`**.

2. If the subject value is not an instance of `name_or_attr` (tested via **`isinstance()`**), the class pattern fails.

3. If no pattern arguments are present, the pattern succeeds. Otherwise, the subsequent steps depend on whether keyword or positional argument patterns are present.

   For a number of built-in types (specified below), a single positional subpattern is accepted which will match the entire subject; for these types keyword patterns also work as for other types.

   If only keyword patterns are present, they are processed as

follows, one by one:

I. The keyword is looked up as an attribute on the subject.

- If this raises an exception other than **`AttributeError`**, the exception bubbles up.
- If this raises **`AttributeError`**, the class pattern has failed.
- Else, the subpattern associated with the keyword pattern is matched against the subject's attribute value. If this fails, the class pattern fails; if this succeeds, the match proceeds to the next keyword.

II. If all keyword patterns succeed, the class pattern succeeds.

If any positional patterns are present, they are converted to keyword patterns using the **`__match_args__`** attribute on the class `name_or_attr` before matching:

I. The equivalent of `getattr(cls, "__match_args__", ())` is called.

- If this raises an exception, the exception bubbles up.
- If the returned value is not a tuple, the conversion fails and **`TypeError`** is raised.
- If there are more positional patterns than `len(cls.__match_args__)`, **`TypeError`** is raised.
- Otherwise, positional pattern `i` is converted to a keyword pattern using `__match_args__[i]` as the keyword. `__match_args__[i]` must be a string; if not **`TypeError`** is raised.
- If there are duplicate keywords, **`TypeError`** is raised.

See also

Customizing positional arguments in class pattern matching

II. Once all positional patterns have been converted to keyword patterns,
the match proceeds as if there were only keyword patterns.

For the following built-in types the handling of positional subpatterns is different:

- **bool**
- **bytearray**
- **bytes**
- **dict**
- **float**
- **frozenset**
- **int**
- **list**
- **set**
- **str**
- **tuple**

These classes accept a single positional argument, and the pattern there is matched against the whole object rather than an attribute. For example `int(0|1)` matches the value `0`, but not the value `0.0`.

In simple terms `CLS(P1, attr=P2)` matches only if the following happens:

- `isinstance(<subject>, CLS)`
- convert `P1` to a keyword pattern using `CLS.__match_args__`
- For each keyword argument `attr=P2`:
  - `hasattr(<subject>, "attr")`
  - `P2` matches `<subject>.attr`

- … and so on for the corresponding keyword argument/ pattern pair.

- **PEP 636** [https://peps.python.org/pep-0636/] – Structural Pattern Matching: Tutorial

8.7. Function definitions

A function definition defines a user-defined function object (see section The standard type hierarchy):

```
funcdef                 ::=  [decorators] "def" funcna
                             ["->" expression] ":" sui
decorators              ::=  decorator+
decorator               ::=  "@" assignment_expressio
parameter_list          ::=  defparameter ("," defpara
                               | parameter_list_no_pos
parameter_list_no_posonly ::=  defparameter ("," defpara
                             | parameter_list_starargs
parameter_list_starargs ::=  "*" [parameter] ("," defp
                             | "**" parameter [","]
parameter               ::=  identifier [":" expressio
defparameter            ::=  parameter ["=" expressio
funcname                ::=  identifier
```

A function definition is an executable statement. Its execution binds the function name in the current local namespace to a function object (a wrapper around the executable code for the function). This function object contains a reference to the current global namespace as the global namespace to be used when the function is called.

The function definition does not execute the function body; this gets executed only when the function is called. 4

A function definition may be wrapped by one or more decorator expressions. Decorator expressions are evaluated when the function is defined, in the scope that contains the function definition. The result must be a callable, which is invoked with the function object as the only argument. The returned value is bound to the function name instead of the function object. Multiple decorators are applied in nested fashion. For example, the following code

```
@f1(arg)
@f2
def func(): pass
```

is roughly equivalent to

```
def func(): pass
func = f1(arg)(f2(func))
```

except that the original function is not temporarily bound to the name `func`.

Changed in version 3.9: Functions may be decorated with any valid **`assignment_expression`**. Previously, the grammar was much more restrictive; see **PEP 614** [https://peps.python.org/pep-0614/] for details.

When one or more parameters have the form *parameter* `=` *expression*, the function is said to have "default parameter values." For a parameter with a default value, the corresponding argument may be omitted from a call, in which case the parameter's default value is substituted. If a parameter has a default value, all following parameters up until the "`*`" must also have a default value — this is a syntactic restriction that is not expressed by the grammar.

Default parameter values are evaluated from left to right when the function definition is executed. This means that the expression is evaluated once, when the function is defined, and that the same "pre-computed" value is used for each call. This is especially important to understand when a default parameter value is a mutable object, such as a list or a dictionary: if the function modifies the object (e.g. by appending an item to a list), the default parameter value is in effect modified. This is generally not what

was intended. A way around this is to use `None` as the default, and explicitly test for it in the body of the function, e.g.:

```
def whats_on_the_telly(penguin=None):
    if penguin is None:
        penguin = []
    penguin.append("property of the zoo")
    return penguin
```

Function call semantics are described in more detail in section Calls. A function call always assigns values to all parameters mentioned in the parameter list, either from positional arguments, from keyword arguments, or from default values. If the form "`*identifier`" is present, it is initialized to a tuple receiving any excess positional parameters, defaulting to the empty tuple. If the form "`**identifier`" is present, it is initialized to a new ordered mapping receiving any excess keyword arguments, defaulting to a new empty mapping of the same type. Parameters after "`*`" or "`*identifier`" are keyword-only parameters and may only be passed by keyword arguments. Parameters before "`/`" are positional-only parameters and may only be passed by positional arguments.

Changed in version 3.8: The `/` function parameter syntax may be used to indicate positional-only parameters. See **PEP 570** [https://peps.python.org/pep-0570/] for details.

Parameters may have an annotation of the form "`: expression`" following the parameter name. Any parameter may have an annotation, even those of the form `*identifier` or `**identifier`. Functions may have "return" annotation of the form "`-> expression`" after the parameter list. These annotations can be any valid Python expression. The presence of annotations does not change the semantics of a function. The annotation values are available as values of a dictionary keyed by the parameters' names in the **`__annotations__`** attribute of the function object. If the `annotations` import from **`__future__`** is used, annotations are preserved as strings at runtime which enables postponed evaluation. Otherwise, they are evaluated when the function definition is executed. In this case annotations may be

evaluated in a different order than they appear in the source code.

It is also possible to create anonymous functions (functions not bound to a name), for immediate use in expressions. This uses lambda expressions, described in section Lambdas. Note that the lambda expression is merely a shorthand for a simplified function definition; a function defined in a "**def**" statement can be passed around or assigned to another name just like a function defined by a lambda expression. The "**def**" form is actually more powerful since it allows the execution of multiple statements and annotations.

Programmer's note: Functions are first-class objects. A "def" statement executed inside a function definition defines a local function that can be returned or passed around. Free variables used in the nested function can access the local variables of the function containing the def. See section Naming and binding for details.

The original specification for function annotations.

PEP 484 [https://peps.python.org/pep-0484/] - Type Hints
Definition of a standard meaning for annotations: type hints.

PEP 526 [https://peps.python.org/pep-0526/] - Syntax for Variable Annotations
Ability to type hint variable declarations, including class variables and instance variables

PEP 563 [https://peps.python.org/pep-0563/] - Postponed Evaluation of Annotations
Support for forward references within annotations by preserving annotations in a string form at runtime instead of eager evaluation.

8.8. Class definitions

A class definition defines a class object (see section The standard type hierarchy):

```
classdef    ::=  [decorators] "class" classname [inherit
inheritance ::=  "(" [argument_list] ")"
classname   ::=  identifier
```

A class definition is an executable statement. The inheritance list usually gives a list of base classes (see Metaclasses for more advanced uses), so each item in the list should evaluate to a class object which allows subclassing. Classes without an inheritance list inherit, by default, from the base class **object**; hence,

```
class Foo:
    pass
```

is equivalent to

```
class Foo(object):
    pass
```

The class's suite is then executed in a new execution frame (see Naming and binding), using a newly created local namespace and the original global namespace. (Usually, the suite contains mostly function definitions.) When the class's suite finishes execution, its execution frame is discarded but its local namespace is saved. 5 A class object is then created using the inheritance list for the base classes and the saved local namespace for the attribute dictionary. The class name is bound to this class object in the original local namespace.

The order in which attributes are defined in the class body is preserved in the new class's `__dict__`. Note that this is reliable only right after the class is created and only for classes that were defined using the definition syntax.

Class creation can be customized heavily using metaclasses.

Classes can also be decorated: just like when decorating functions,

```
@f1(arg)
```

```
@f2
class Foo: pass
```

is roughly equivalent to

```
class Foo: pass
Foo = f1(arg)(f2(Foo))
```

The evaluation rules for the decorator expressions are the same as for function decorators. The result is then bound to the class name.

Changed in version 3.9: Classes may be decorated with any valid **assignment_expression**. Previously, the grammar was much more restrictive; see **PEP 614** [https://peps.python.org/pep-0614/] for details.

Programmer's note: Variables defined in the class definition are class attributes; they are shared by instances. Instance attributes can be set in a method with `self.name = value`. Both class and instance attributes are accessible through the notation "`self.name`", and an instance attribute hides a class attribute with the same name when accessed in this way. Class attributes can be used as defaults for instance attributes, but using mutable values there can lead to unexpected results. Descriptors can be used to create instance variables with different implementation details.

PEP 3115 **[https://peps.python.org/pep-3115/]** **- Metaclasses in Python 3000**
The proposal that changed the declaration of metaclasses to the current syntax, and the semantics for how classes with metaclasses are constructed.

PEP 3129 **[https://peps.python.org/pep-3129/]** **- Class Decorators**
The proposal that added class decorators. Function and method decorators were introduced in **PEP 318** [https://peps.python.org/pep-0318/].

8.9. Coroutines

New in version 3.5.

8.9.1. Coroutine function definition

```
async_funcdef ::=  [decorators] "async" "def" funcname "
                   ["->" expression] ":" suite
```

Execution of Python coroutines can be suspended and resumed at many points (see coroutine). **await** expressions, **async for** and **async with** can only be used in the body of a coroutine function.

Functions defined with `async def` syntax are always coroutine functions, even if they do not contain `await` or `async` keywords.

It is a **SyntaxError** to use a `yield from` expression inside the body of a coroutine function.

An example of a coroutine function:

```
async def func(param1, param2):
    do_stuff()
    await some_coroutine()
```

Changed in version 3.7: `await` and `async` are now keywords; previously they were only treated as such inside the body of a coroutine function.

8.9.2. The **async for** statement

```
async_for_stmt ::=  "async" for_stmt
```

An asynchronous iterable provides an `__aiter__` method that directly returns an asynchronous iterator, which can call asynchronous code in its `__anext__` method.

The `async for` statement allows convenient iteration over asynchronous iterables.

The following code:

```
async for TARGET in ITER:
```

```
    SUITE
else:
    SUITE2
```

Is semantically equivalent to:

```
iter = (ITER)
iter = type(iter).__aiter__(iter)
running = True

while running:
    try:
        TARGET = await type(iter).__anext__(iter)
    except StopAsyncIteration:
        running = False
    else:
        SUITE
else:
    SUITE2
```

See also **`__aiter__()`** and **`__anext__()`** for details.

It is a **`SyntaxError`** to use an `async for` statement outside the body of a coroutine function.

8.9.3. The `async with` statement

`async_with_stmt` `::=` `"async"` **`with_stmt`**

An asynchronous context manager is a context manager that is able to suspend execution in its *enter* and *exit* methods.

The following code:

```
async with EXPRESSION as TARGET:
    SUITE
```

is semantically equivalent to:

```
manager = (EXPRESSION)
```

```
aenter = type(manager).__aenter__
aexit = type(manager).__aexit__
value = await aenter(manager)
hit_except = False

try:
    TARGET = value
    SUITE
except:
    hit_except = True
    if not await aexit(manager, *sys.exc_info()):
        raise
finally:
    if not hit_except:
        await aexit(manager, None, None, None)
```

See also **`__aenter__()`** and **`__aexit__()`** for details.

It is a **`SyntaxError`** to use an `async with` statement outside the body of a coroutine function.

See also

PEP 492 **[https://peps.python.org/pep-0492/]** **- Coroutines with async and await syntax**
: The proposal that made coroutines a proper standalone concept in Python, and added supporting syntax.

Footnotes

1
: The exception is propagated to the invocation stack unless there is a **`finally`** clause which happens to raise another exception. That new exception causes the old one to be lost.

2
: In pattern matching, a sequence is defined as one of the following:

- a class that inherits from **collections.abc.Sequence**
- a Python class that has been registered as **collections.abc.Sequence**
- a builtin class that has its (CPython) **Py_TPFLAGS_SEQUENCE** bit set
- a class that inherits from any of the above

The following standard library classes are sequences:

- **array.array**
- **collections.deque**
- **list**
- **memoryview**
- **range**
- **tuple**

Note

Subject values of type `str`, `bytes`, and `bytearray` do not match sequence patterns.

3

In pattern matching, a mapping is defined as one of the following:

- a class that inherits from **collections.abc.Mapping**
- a Python class that has been registered as **collections.abc.Mapping**
- a builtin class that has its (CPython) **Py_TPFLAGS_MAPPING** bit set
- a class that inherits from any of the above

The standard library classes **dict** and **types.MappingProxyType** are mappings.

4

A string literal appearing as the first statement in the function body is transformed into the function's `__doc__` attribute and therefore the function's docstring.

5

A string literal appearing as the first statement in the class body is transformed into the namespace's `__doc__` item and therefore the class's docstring.

9. Top-level components

The Python interpreter can get its input from a number of sources: from a script passed to it as standard input or as program argument, typed in interactively, from a module source file, etc. This chapter gives the syntax used in these cases.

9.1. Complete Python programs

While a language specification need not prescribe how the language interpreter is invoked, it is useful to have a notion of a complete Python program. A complete Python program is executed in a minimally initialized environment: all built-in and standard modules are available, but none have been initialized, except for **sys** (various system services), **builtins** (built-in functions, exceptions and `None`) and **__main__**. The latter is used to provide the local and global namespace for execution of the complete program.

The syntax for a complete Python program is that for file input, described in the next section.

The interpreter may also be invoked in interactive mode; in this case, it does not read and execute a complete program but reads and executes one statement (possibly compound) at a time. The initial environment is identical to that of a complete program; each statement is executed in the namespace of **__main__**.

A complete program can be passed to the interpreter in three forms: with the **-c** *string* command line option, as a file passed as the first command line argument, or as standard input. If the file or standard input is a tty device, the interpreter enters interactive mode; otherwise, it executes the file as a complete program.

9.2. File input

All input read from non-interactive files has the same form:

```
file_input ::=  (NEWLINE | statement)*
```

This syntax is used in the following situations:

- when parsing a complete Python program (from a file or from a string);
- when parsing a module;
- when parsing a string passed to the `exec()` function;

9.3. Interactive input

Input in interactive mode is parsed using the following grammar:

```
interactive_input ::=  [stmt_list] NEWLINE | compound_st
```

Note that a (top-level) compound statement must be followed by a blank line in interactive mode; this is needed to help the parser detect the end of the input.

9.4. Expression input

`eval()` is used for expression input. It ignores leading whitespace. The string argument to `eval()` must have the following form:

```
eval_input ::=  expression_list NEWLINE*
```

10. Full Grammar specification

This is the full Python grammar, derived directly from the grammar used to generate the CPython parser (see Grammar/python.gram [https://github.com/python/cpython/tree/3.11/Grammar/python.gram]). The version here omits details related to code generation and error recovery.

The notation is a mixture of EBNF [https://en.wikipedia.org/wiki/Extended_Backus%E2%80%93Naur_form] and PEG [https://en.wikipedia.org/wiki/Parsing_expression_grammar]. In particular, `&` followed by a symbol, token or parenthesized group indicates a positive lookahead (i.e., is required to match but not consumed), while `!` indicates a negative lookahead (i.e., is required *not* to match). We use the `|` separator to mean PEG's "ordered choice" (written as `/` in traditional PEG grammars). See **PEP 617** [https://peps.python.org/pep-0617/] for more details on the grammar's syntax.

```
# PEG grammar for Python

# ========================= START OF THE GRAMMAR =======

# General grammatical elements and rules:
#
# * Strings with double quotes (") denote SOFT KEYWORDS
# * Strings with single quotes (') denote KEYWORDS
# * Upper case names (NAME) denote tokens in the Grammar
# * Rule names starting with "invalid_" are used for spe
#     - These rules are NOT used in the first pass of th
#     - Only if the first pass fails to parse, a second
#       rules will be executed.
#     - If the parser fails in the second phase with a g
#       location of the generic failure of the first pas
```

```
#       reporting incorrect locations due to the invalid
#     - The order of the alternatives involving invalid
#       (like any rule in PEG).
#
# Grammar Syntax (see PEP 617 for more information):
#
# rule_name: expression
#   Optionally, a type can be included right after the r
#   specifies the return type of the C or Python functio
#   rule:
# rule_name[return_type]: expression
#   If the return type is omitted, then a void * is retu
#   Python.
# e1 e2
#   Match e1, then match e2.
# e1 | e2
#   Match e1 or e2.
#   The first alternative can also appear on the line af
#   formatting purposes. In that case, a | must be used
#   alternative, like so:
#       rule_name[return_type]:
#            | first_alt
#            | second_alt
# ( e )
#   Match e (allows also to use other operators in the g
# [ e ] or e?
#   Optionally match e.
# e*
#   Match zero or more occurrences of e.
# e+
#   Match one or more occurrences of e.
# s.e+
#   Match one or more occurrences of e, separated by s.
#   does not include the separator. This is otherwise id
# &e
#   Succeed if e can be parsed, without consuming any in
# !e
#   Fail if e can be parsed, without consuming any input
```

```
# ~
#   Commit to the current alternative, even if it fails
#

The Python Standard Library

While The Python Language Reference describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python's standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually include the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is an active collection of hundreds of thousands of components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index [https://pypi.org].

- Introduction
  - Notes on availability
- Built-in Functions

- Built-in Constants
  - Constants added by the **site** module
- Built-in Types
  - Truth Value Testing
  - Boolean Operations — **and**, **or**, **not**
  - Comparisons
  - Numeric Types — **int**, **float**, **complex**
  - Iterator Types
  - Sequence Types — **list**, **tuple**, **range**
  - Text Sequence Type — **str**
  - Binary Sequence Types — **bytes**, **bytearray**, **memoryview**
  - Set Types — **set**, **frozenset**
  - Mapping Types — **dict**
  - Context Manager Types
  - Type Annotation Types — Generic Alias, Union
  - Other Built-in Types
  - Special Attributes
  - Integer string conversion length limitation
- Built-in Exceptions
  - Exception context
  - Inheriting from built-in exceptions
  - Base classes
  - Concrete exceptions
  - Warnings
  - Exception groups
  - Exception hierarchy
- Text Processing Services
  - **string** — Common string operations
  - **re** — Regular expression operations
  - **difflib** — Helpers for computing deltas
  - **textwrap** — Text wrapping and filling
  - **unicodedata** — Unicode Database
  - **stringprep** — Internet String Preparation

    - **readline** — GNU readline interface
    - **rlcompleter** — Completion function for GNU readline

- Binary Data Services
    - **struct** — Interpret bytes as packed binary data
    - **codecs** — Codec registry and base classes

- Data Types
    - **datetime** — Basic date and time types
    - **zoneinfo** — IANA time zone support
    - **calendar** — General calendar-related functions
    - **collections** — Container datatypes
    - **collections.abc** — Abstract Base Classes for Containers
    - **heapq** — Heap queue algorithm
    - **bisect** — Array bisection algorithm
    - **array** — Efficient arrays of numeric values
    - **weakref** — Weak references
    - **types** — Dynamic type creation and names for built-in types
    - **copy** — Shallow and deep copy operations
    - **pprint** — Data pretty printer
    - **reprlib** — Alternate **repr()** implementation
    - **enum** — Support for enumerations
    - **graphlib** — Functionality to operate with graph-like structures

- Numeric and Mathematical Modules
    - **numbers** — Numeric abstract base classes
    - **math** — Mathematical functions
    - **cmath** — Mathematical functions for complex numbers
    - **decimal** — Decimal fixed point and floating point arithmetic
    - **fractions** — Rational numbers
    - **random** — Generate pseudo-random numbers
    - **statistics** — Mathematical statistics functions

- Functional Programming Modules
  - **itertools** — Functions creating iterators for efficient looping
  - **functools** — Higher-order functions and operations on callable objects
  - **operator** — Standard operators as functions
- File and Directory Access
  - **pathlib** — Object-oriented filesystem paths
  - **os.path** — Common pathname manipulations
  - **fileinput** — Iterate over lines from multiple input streams
  - **stat** — Interpreting **stat()** results
  - **filecmp** — File and Directory Comparisons
  - **tempfile** — Generate temporary files and directories
  - **glob** — Unix style pathname pattern expansion
  - **fnmatch** — Unix filename pattern matching
  - **linecache** — Random access to text lines
  - **shutil** — High-level file operations
- Data Persistence
  - **pickle** — Python object serialization
  - **copyreg** — Register **pickle** support functions
  - **shelve** — Python object persistence
  - **marshal** — Internal Python object serialization
  - **dbm** — Interfaces to Unix “databases”
  - **sqlite3** — DB-API 2.0 interface for SQLite databases
- Data Compression and Archiving
  - **zlib** — Compression compatible with **gzip**
  - **gzip** — Support for **gzip** files
  - **bz2** — Support for **bzip2** compression
  - **lzma** — Compression using the LZMA algorithm
  - **zipfile** — Work with ZIP archives
  - **tarfile** — Read and write tar archive files
- File Formats

    - **csv** — CSV File Reading and Writing
    - **configparser** — Configuration file parser
    - **tomllib** — Parse TOML files
    - **netrc** — netrc file processing
    - **plistlib** — Generate and parse Apple **.plist** files

- Cryptographic Services

    - **hashlib** — Secure hashes and message digests
    - **hmac** — Keyed-Hashing for Message Authentication
    - **secrets** — Generate secure random numbers for managing secrets

- Generic Operating System Services

    - **os** — Miscellaneous operating system interfaces
    - **io** — Core tools for working with streams
    - **time** — Time access and conversions
    - **argparse** — Parser for command-line options, arguments and sub-commands
    - **getopt** — C-style parser for command line options
    - **logging** — Logging facility for Python
    - **logging.config** — Logging configuration
    - **logging.handlers** — Logging handlers
    - **getpass** — Portable password input
    - **curses** — Terminal handling for character-cell displays
    - **curses.textpad** — Text input widget for curses programs
    - **curses.ascii** — Utilities for ASCII characters
    - **curses.panel** — A panel stack extension for curses
    - **platform** — Access to underlying platform's identifying data
    - **errno** — Standard errno system symbols
    - **ctypes** — A foreign function library for Python

- Concurrent Execution

    - **threading** — Thread-based parallelism
    - **multiprocessing** — Process-based parallelism
    - **multiprocessing.shared_memory** — Shared

memory for direct access across processes
- The `concurrent` package
- `concurrent.futures` — Launching parallel tasks
- `subprocess` — Subprocess management
- `sched` — Event scheduler
- `queue` — A synchronized queue class
- `contextvars` — Context Variables
- `_thread` — Low-level threading API

- Networking and Interprocess Communication
  - `asyncio` — Asynchronous I/O
  - `socket` — Low-level networking interface
  - `ssl` — TLS/SSL wrapper for socket objects
  - `select` — Waiting for I/O completion
  - `selectors` — High-level I/O multiplexing
  - `signal` — Set handlers for asynchronous events
  - `mmap` — Memory-mapped file support

- Internet Data Handling
  - `email` — An email and MIME handling package
  - `json` — JSON encoder and decoder
  - `mailbox` — Manipulate mailboxes in various formats
  - `mimetypes` — Map filenames to MIME types
  - `base64` — Base16, Base32, Base64, Base85 Data Encodings
  - `binascii` — Convert between binary and ASCII
  - `quopri` — Encode and decode MIME quoted-printable data

- Structured Markup Processing Tools
  - `html` — HyperText Markup Language support
  - `html.parser` — Simple HTML and XHTML parser
  - `html.entities` — Definitions of HTML general entities
  - XML Processing Modules
  - `xml.etree.ElementTree` — The ElementTree XML API
  - `xml.dom` — The Document Object Model API

- **xml.dom.minidom** — Minimal DOM implementation
- **xml.dom.pulldom** — Support for building partial DOM trees
- **xml.sax** — Support for SAX2 parsers
- **xml.sax.handler** — Base classes for SAX handlers
- **xml.sax.saxutils** — SAX Utilities
- **xml.sax.xmlreader** — Interface for XML parsers
- **xml.parsers.expat** — Fast XML parsing using Expat

- Internet Protocols and Support
  - **webbrowser** — Convenient web-browser controller
  - **wsgiref** — WSGI Utilities and Reference Implementation
  - **urllib** — URL handling modules
  - **urllib.request** — Extensible library for opening URLs
  - **urllib.response** — Response classes used by urllib
  - **urllib.parse** — Parse URLs into components
  - **urllib.error** — Exception classes raised by urllib.request
  - **urllib.robotparser** — Parser for robots.txt
  - **http** — HTTP modules
  - **http.client** — HTTP protocol client
  - **ftplib** — FTP protocol client
  - **poplib** — POP3 protocol client
  - **imaplib** — IMAP4 protocol client
  - **smtplib** — SMTP protocol client
  - **uuid** — UUID objects according to **RFC 4122**
  - **socketserver** — A framework for network servers
  - **http.server** — HTTP servers
  - **http.cookies** — HTTP state management
  - **http.cookiejar** — Cookie handling for HTTP clients
  - **xmlrpc** — XMLRPC server and client modules
  - **xmlrpc.client** — XML-RPC client access
  - **xmlrpc.server** — Basic XML-RPC servers
  - **ipaddress** — IPv4/IPv6 manipulation library

- Multimedia Services
  - **wave** — Read and write WAV files

    - **colorsys** — Conversions between color systems

- Internationalization

    - **gettext** — Multilingual internationalization services
    - **locale** — Internationalization services

- Program Frameworks

    - **turtle** — Turtle graphics
    - **cmd** — Support for line-oriented command interpreters
    - **shlex** — Simple lexical analysis

- Graphical User Interfaces with Tk

    - **tkinter** — Python interface to Tcl/Tk
    - **tkinter.colorchooser** — Color choosing dialog
    - **tkinter.font** — Tkinter font wrapper
    - Tkinter Dialogs
    - **tkinter.messagebox** — Tkinter message prompts
    - **tkinter.scrolledtext** — Scrolled Text Widget
    - **tkinter.dnd** — Drag and drop support
    - **tkinter.ttk** — Tk themed widgets
    - **tkinter.tix** — Extension widgets for Tk
    - IDLE

- Development Tools

    - **typing** — Support for type hints
    - **pydoc** — Documentation generator and online help system
    - Python Development Mode
    - Effects of the Python Development Mode
    - ResourceWarning Example
    - Bad file descriptor error example
    - **doctest** — Test interactive Python examples
    - **unittest** — Unit testing framework
    - **unittest.mock** — mock object library
    - **unittest.mock** — getting started
    - 2to3 — Automated Python 2 to 3 code translation
    - **test** — Regression tests package for Python

    - **test.support** — Utilities for the Python test suite
    - **test.support.socket_helper** — Utilities for socket tests
    - **test.support.script_helper** — Utilities for the Python execution tests
    - **test.support.bytecode_helper** — Support tools for testing correct bytecode generation
    - **test.support.threading_helper** — Utilities for threading tests
    - **test.support.os_helper** — Utilities for os tests
    - **test.support.import_helper** — Utilities for import tests
    - **test.support.warnings_helper** — Utilities for warnings tests

- Debugging and Profiling

    - Audit events table
    - **bdb** — Debugger framework
    - **faulthandler** — Dump the Python traceback
    - **pdb** — The Python Debugger
    - The Python Profilers
    - **timeit** — Measure execution time of small code snippets
    - **trace** — Trace or track Python statement execution
    - **tracemalloc** — Trace memory allocations

- Software Packaging and Distribution

    - **distutils** — Building and installing Python modules
    - **ensurepip** — Bootstrapping the **pip** installer
    - **venv** — Creation of virtual environments
    - **zipapp** — Manage executable Python zip archives

- Python Runtime Services

    - **sys** — System-specific parameters and functions
    - **sysconfig** — Provide access to Python's configuration information
    - **builtins** — Built-in objects
    - **__main__** — Top-level code environment

    - **warnings** — Warning control
    - **dataclasses** — Data Classes
    - **contextlib** — Utilities for **with**-statement contexts
    - **abc** — Abstract Base Classes
    - **atexit** — Exit handlers
    - **traceback** — Print or retrieve a stack traceback
    - **__future__** — Future statement definitions
    - **gc** — Garbage Collector interface
    - **inspect** — Inspect live objects
    - **site** — Site-specific configuration hook

- Custom Python Interpreters

    - **code** — Interpreter base classes
    - **codeop** — Compile Python code

- Importing Modules

    - **zipimport** — Import modules from Zip archives
    - **pkgutil** — Package extension utility
    - **modulefinder** — Find modules used by a script
    - **runpy** — Locating and executing Python modules
    - **importlib** — The implementation of **import**
    - **importlib.resources** – Resources
    - Deprecated functions
    - **importlib.resources.abc** – Abstract base classes for resources
    - Using **importlib.metadata**
    - The initialization of the **sys.path** module search path

- Python Language Services

    - **ast** — Abstract Syntax Trees
    - **symtable** — Access to the compiler's symbol tables
    - **token** — Constants used with Python parse trees
    - **keyword** — Testing for Python keywords
    - **tokenize** — Tokenizer for Python source
    - **tabnanny** — Detection of ambiguous indentation
    - **pyclbr** — Python module browser support
    - **py_compile** — Compile Python source files
    - **compileall** — Byte-compile Python libraries

    - **dis** — Disassembler for Python bytecode
    - **pickletools** — Tools for pickle developers

- MS Windows Specific Services

    - **msvcrt** — Useful routines from the MS VC++ runtime
    - **winreg** — Windows registry access
    - **winsound** — Sound-playing interface for Windows

- Unix Specific Services

    - **posix** — The most common POSIX system calls
    - **pwd** — The password database
    - **grp** — The group database
    - **termios** — POSIX style tty control
    - **tty** — Terminal control functions
    - **pty** — Pseudo-terminal utilities
    - **fcntl** — The **fcntl** and **ioctl** system calls
    - **resource** — Resource usage information
    - **syslog** — Unix syslog library routines

- Superseded Modules

    - **aifc** — Read and write AIFF and AIFC files
    - **asynchat** — Asynchronous socket command/response handler
    - **asyncore** — Asynchronous socket handler
    - **audioop** — Manipulate raw audio data
    - **cgi** — Common Gateway Interface support
    - **cgitb** — Traceback manager for CGI scripts
    - **chunk** — Read IFF chunked data
    - **crypt** — Function to check Unix passwords
    - **imghdr** — Determine the type of an image
    - **imp** — Access the import internals
    - **mailcap** — Mailcap file handling
    - **msilib** — Read and write Microsoft Installer files
    - **nis** — Interface to Sun's NIS (Yellow Pages)
    - **nntplib** — NNTP protocol client
    - **optparse** — Parser for command line options
    - **ossaudiodev** — Access to OSS-compatible audio

devices
    - **pipes** — Interface to shell pipelines
    - **smtpd** — SMTP Server
    - **sndhdr** — Determine type of sound file
    - **spwd** — The shadow password database
    - **sunau** — Read and write Sun AU files
    - **telnetlib** — Telnet client
    - **uu** — Encode and decode uuencode files
    - **xdrlib** — Encode and decode XDR data

- Security Considerations

Introduction

The “Python library” contains several different kinds of components.

It contains data types that would normally be considered part of the “core” of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions — objects that can be used by all Python code without the need of an `import` statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, such as access to specific hardware; others provide interfaces that are specific to a particular application domain, like the World Wide Web. Some modules are available in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized “from the inside out:” it first describes the built-in functions, data types and exceptions, and finally the modules, grouped in chapters of related modules.

This means that if you start reading this manual from the start, and

skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don't *have* to read it like a novel — you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module **`random`**) and read a section or two. Regardless of the order in which you read the sections of this manual, it helps to start with chapter Built-in Functions, as the remainder of the manual assumes familiarity with this material.

Let the show begin!

Notes on availability

- An "Availability: Unix" note means that this function is commonly found on Unix systems. It does not make any claims about its existence on a specific operating system.
- If not separately noted, all functions that claim "Availability: Unix" are supported on macOS, which builds on a Unix core.
- If an availability note contains both a minimum Kernel version and a minimum libc version, then both conditions must hold. For example a feature with note *Availability: Linux >= 3.17 with glibc >= 2.27* requires both Linux 3.17 or newer and glibc 2.27 or newer.

WebAssembly platforms

The WebAssembly [https://webassembly.org/] platforms `wasm32-emscripten` (Emscripten [https://emscripten.org/]) and `wasm32-wasi` (WASI [https://wasi.dev/]) provide a subset of POSIX APIs. WebAssembly runtimes and browsers are sandboxed and have limited access to the host and external resources. Any Python standard library module that uses processes, threading, networking, signals, or other forms of inter-process communication (IPC), is either not available or may not work as on other Unix-like systems. File I/O, file system, and Unix permission-related functions are restricted, too. Emscripten does not permit blocking I/O. Other

blocking operations like **`sleep()`** block the browser event loop.

The properties and behavior of Python on WebAssembly platforms depend on the Emscripten [https://emscripten.org/]-SDK or WASI [https://wasi.dev/]-SDK version, WASM runtimes (browser, NodeJS, wasmtime [https://wasmtime.dev/]), and Python build time flags. WebAssembly, Emscripten, and WASI are evolving standards; some features like networking may be supported in the future.

For Python in the browser, users should consider Pyodide [https://pyodide.org/] or PyScript [https://pyscript.net/]. PyScript is built on top of Pyodide, which itself is built on top of CPython and Emscripten. Pyodide provides access to browsers' JavaScript and DOM APIs as well as limited networking capabilities with JavaScript's `XMLHttpRequest` and `Fetch` APIs.

- Process-related APIs are not available or always fail with an error. That includes APIs that spawn new processes (**`fork()`**, **`execve()`**), wait for processes (**`waitpid()`**), send signals (**`kill()`**), or otherwise interact with processes. The **`subprocess`** is importable but does not work.
- The **`socket`** module is available, but is limited and behaves differently from other platforms. On Emscripten, sockets are always non-blocking and require additional JavaScript code and helpers on the server to proxy TCP through WebSockets; see Emscripten Networking [https://emscripten.org/docs/porting/networking.html>] for more information. WASI snapshot preview 1 only permits sockets from an existing file descriptor.
- Some functions are stubs that either don't do anything and always return hardcoded values.
- Functions related to file descriptors, file permissions, file ownership, and links are limited and don't support some operations. For example, WASI does not permit symlinks with absolute file names.

Built-in Functions

The Python interpreter has a number of functions and types built into it that are always available. They are listed here in alphabetical order.

Built-in Functions

R			
M			
S			
O			
P			
V			
Z			

abs(*x*)

Return the absolute value of a number. The argument may be an integer, a floating point number, or an object implementing **`__abs__()`**. If the argument is a complex number, its magnitude is returned.

aiter(*async_iterable*)

Return an asynchronous iterator for an asynchronous iterable. Equivalent to calling `x.__aiter__()`.

Note: Unlike **`iter()`**, **`aiter()`** has no 2-argument variant.

New in version 3.10.

all(*iterable*)

Return `True` if all elements of the *iterable* are true (or if the iterable is empty). Equivalent to:

```
def all(iterable):
    for element in iterable:
        if not element:
            return False
    return True
```

awaitable anext(*async_iterator*)

awaitable anext(*async_iterator*, *default*)

When awaited, return the next item from the given asynchronous iterator, or *default* if given and the iterator is exhausted.

This is the async variant of the **`next()`** builtin, and behaves similarly.

This calls the **`__anext__()`** method of *async_iterator*, returning an awaitable. Awaiting this returns the next value of the iterator. If *default* is given, it is returned if the iterator is exhausted, otherwise **`StopAsyncIteration`** is raised.

New in version 3.10.

any(*iterable*)

Return `True` if any element of the *iterable* is true. If the iterable is empty, return `False`. Equivalent to:

```
def any(iterable):
    for element in iterable:
        if element:
            return True
    return False
```

ascii(*object*)

As **`repr()`**, return a string containing a printable representation of an object, but escape the non-ASCII characters in the string returned by **`repr()`** using `\x`, `\u`, or `\U` escapes. This generates a string similar to that returned by **`repr()`** in Python 2.

bin(*x*)

Convert an integer number to a binary string prefixed with "0b". The result is a valid Python expression. If *x* is not a Python **`int`** object, it has to define an **`__index__()`** method that returns an integer. Some examples:

```
>>> bin(3)
'0b11'
>>> bin(-10)
'-0b1010'
```

If the prefix "0b" is desired or not, you can use either of the following ways.

```
>>> format(14, '#b'), format(14, 'b')
('0b1110', '1110')
>>> f'{14:#b}', f'{14:b}'
('0b1110', '1110')
```

See also **`format()`** for more information.

class bool(*x=False*)

Return a Boolean value, i.e. one of `True` or `False`. *x* is converted using the standard truth testing procedure. If *x* is false or omitted, this returns `False`; otherwise, it returns `True`. The **`bool`** class is a subclass of **`int`** (see Numeric Types — int, float, complex). It cannot be subclassed further. Its only instances are `False` and `True` (see Boolean Values).

Changed in version 3.7: *x* is now a positional-only parameter.

breakpoint(**args*, ***kws*)

This function drops you into the debugger at the call site. Specifically, it calls **`sys.breakpointhook()`**, passing `args` and `kws` straight through. By default, `sys.breakpointhook()` calls **`pdb.set_trace()`** expecting no arguments. In this case, it is purely a convenience function so you don't have to explicitly import **`pdb`** or type as much code to enter the debugger. However, **`sys.breakpointhook()`** can be set to some other function and **`breakpoint()`** will automatically call that, allowing you to drop into the debugger of choice. If **`sys.breakpointhook()`** is not accessible, this function will raise **`RuntimeError`**.

Raises an auditing event `builtins.breakpoint` with argument `breakpointhook`.

New in version 3.7.

class bytearray(*source=b''*)

class bytearray(*source*, *encoding*)

class bytearray(*source*, *encoding*, *errors*)

Return a new array of bytes. The **`bytearray`** class is a mutable sequence of integers in the range 0 <= x < 256. It has most of the usual methods of mutable sequences, described in Mutable Sequence Types, as well as most methods that the **`bytes`** type has, see Bytes and Bytearray Operations.

The optional *source* parameter can be used to initialize the array in a few different ways:

- If it is a *string*, you must also give the *encoding* (and optionally, *errors*) parameters; **`bytearray()`** then converts the string to bytes using **`str.encode()`**.
- If it is an *integer*, the array will have that size and will be initialized with null bytes.
- If it is an object conforming to the buffer interface, a read-only buffer of the object will be used to initialize the bytes array.
- If it is an *iterable*, it must be an iterable of integers in the range `0 <= x < 256`, which are used as the initial contents of the array.

Without an argument, an array of size 0 is created.

See also Binary Sequence Types — bytes, bytearray, memoryview and Bytearray Objects.

class bytes(*source*=*b''*)

class bytes(*source*, *encoding*)

class bytes(*source*, *encoding*, *errors*)

Return a new "bytes" object which is an immutable sequence of integers in the range `0 <= x < 256`. **`bytes`** is an immutable version of **`bytearray`** – it has the same non-mutating methods and the same indexing and slicing behavior.

Accordingly, constructor arguments are interpreted as for **`bytearray()`**.

Bytes objects can also be created with literals, see String and Bytes literals.

See also Binary Sequence Types — bytes, bytearray, memoryview, Bytes Objects, and Bytes and Bytearray Operations.

callable(*object*)

Return **`True`** if the *object* argument appears callable, **`False`** if not. If this returns `True`, it is still possible that a call fails, but if it is `False`, calling *object* will never succeed. Note that classes are callable (calling a class returns a new instance); instances are callable if their class has a **`__call__()`** method.

New in version 3.2: This function was first removed in Python 3.0 and then brought back in Python 3.2.

chr(*i*)

Return the string representing a character whose Unicode code point is the integer *i*. For example, `chr(97)` returns the string `'a'`, while `chr(8364)` returns the string `'€'`. This is the inverse of **`ord()`**.

The valid range for the argument is from 0 through 1,114,111 (0x10FFFF in base 16). **`ValueError`** will be raised if *i* is outside that range.

@classmethod

Transform a method into a class method.

A class method receives the class as an implicit first argument, just like an instance method receives the instance. To declare a class method, use this idiom:

```
class C:
    @classmethod
    def f(cls, arg1, arg2): ...
```

The `@classmethod` form is a function decorator – see Function definitions for details.

A class method can be called either on the class (such as `C.f()`) or on an instance (such as `C().f()`). The instance is ignored except for its class. If a class method is called for a derived class, the derived class object is passed as the implied first argument.

Class methods are different than C++ or Java static methods. If you want those, see **staticmethod()** in this section. For more information on class methods, see The standard type hierarchy.

Changed in version 3.9: Class methods can now wrap other descriptors such as **property()**.

Changed in version 3.10: Class methods now inherit the method attributes (`__module__`, `__name__`, `__qualname__`, `__doc__` and `__annotations__`) and have a new `__wrapped__` attribute.

Changed in version 3.11: Class methods can no longer wrap other descriptors such as **property()**.

compile(*source*, *filename*, *mode*, *flags=0*, *dont_inherit=False*, *optimize=-1*)

Compile the *source* into a code or AST object. Code objects can be executed by **exec()** or **eval()**. *source* can either be a normal string, a byte string, or an AST object. Refer to the **ast** module documentation for information on how to work with AST objects.

The *filename* argument should give the file from which the code was read; pass some recognizable value if it wasn't read from a file (`'<string>'` is commonly used).

The *mode* argument specifies what kind of code must be compiled; it can be `'exec'` if *source* consists of a sequence of statements, `'eval'` if it consists of a single expression, or `'single'` if it consists of a single interactive statement (in the latter case, expression statements that evaluate to something other than `None` will be printed).

The optional arguments *flags* and *dont_inherit* control which compiler options should be activated and which future features should be allowed. If neither is present (or both are zero) the code is compiled with the same flags that affect the code that is calling **compile()**. If the *flags* argument is

given and *dont_inherit* is not (or is zero) then the compiler options and the future statements specified by the *flags* argument are used in addition to those that would be used anyway. If *dont_inherit* is a non-zero integer then the *flags* argument is it – the flags (future features and compiler options) in the surrounding code are ignored.

Compiler options and future statements are specified by bits which can be bitwise ORed together to specify multiple options. The bitfield required to specify a given future feature can be found as the **`compiler_flag`** attribute on the **`_Feature`** instance in the **`__future__`** module. Compiler flags can be found in **`ast`** module, with `PyCF_` prefix.

The argument *optimize* specifies the optimization level of the compiler; the default value of `-1` selects the optimization level of the interpreter as given by **`-O`** options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

This function raises **`SyntaxError`** if the compiled source is invalid, and **`ValueError`** if the source contains null bytes.

If you want to parse Python code into its AST representation, see **`ast.parse()`**.

Raises an auditing event `compile` with arguments `source` and `filename`. This event may also be raised by implicit compilation.

Note

When compiling a string with multi-line code in `'single'` or `'eval'` mode, input must be terminated by at least one newline character. This is to facilitate detection of incomplete and complete statements in the **`code`** module.

Warning

It is possible to crash the Python interpreter with a sufficiently large/complex string when compiling to an AST object due to stack depth limitations in Python's AST compiler.

Changed in version 3.2: Allowed use of Windows and Mac newlines. Also, input in `'exec'` mode does not have to end in a newline anymore. Added the *optimize* parameter.

Changed in version 3.5: Previously, **`TypeError`** was raised when null bytes were encountered in *source*.

New in version 3.8: `ast.PyCF_ALLOW_TOP_LEVEL_AWAIT` can now be passed in flags to enable support for top-level `await`, `async for`, and `async with`.

class complex(*real*=*0*, *imag*=*0*)

class complex(*string*)

Return a complex number with the value *real* + *imag**1j or convert a string or number to a complex number. If the first parameter is a string, it will be interpreted as a complex number and the function must be called without a second parameter. The second parameter can never be a string. Each argument may be any numeric type (including complex). If *imag* is omitted, it defaults to zero and the constructor serves as a numeric conversion like **`int`** and **`float`**. If both arguments are omitted, returns `0j`.

For a general Python object `x`, `complex(x)` delegates to `x.__complex__()`. If `__complex__()` is not defined then it falls back to **`__float__()`**. If `__float__()` is not defined then it falls back to **`__index__()`**.

Note

When converting from a string, the string must not contain whitespace around the central `+` or `-` operator. For example, `complex('1+2j')` is fine, but `complex('1`

`+ 2j')` raises **`ValueError`**.

The complex type is described in Numeric Types — int, float, complex.

Changed in version 3.6: Grouping digits with underscores as in code literals is allowed.

Changed in version 3.8: Falls back to **`__index__()`** if **`__complex__()`** and **`__float__()`** are not defined.

delattr(*object*, *name*)

This is a relative of **`setattr()`**. The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, `delattr(x, 'foobar')` is equivalent to `del x.foobar`. *name* need not be a Python identifier (see **`setattr()`**).

class dict(***kwarg*)

class dict(*mapping*, ***kwarg*)

class dict(*iterable*, ***kwarg*)

Create a new dictionary. The **`dict`** object is the dictionary class. See **`dict`** and Mapping Types — dict for documentation about this class.

For other containers see the built-in **`list`**, **`set`**, and **`tuple`** classes, as well as the **`collections`** module.

dir()

dir(*object*)

Without arguments, return the list of names in the current local scope. With an argument, attempt to return a list of valid attributes for that object.

If the object has a method named **`__dir__()`**, this method will be called and must return the list of attributes. This allows objects that implement a custom **`__getattr__()`** or

__getattribute__() function to customize the way **dir()** reports their attributes.

If the object does not provide **__dir__()**, the function tries its best to gather information from the object's **__dict__** attribute, if defined, and from its type object. The resulting list is not necessarily complete and may be inaccurate when the object has a custom **__getattr__()**.

The default **dir()** mechanism behaves differently with different types of objects, as it attempts to produce the most relevant, rather than complete, information:

- If the object is a module object, the list contains the names of the module's attributes.
- If the object is a type or class object, the list contains the names of its attributes, and recursively of the attributes of its bases.
- Otherwise, the list contains the object's attributes' names, the names of its class's attributes, and recursively of the attributes of its class's base classes.

The resulting list is sorted alphabetically. For example:

```
>>> import struct
>>> dir()   # show the names in the module namespac
['__builtins__', '__name__', 'struct']
>>> dir(struct)   # show the names in the struct mo
['Struct', '__all__', '__builtins__', '__cached__',
 '__initializing__', '__loader__', '__name__', '__p
 '_clearcache', 'calcsize', 'error', 'pack', 'pack_
 'unpack', 'unpack_from']
>>> class Shape:
...     def __dir__(self):
...         return ['area', 'perimeter', 'location'
>>> s = Shape()
>>> dir(s)
['area', 'location', 'perimeter']
```

Note

Because **`dir()`** is supplied primarily as a convenience for use at an interactive prompt, it tries to supply an interesting set of names more than it tries to supply a rigorously or consistently defined set of names, and its detailed behavior may change across releases. For example, metaclass attributes are not in the result list when the argument is a class.

divmod(*a*, *b*)

Take two (non-complex) numbers as arguments and return a pair of numbers consisting of their quotient and remainder when using integer division. With mixed operand types, the rules for binary arithmetic operators apply. For integers, the result is the same as `(a // b, a % b)`. For floating point numbers the result is `(q, a % b)`, where *q* is usually `math.floor(a / b)` but may be 1 less than that. In any case `q * b + a % b` is very close to *a*, if `a % b` is non-zero it has the same sign as *b*, and `0 <= abs(a % b) < abs(b)`.

enumerate(*iterable*, *start*=*0*)

Return an enumerate object. *iterable* must be a sequence, an iterator, or some other object which supports iteration. The **`__next__()`** method of the iterator returned by **`enumerate()`** returns a tuple containing a count (from *start* which defaults to 0) and the values obtained from iterating over *iterable*.

```
>>> seasons = ['Spring', 'Summer', 'Fall', 'Winter'
>>> list(enumerate(seasons))
[(0, 'Spring'), (1, 'Summer'), (2, 'Fall'), (3, 'Wi
>>> list(enumerate(seasons, start=1))
[(1, 'Spring'), (2, 'Summer'), (3, 'Fall'), (4, 'Wi
```

Equivalent to:

```
def enumerate(sequence, start=0):
    n = start
```

```
    for elem in sequence:
        yield n, elem
        n += 1
```

eval(*expression*, /, *globals*=*None*, *locals*=*None*)

The arguments are a string and optional globals and locals. If provided, *globals* must be a dictionary. If provided, *locals* can be any mapping object.

The *expression* argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the *globals* and *locals* dictionaries as global and local namespace. If the *globals* dictionary is present and does not contain a value for the key `__builtins__`, a reference to the dictionary of the built-in module **`builtins`** is inserted under that key before *expression* is parsed. That way you can control what builtins are available to the executed code by inserting your own `__builtins__` dictionary into *globals* before passing it to **`eval()`**. If the *locals* dictionary is omitted it defaults to the *globals* dictionary. If both dictionaries are omitted, the expression is executed with the *globals* and *locals* in the environment where **`eval()`** is called. Note, *eval()* does not have access to the nested scopes (non-locals) in the enclosing environment.

The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```
>>> x = 1
>>> eval('x+1')
2
```

This function can also be used to execute arbitrary code objects (such as those created by **`compile()`**). In this case, pass a code object instead of a string. If the code object has been compiled with `'exec'` as the *mode* argument, **`eval()`**'s return value will be `None`.

Hints: dynamic execution of statements is supported by the **`exec()`** function. The **`globals()`** and **`locals()`** functions

return the current global and local dictionary, respectively, which may be useful to pass around for use by **`eval()`** or **`exec()`**.

If the given source is a string, then leading and trailing spaces and tabs are stripped.

See **`ast.literal_eval()`** for a function that can safely evaluate strings with expressions containing only literals.

Raises an auditing event `exec` with the code object as the argument. Code compilation events may also be raised.

exec(*object*, *globals*=*None*, *locals*=*None*, */*, *, *closure*=*None*)

This function supports dynamic execution of Python code. *object* must be either a string or a code object. If it is a string, the string is parsed as a suite of Python statements which is then executed (unless a syntax error occurs). 1 If it is a code object, it is simply executed. In all cases, the code that's executed is expected to be valid as file input (see the section File input in the Reference Manual). Be aware that the **`nonlocal`**, **`yield`**, and **`return`** statements may not be used outside of function definitions even within the context of code passed to the **`exec()`** function. The return value is `None`.

In all cases, if the optional parts are omitted, the code is executed in the current scope. If only *globals* is provided, it must be a dictionary (and not a subclass of dictionary), which will be used for both the global and the local variables. If *globals* and *locals* are given, they are used for the global and local variables, respectively. If provided, *locals* can be any mapping object. Remember that at the module level, globals and locals are the same dictionary. If exec gets two separate objects as *globals* and *locals*, the code will be executed as if it were embedded in a class definition.

If the *globals* dictionary does not contain a value for the key `__builtins__`, a reference to the dictionary of the built-in

module **builtins** is inserted under that key. That way you can control what builtins are available to the executed code by inserting your own `__builtins__` dictionary into *globals* before passing it to **exec()**.

The *closure* argument specifies a closure–a tuple of cellvars. It's only valid when the *object* is a code object containing free variables. The length of the tuple must exactly match the number of free variables referenced by the code object.

Raises an auditing event `exec` with the code object as the argument. Code compilation events may also be raised.

Note

The built-in functions **globals()** and **locals()** return the current global and local dictionary, respectively, which may be useful to pass around for use as the second and third argument to **exec()**.

Note

The default *locals* act as described for function **locals()** below: modifications to the default *locals* dictionary should not be attempted. Pass an explicit *locals* dictionary if you need to see effects of the code on *locals* after function **exec()** returns.

Changed in version 3.11: Added the *closure* parameter.

filter(*function*, *iterable*)

Construct an iterator from those elements of *iterable* for which *function* returns true. *iterable* may be either a sequence, a container which supports iteration, or an iterator. If *function* is `None`, the identity function is assumed, that is, all elements of *iterable* that are false are removed.

Note that `filter(function, iterable)` is equivalent to

the generator expression `(item for item in iterable if function(item))` if function is not `None` and `(item for item in iterable if item)` if function is `None`.

See **`itertools.filterfalse()`** for the complementary function that returns elements of *iterable* for which *function* returns false.

class float(*x=0.0*)

Return a floating point number constructed from a number or string *x*.

If the argument is a string, it should contain a decimal number, optionally preceded by a sign, and optionally embedded in whitespace. The optional sign may be `'+'` or `'-'`; a `'+'` sign has no effect on the value produced. The argument may also be a string representing a NaN (not-a-number), or positive or negative infinity. More precisely, the input must conform to the following grammar after leading and trailing whitespace characters are removed:

```
sign           ::=  "+" | "-"
infinity       ::=  "Infinity" | "inf"
nan            ::=  "nan"
numeric_value  ::=  floatnumber | infinity | nan
numeric_string ::=  [sign] numeric_value
```

Here `floatnumber` is the form of a Python floating-point literal, described in Floating point literals. Case is not significant, so, for example, “inf”, “Inf”, “INFINITY”, and “iNfINity” are all acceptable spellings for positive infinity.

Otherwise, if the argument is an integer or a floating point number, a floating point number with the same value (within Python’s floating point precision) is returned. If the argument is outside the range of a Python float, an **`OverflowError`** will be raised.

For a general Python object `x`, `float(x)` delegates to `x.__float__()`. If `__float__()` is not defined then it

falls back to **`__index__()`**.

If no argument is given, `0.0` is returned.

Examples:

```
>>> float('+1.23')
1.23
>>> float('   -12345\n')
-12345.0
>>> float('1e-003')
0.001
>>> float('+1E6')
1000000.0
>>> float('-Infinity')
-inf
```

The float type is described in Numeric Types — int, float, complex.

Changed in version 3.6: Grouping digits with underscores as in code literals is allowed.

Changed in version 3.7: *x* is now a positional-only parameter.

Changed in version 3.8: Falls back to **`__index__()`** if **`__float__()`** is not defined.

format(*value*, *format_spec*=*''*)

Convert a *value* to a "formatted" representation, as controlled by *format_spec*. The interpretation of *format_spec* will depend on the type of the *value* argument; however, there is a standard formatting syntax that is used by most built-in types: Format Specification Mini-Language.

The default *format_spec* is an empty string which usually gives the same effect as calling **`str(value)`**.

A call to `format(value, format_spec)` is translated to `type(value).__format__(value, format_spec)`

which bypasses the instance dictionary when searching for the value's **`__format__()`** method. A **`TypeError`** exception is raised if the method search reaches **`object`** and the *format_spec* is non-empty, or if either the *format_spec* or the return value are not strings.

Changed in version 3.4:
`object().__format__(format_spec)` raises **`TypeError`** if *format_spec* is not an empty string.

class frozenset(*iterable=set()*)

Return a new **`frozenset`** object, optionally with elements taken from *iterable*. `frozenset` is a built-in class. See **`frozenset`** and Set Types — set, frozenset for documentation about this class.

For other containers see the built-in **`set`**, **`list`**, **`tuple`**, and **`dict`** classes, as well as the **`collections`** module.

getattr(*object*, *name*)
getattr(*object*, *name*, *default*)

Return the value of the named attribute of *object*. *name* must be a string. If the string is the name of one of the object's attributes, the result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`. If the named attribute does not exist, *default* is returned if provided, otherwise **`AttributeError`** is raised. *name* need not be a Python identifier (see **`setattr()`**).

Note

Since private name mangling happens at compilation time, one must manually mangle a private attribute's (attributes with two leading underscores) name in order to retrieve it with **`getattr()`**.

globals()

Return the dictionary implementing the current module namespace. For code within functions, this is set when the function is defined and remains the same regardless of where the function is called.

hasattr(*object*, *name*)

The arguments are an object and a string. The result is `True` if the string is the name of one of the object's attributes, `False` if not. (This is implemented by calling `getattr(object, name)` and seeing whether it raises an **`AttributeError`** or not.)

hash(*object*)

Return the hash value of the object (if it has one). Hash values are integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, as is the case for 1 and 1.0).

Note

For objects with custom **`__hash__()`** methods, note that **`hash()`** truncates the return value based on the bit width of the host machine. See **`__hash__()`** for details.

help()

help(*request*)

Invoke the built-in help system. (This function is intended for interactive use.) If no argument is given, the interactive help system starts on the interpreter console. If the argument is a string, then the string is looked up as the name of a module, function, class, method, keyword, or documentation topic, and a help page is printed on the console. If the argument is any other kind of object, a help page on the object is generated.

Note that if a slash(/) appears in the parameter list of a

function when invoking **help()**, it means that the parameters prior to the slash are positional-only. For more info, see the FAQ entry on positional-only parameters.

This function is added to the built-in namespace by the **site** module.

Changed in version 3.4: Changes to **pydoc** and **inspect** mean that the reported signatures for callables are now more comprehensive and consistent.

hex(*x*)

Convert an integer number to a lowercase hexadecimal string prefixed with "0x". If *x* is not a Python **int** object, it has to define an **__index__()** method that returns an integer. Some examples:

```
>>> hex(255)
'0xff'
>>> hex(-42)
'-0x2a'
```

If you want to convert an integer number to an uppercase or lower hexadecimal string with prefix or not, you can use either of the following ways:

```
>>> '%#x' % 255, '%x' % 255, '%X' % 255
('0xff', 'ff', 'FF')
>>> format(255, '#x'), format(255, 'x'), format(255
('0xff', 'ff', 'FF')
>>> f'{255:#x}', f'{255:x}', f'{255:X}'
('0xff', 'ff', 'FF')
```

See also **format()** for more information.

See also **int()** for converting a hexadecimal string to an integer using a base of 16.

Note

To obtain a hexadecimal string representation for a float, use the **`float.hex()`** method.

id(*object*)

Return the “identity” of an object. This is an integer which is guaranteed to be unique and constant for this object during its lifetime. Two objects with non-overlapping lifetimes may have the same **`id()`** value.

CPython implementation detail: This is the address of the object in memory.

Raises an auditing event `builtins.id` with argument `id`.

input()

input(*prompt*)

If the *prompt* argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, **`EOFError`** is raised. Example:

```
>>> s = input('--> ')
--> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
```

If the **`readline`** module was loaded, then **`input()`** will use it to provide elaborate line editing and history features.

Raises an auditing event `builtins.input` with argument `prompt` before reading input

Raises an auditing event `builtins.input/result` with the result after successfully reading input.

class int(*x=0*)
class int(*x*, *base=10*)

Return an integer object constructed from a number or string *x*, or return `0` if no arguments are given. If *x* defines **`__int__()`**, `int(x)` returns `x.__int__()`. If *x* defines **`__index__()`**, it returns `x.__index__()`. If *x* defines **`__trunc__()`**, it returns `x.__trunc__()`. For floating point numbers, this truncates towards zero.

If *x* is not a number or if *base* is given, then *x* must be a string, **`bytes`**, or **`bytearray`** instance representing an integer literal in radix *base*. Optionally, the literal can be preceded by `+` or `-` (with no space in between) and surrounded by whitespace. A base-n literal consists of the digits 0 to n-1, with `a` to `z` (or `A` to `Z`) having values 10 to 35. The default *base* is 10. The allowed values are 0 and 2–36. Base-2, -8, and -16 literals can be optionally prefixed with `0b`/`0B`, `0o`/`0O`, or `0x`/`0X`, as with integer literals in code. Base 0 means to interpret exactly as a code literal, so that the actual base is 2, 8, 10, or 16, and so that `int('010', 0)` is not legal, while `int('010')` is, as well as `int('010', 8)`.

The integer type is described in Numeric Types — int, float, complex.

Changed in version 3.4: If *base* is not an instance of **`int`** and the *base* object has a **`base.__index__`** method, that method is called to obtain an integer for the base. Previous versions used **`base.__int__`** instead of **`base.__index__`**.

Changed in version 3.6: Grouping digits with underscores as in code literals is allowed.

Changed in version 3.7: *x* is now a positional-only parameter.

Changed in version 3.8: Falls back to **`__index__()`** if **`__int__()`** is not defined.

Changed in version 3.11: The delegation to **`__trunc__()`** is deprecated.

Changed in version 3.11: **`int`** string inputs and string representations can be limited to help avoid denial of service attacks. A **`ValueError`** is raised when the limit is exceeded while converting a string *x* to an **`int`** or when converting an **`int`** into a string would exceed the limit. See the integer string conversion length limitation documentation.

isinstance(*object*, *classinfo*)

Return `True` if the *object* argument is an instance of the *classinfo* argument, or of a (direct, indirect, or virtual) subclass thereof. If *object* is not an object of the given type, the function always returns `False`. If *classinfo* is a tuple of type objects (or recursively, other such tuples) or a Union Type of multiple types, return `True` if *object* is an instance of any of the types. If *classinfo* is not a type or tuple of types and such tuples, a **`TypeError`** exception is raised. **`TypeError`** may not be raised for an invalid type if an earlier check succeeds.

Changed in version 3.10: *classinfo* can be a Union Type.

issubclass(*class*, *classinfo*)

Return `True` if *class* is a subclass (direct, indirect, or virtual) of *classinfo*. A class is considered a subclass of itself. *classinfo* may be a tuple of class objects (or recursively, other such tuples) or a Union Type, in which case return `True` if *class* is a subclass of any entry in *classinfo*. In any other case, a **`TypeError`** exception is raised.

Changed in version 3.10: *classinfo* can be a Union Type.

iter(*object*)
iter(*object*, *sentinel*)

Return an iterator object. The first argument is interpreted very differently depending on the presence of the second argument. Without a second argument, *object* must be a

collection object which supports the iterable protocol (the **`__iter__()`** method), or it must support the sequence protocol (the **`__getitem__()`** method with integer arguments starting at `0`). If it does not support either of those protocols, **`TypeError`** is raised. If the second argument, *sentinel*, is given, then *object* must be a callable object. The iterator created in this case will call *object* with no arguments for each call to its **`__next__()`** method; if the value returned is equal to *sentinel*, **`StopIteration`** will be raised, otherwise the value will be returned.

See also Iterator Types.

One useful application of the second form of **`iter()`** is to build a block-reader. For example, reading fixed-width blocks from a binary database file until the end of file is reached:

```
from functools import partial
with open('mydata.db', 'rb') as f:
    for block in iter(partial(f.read, 64), b''):
        process_block(block)
```

len(*s*)

Return the length (the number of items) of an object. The argument may be a sequence (such as a string, bytes, tuple, list, or range) or a collection (such as a dictionary, set, or frozen set).

CPython implementation detail: `len` raises **`OverflowError`** on lengths larger than **`sys.maxsize`**, such as **`range(2 ** 100)`**.

class list

class list(*iterable*)

Rather than being a function, **`list`** is actually a mutable sequence type, as documented in Lists and Sequence Types — list, tuple, range.

locals()

Update and return a dictionary representing the current local symbol table. Free variables are returned by `locals()` when it is called in function blocks, but not in class blocks. Note that at the module level, `locals()` and `globals()` are the same dictionary.

Note

The contents of this dictionary should not be modified; changes may not affect the values of local and free variables used by the interpreter.

map(*function*, *iterable*, **iterables*)

Return an iterator that applies *function* to every item of *iterable*, yielding the results. If additional *iterables* arguments are passed, *function* must take that many arguments and is applied to the items from all iterables in parallel. With multiple iterables, the iterator stops when the shortest iterable is exhausted. For cases where the function inputs are already arranged into argument tuples, see `itertools.starmap()`.

max(*iterable*, ***, *key*=*None*)
max(*iterable*, ***, *default*, *key*=*None*)
max(*arg1*, *arg2*, **args*, *key*=*None*)

Return the largest item in an iterable or the largest of two or more arguments.

If one positional argument is provided, it should be an iterable. The largest item in the iterable is returned. If two or more positional arguments are provided, the largest of the positional arguments is returned.

There are two optional keyword-only arguments. The *key* argument specifies a one-argument ordering function like that used for `list.sort()`. The *default* argument specifies an object to return if the provided iterable is empty. If the iterable is empty and *default* is not provided, a `ValueError`

is raised.

If multiple items are maximal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as `sorted(iterable, key=keyfunc, reverse=True)[0]` and `heapq.nlargest(1, iterable, key=keyfunc)`.

New in version 3.4: The *default* keyword-only argument.

Changed in version 3.8: The *key* can be `None`.

class memoryview(*object*)

Return a "memory view" object created from the given argument. See Memory Views for more information.

min(*iterable*, *, *key*=*None*)
min(*iterable*, *, *default*, *key*=*None*)
min(*arg1*, *arg2*, **args*, *key*=*None*)

Return the smallest item in an iterable or the smallest of two or more arguments.

If one positional argument is provided, it should be an iterable. The smallest item in the iterable is returned. If two or more positional arguments are provided, the smallest of the positional arguments is returned.

There are two optional keyword-only arguments. The *key* argument specifies a one-argument ordering function like that used for **`list.sort()`**. The *default* argument specifies an object to return if the provided iterable is empty. If the iterable is empty and *default* is not provided, a **`ValueError`** is raised.

If multiple items are minimal, the function returns the first one encountered. This is consistent with other sort-stability preserving tools such as `sorted(iterable, key=keyfunc)[0]` and `heapq.nsmallest(1, iterable, key=keyfunc)`.

New in version 3.4: The *default* keyword-only argument.

Changed in version 3.8: The *key* can be `None`.

next(*iterator*)
next(*iterator*, *default*)

Retrieve the next item from the iterator by calling its **`__next__()`** method. If *default* is given, it is returned if the iterator is exhausted, otherwise **`StopIteration`** is raised.

class object

Return a new featureless object. **`object`** is a base for all classes. It has methods that are common to all instances of Python classes. This function does not accept any arguments.

Note

`object` does *not* have a **`__dict__`**, so you can't assign arbitrary attributes to an instance of the **`object`** class.

oct(*x*)

Convert an integer number to an octal string prefixed with "0o". The result is a valid Python expression. If *x* is not a Python **`int`** object, it has to define an **`__index__()`** method that returns an integer. For example:

```
>>> oct(8)
'0o10'
>>> oct(-56)
'-0o70'
```

If you want to convert an integer number to an octal string either with the prefix "0o" or not, you can use either of the following ways.

```
>>> '%#o' % 10, '%o' % 10
('0o12', '12')
>>> format(10, '#o'), format(10, 'o')
```

```
('0o12', '12')
>>> f'{10:#o}', f'{10:o}'
('0o12', '12')
```

See also **`format()`** for more information.

open(*file*, *mode*='r', *buffering*=-1, *encoding*=None, *errors*=None, *newline*=None, *closefd*=True, *opener*=None)

Open *file* and return a corresponding file object. If the file cannot be opened, an **`OSError`** is raised. See Reading and Writing Files for more examples of how to use this function.

file is a path-like object giving the pathname (absolute or relative to the current working directory) of the file to be opened or an integer file descriptor of the file to be wrapped. (If a file descriptor is given, it is closed when the returned I/O object is closed unless *closefd* is set to `False`.)

mode is an optional string that specifies the mode in which the file is opened. It defaults to `'r'` which means open for reading in text mode. Other common values are `'w'` for writing (truncating the file if it already exists), `'x'` for exclusive creation, and `'a'` for appending (which on *some* Unix systems, means that *all* writes append to the end of the file regardless of the current seek position). In text mode, if *encoding* is not specified the encoding used is platform-dependent: **`locale.getencoding()`** is called to get the current locale encoding. (For reading and writing raw bytes use binary mode and leave *encoding* unspecified.) The available modes are:

Character	Meaning
`'r'`	open for reading (default)
`'w'`	open for writing, truncating the file first
`'x'`	open for exclusive creation, failing if the file already exists
`'a'`	open for writing, appending to the end of file if it exists
`'b'`	binary mode

`'t'`	text mode (default)
`'+'`	open for updating (reading and writing)

The default mode is `'r'` (open for reading text, a synonym of `'rt'`). Modes `'w+'` and `'w+b'` open and truncate the file. Modes `'r+'` and `'r+b'` open the file with no truncation.

As mentioned in the Overview, Python distinguishes between binary and text I/O. Files opened in binary mode (including `'b'` in the *mode* argument) return contents as **`bytes`** objects without any decoding. In text mode (the default, or when `'t'` is included in the *mode* argument), the contents of the file are returned as **`str`**, the bytes having been first decoded using a platform-dependent encoding or using the specified *encoding* if given.

Note

Python doesn't depend on the underlying operating system's notion of text files; all the processing is done by Python itself, and is therefore platform-independent.

buffering is an optional integer used to set the buffering policy. Pass 0 to switch buffering off (only allowed in binary mode), 1 to select line buffering (only usable in text mode), and an integer > 1 to indicate the size in bytes of a fixed-size chunk buffer. Note that specifying a buffer size this way applies for binary buffered I/O, but `TextIOWrapper` (i.e., files opened with `mode='r+'`) would have another buffering. To disable buffering in `TextIOWrapper`, consider using the `write_through` flag for **`io.TextIOWrapper.reconfigure()`**. When no *buffering* argument is given, the default buffering policy works as follows:

- Binary files are buffered in fixed-size chunks; the size of the buffer is chosen using a heuristic trying to determine the underlying device's "block size" and falling back on **`io.DEFAULT_BUFFER_SIZE`**. On

many systems, the buffer will typically be 4096 or 8192 bytes long.
- "Interactive" text files (files for which **`isatty()`** returns `True`) use line buffering. Other text files use the policy described above for binary files.

encoding is the name of the encoding used to decode or encode the file. This should only be used in text mode. The default encoding is platform dependent (whatever **`locale.getencoding()`** returns), but any text encoding supported by Python can be used. See the **`codecs`** module for the list of supported encodings.

errors is an optional string that specifies how encoding and decoding errors are to be handled—this cannot be used in binary mode. A variety of standard error handlers are available (listed under Error Handlers), though any error handling name that has been registered with **`codecs.register_error()`** is also valid. The standard names include:

- `'strict'` to raise a **`ValueError`** exception if there is an encoding error. The default value of `None` has the same effect.
- `'ignore'` ignores errors. Note that ignoring encoding errors can lead to data loss.
- `'replace'` causes a replacement marker (such as `'?'`) to be inserted where there is malformed data.
- `'surrogateescape'` will represent any incorrect bytes as low surrogate code units ranging from U+DC80 to U+DCFF. These surrogate code units will then be turned back into the same bytes when the `surrogateescape` error handler is used when writing data. This is useful for processing files in an unknown encoding.
- `'xmlcharrefreplace'` is only supported when writing to a file. Characters not supported by the encoding are replaced with the appropriate XML character reference `&#nnn;`.
- `'backslashreplace'` replaces malformed data by Python's backslashed escape sequences.

- `'namereplace'` (also only supported when writing) replaces unsupported characters with `\N{...}` escape sequences.

newline determines how to parse newline characters from the stream. It can be `None`, `''`, `'\n'`, `'\r'`, and `'\r\n'`. It works as follows:

- When reading input from the stream, if *newline* is `None`, universal newlines mode is enabled. Lines in the input can end in `'\n'`, `'\r'`, or `'\r\n'`, and these are translated into `'\n'` before being returned to the caller. If it is `''`, universal newlines mode is enabled, but line endings are returned to the caller untranslated. If it has any of the other legal values, input lines are only terminated by the given string, and the line ending is returned to the caller untranslated.
- When writing output to the stream, if *newline* is `None`, any `'\n'` characters written are translated to the system default line separator, **`os.linesep`**. If *newline* is `''` or `'\n'`, no translation takes place. If *newline* is any of the other legal values, any `'\n'` characters written are translated to the given string.

If *closefd* is `False` and a file descriptor rather than a filename was given, the underlying file descriptor will be kept open when the file is closed. If a filename is given *closefd* must be `True` (the default); otherwise, an error will be raised.

A custom opener can be used by passing a callable as *opener*. The underlying file descriptor for the file object is then obtained by calling *opener* with (*file*, *flags*). *opener* must return an open file descriptor (passing **`os.open`** as *opener* results in functionality similar to passing `None`).

The newly created file is non-inheritable.

The following example uses the dir_fd parameter of the **`os.open()`** function to open a file relative to a given directory:

```
>>> import os
>>> dir_fd = os.open('somedir', os.O_RDONLY)
>>> def opener(path, flags):
...     return os.open(path, flags, dir_fd=dir_fd)
...
>>> with open('spamspam.txt', 'w', opener=opener) a
...     print('This will be written to somedir/spam
...
>>> os.close(dir_fd)  # don't leak a file descripto
```

The type of file object returned by the **`open()`** function depends on the mode. When **`open()`** is used to open a file in a text mode (`'w'`, `'r'`, `'wt'`, `'rt'`, etc.), it returns a subclass of **`io.TextIOBase`** (specifically **`io.TextIOWrapper`**). When used to open a file in a binary mode with buffering, the returned class is a subclass of **`io.BufferedIOBase`**. The exact class varies: in read binary mode, it returns an **`io.BufferedReader`**; in write binary and append binary modes, it returns an **`io.BufferedWriter`**, and in read/write mode, it returns an **`io.BufferedRandom`**. When buffering is disabled, the raw stream, a subclass of **`io.RawIOBase`**, **`io.FileIO`**, is returned.

See also the file handling modules, such as **`fileinput`**, **`io`** (where **`open()`** is declared), **`os`**, **`os.path`**, **`tempfile`**, and **`shutil`**.

Raises an auditing event `open` with arguments `file`, `mode`, `flags`.

The `mode` and `flags` arguments may have been modified or inferred from the original call.

Changed in version 3.3:

- The *opener* parameter was added.
- The `'x'` mode was added.
- **`IOError`** used to be raised, it is now an alias of **`OSError`**.
- **`FileExistsError`** is now raised if the file opened in

exclusive creation mode (`'x'`) already exists.

Changed in version 3.4:

- The file is now non-inheritable.

Changed in version 3.5:

- If the system call is interrupted and the signal handler does not raise an exception, the function now retries the system call instead of raising an **`InterruptedError`** exception (see **PEP 475** [https://peps.python.org/pep-0475/] for the rationale).
- The `'namereplace'` error handler was added.

Changed in version 3.6:

- Support added to accept objects implementing **`os.PathLike`**.
- On Windows, opening a console buffer may return a subclass of **`io.RawIOBase`** other than **`io.FileIO`**.

Changed in version 3.11: The `'U'` mode has been removed.

ord(*c*)

Given a string representing one Unicode character, return an integer representing the Unicode code point of that character. For example, `ord('a')` returns the integer `97` and `ord('€')` (Euro sign) returns `8364`. This is the inverse of **`chr()`**.

pow(*base*, *exp*, *mod*=*None*)

Return *base* to the power *exp*; if *mod* is present, return *base* to the power *exp*, modulo *mod* (computed more efficiently than `pow(base, exp) % mod`). The two-argument form `pow(base, exp)` is equivalent to using the power operator: `base**exp`.

The arguments must have numeric types. With mixed operand types, the coercion rules for binary arithmetic operators

apply. For **int** operands, the result has the same type as the operands (after coercion) unless the second argument is negative; in that case, all arguments are converted to float and a float result is delivered. For example, `pow(10, 2)` returns `100`, but `pow(10, -2)` returns `0.01`. For a negative base of type **int** or **float** and a non-integral exponent, a complex result is delivered. For example, `pow(-9, 0.5)` returns a value close to `3j`.

For **int** operands *base* and *exp*, if *mod* is present, *mod* must also be of integer type and *mod* must be nonzero. If *mod* is present and *exp* is negative, *base* must be relatively prime to *mod*. In that case, `pow(inv_base, -exp, mod)` is returned, where *inv_base* is an inverse to *base* modulo *mod*.

Here's an example of computing an inverse for `38` modulo `97`:

```
>>> pow(38, -1, mod=97)
23
>>> 23 * 38 % 97 == 1
True
```

Changed in version 3.8: For **int** operands, the three-argument form of `pow` now allows the second argument to be negative, permitting computation of modular inverses.

Changed in version 3.8: Allow keyword arguments. Formerly, only positional arguments were supported.

print(**objects*, *sep*=' ', *end*='\n', *file*=*None*, *flush*=*False*)

Print *objects* to the text stream *file*, separated by *sep* and followed by *end*. *sep*, *end*, *file*, and *flush*, if present, must be given as keyword arguments.

All non-keyword arguments are converted to strings like **str()** does and written to the stream, separated by *sep* and followed by *end*. Both *sep* and *end* must be strings; they can also be `None`, which means to use the default values. If no *objects* are given, **print()** will just write *end*.

The *file* argument must be an object with a `write(string)` method; if it is not present or `None`, **`sys.stdout`** will be used. Since printed arguments are converted to text strings, **`print()`** cannot be used with binary mode file objects. For these, use `file.write(...)` instead.

Whether the output is buffered is usually determined by *file*, but if the *flush* keyword argument is true, the stream is forcibly flushed.

Changed in version 3.3: Added the *flush* keyword argument.

class property(*fget=None*, *fset=None*, *fdel=None*, *doc=None*)

Return a property attribute.

fget is a function for getting an attribute value. *fset* is a function for setting an attribute value. *fdel* is a function for deleting an attribute value. And *doc* creates a docstring for the attribute.

A typical use is to define a managed attribute `x`:

```
class C:
    def __init__(self):
        self._x = None

    def getx(self):
        return self._x

    def setx(self, value):
        self._x = value

    def delx(self):
        del self._x

    x = property(getx, setx, delx, "I'm the 'x' pro
```

If *c* is an instance of *C*, `c.x` will invoke the getter, `c.x = value` will invoke the setter, and `del c.x` the deleter.

If given, *doc* will be the docstring of the property attribute. Otherwise, the property will copy *fget*'s docstring (if it exists). This makes it possible to create read-only properties easily using **`property()`** as a decorator:

```
class Parrot:
    def __init__(self):
        self._voltage = 100000

    @property
    def voltage(self):
        """Get the current voltage."""
        return self._voltage
```

The `@property` decorator turns the **`voltage()`** method into a "getter" for a read-only attribute with the same name, and it sets the docstring for *voltage* to "Get the current voltage."

A property object has **`getter`**, **`setter`**, and **`deleter`** methods usable as decorators that create a copy of the property with the corresponding accessor function set to the decorated function. This is best explained with an example:

```
class C:
    def __init__(self):
        self._x = None

    @property
    def x(self):
        """I'm the 'x' property."""
        return self._x

    @x.setter
    def x(self, value):
        self._x = value

    @x.deleter
    def x(self):
        del self._x
```

This code is exactly equivalent to the first example. Be sure to give the additional functions the same name as the original property (`x` in this case.)

The returned property object also has the attributes `fget`, `fset`, and `fdel` corresponding to the constructor arguments.

Changed in version 3.5: The docstrings of property objects are now writeable.

class range(*stop*)

class range(*start*, *stop*, *step* = *1*)

Rather than being a function, **`range`** is actually an immutable sequence type, as documented in Ranges and Sequence Types — list, tuple, range.

repr(*object*)

Return a string containing a printable representation of an object. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to **`eval()`**; otherwise, the representation is a string enclosed in angle brackets that contains the name of the type of the object together with additional information often including the name and address of the object. A class can control what this function returns for its instances by defining a **`__repr__()`** method. If **`sys.displayhook()`** is not accessible, this function will raise **`RuntimeError`**.

reversed(*seq*)

Return a reverse iterator. *seq* must be an object which has a **`__reversed__()`** method or supports the sequence protocol (the **`__len__()`** method and the **`__getitem__()`** method with integer arguments starting at `0`).

round(*number*, *ndigits* = *None*)

Return *number* rounded to *ndigits* precision after the decimal point. If *ndigits* is omitted or is `None`, it returns the nearest integer to its input.

For the built-in types supporting **round()**, values are rounded to the closest multiple of 10 to the power minus *ndigits*; if two multiples are equally close, rounding is done toward the even choice (so, for example, both `round(0.5)` and `round(-0.5)` are `0`, and `round(1.5)` is `2`). Any integer value is valid for *ndigits* (positive, zero, or negative). The return value is an integer if *ndigits* is omitted or `None`. Otherwise, the return value has the same type as *number*.

For a general Python object `number`, `round` delegates to `number.__round__`.

Note

The behavior of **round()** for floats can be surprising: for example, `round(2.675, 2)` gives `2.67` instead of the expected `2.68`. This is not a bug: it's a result of the fact that most decimal fractions can't be represented exactly as a float. See Floating Point Arithmetic: Issues and Limitations for more information.

class set

class set(*iterable*)

Return a new **set** object, optionally with elements taken from *iterable*. `set` is a built-in class. See **set** and Set Types — set, frozenset for documentation about this class.

For other containers see the built-in **frozenset**, **list**, **tuple**, and **dict** classes, as well as the **collections** module.

setattr(*object*, *name*, *value*)

This is the counterpart of **getattr()**. The arguments are an object, a string, and an arbitrary value. The string may name an existing attribute or a new attribute. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

name need not be a Python identifier as defined in Identifiers and keywords unless the object chooses to enforce that, for example in a custom **`__getattribute__()`** or via **`__slots__`**. An attribute whose name is not an identifier will not be accessible using the dot notation, but is accessible through **`getattr()`** etc..

Note

Since private name mangling happens at compilation time, one must manually mangle a private attribute's (attributes with two leading underscores) name in order to set it with **`setattr()`**.

class slice(*stop*)

class slice(*start*, *stop*, *step* = *1*)

Return a slice object representing the set of indices specified by `range(start, stop, step)`. The *start* and *step* arguments default to `None`. Slice objects have read-only data attributes **`start`**, **`stop`**, and **`step`** which merely return the argument values (or their default). They have no other explicit functionality; however, they are used by NumPy and other third-party packages. Slice objects are also generated when extended indexing syntax is used. For example: `a[start:stop:step]` or `a[start:stop, i]`. See **`itertools.islice()`** for an alternate version that returns an iterator.

sorted(*iterable*, */*, ***, *key* = *None*, *reverse* = *False*)

Return a new sorted list from the items in *iterable*.

Has two optional arguments which must be specified as keyword arguments.

key specifies a function of one argument that is used to extract a comparison key from each element in *iterable* (for example, `key=str.lower`). The default value is `None` (compare the elements directly).

reverse is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

Use **`functools.cmp_to_key()`** to convert an old-style *cmp* function to a *key* function.

The built-in **`sorted()`** function is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

The sort algorithm uses only `<` comparisons between items. While defining an **`__lt__()`** method will suffice for sorting, **PEP 8** [https://peps.python.org/pep-0008/] recommends that all six rich comparisons be implemented. This will help avoid bugs when using the same data with other ordering tools such as **`max()`** that rely on a different underlying method. Implementing all six comparisons also helps avoid confusion for mixed type comparisons which can call reflected the **`__gt__()`** method.

For sorting examples and a brief sorting tutorial, see Sorting HOW TO.

@staticmethod

Transform a method into a static method.

A static method does not receive an implicit first argument. To declare a static method, use this idiom:

```
class C:
    @staticmethod
    def f(arg1, arg2, ...): ...
```

The `@staticmethod` form is a function decorator – see Function definitions for details.

A static method can be called either on the class (such as `C.f()`) or on an instance (such as `C().f()`). Moreover, they can be called as regular functions (such as `f()`).

Static methods in Python are similar to those found in Java or C++. Also, see **`classmethod()`** for a variant that is useful for creating alternate class constructors.

Like all decorators, it is also possible to call `staticmethod` as a regular function and do something with its result. This is needed in some cases where you need a reference to a function from a class body and you want to avoid the automatic transformation to instance method. For these cases, use this idiom:

```
def regular_function():
    ...

class C:
    method = staticmethod(regular_function)
```

For more information on static methods, see The standard type hierarchy.

Changed in version 3.10: Static methods now inherit the method attributes (`__module__`, `__name__`, `__qualname__`, `__doc__` and `__annotations__`), have a new `__wrapped__` attribute, and are now callable as regular functions.

class str(*object=''*)
class str(*object=b''*, *encoding='utf-8'*, *errors='strict'*)

Return a **`str`** version of *object*. See **`str()`** for details.

`str` is the built-in string class. For general information about strings, see Text Sequence Type — str.

sum(*iterable*, */*, *start=0*)

Sums *start* and the items of an *iterable* from left to right and returns the total. The *iterable*'s items are normally numbers, and the start value is not allowed to be a string.

For some use cases, there are good alternatives to **`sum()`**.

The preferred, fast way to concatenate a sequence of strings is by calling `''.join(sequence)`. To add floating point values with extended precision, see **`math.fsum()`**. To concatenate a series of iterables, consider using **`itertools.chain()`**.

Changed in version 3.8: The *start* parameter can be specified as a keyword argument.

class super

class super(*type*, *object_or_type*=*None*)

Return a proxy object that delegates method calls to a parent or sibling class of *type*. This is useful for accessing inherited methods that have been overridden in a class.

The *object_or_type* determines the method resolution order to be searched. The search starts from the class right after the *type*.

For example, if **`__mro__`** of *object_or_type* is `D -> B -> C -> A -> object` and the value of *type* is `B`, then **`super()`** searches `C -> A -> object`.

The **`__mro__`** attribute of the *object_or_type* lists the method resolution search order used by both **`getattr()`** and **`super()`**. The attribute is dynamic and can change whenever the inheritance hierarchy is updated.

If the second argument is omitted, the super object returned is unbound. If the second argument is an object, `isinstance(obj, type)` must be true. If the second argument is a type, `issubclass(type2, type)` must be true (this is useful for classmethods).

There are two typical use cases for *super*. In a class hierarchy with single inheritance, *super* can be used to refer to parent classes without naming them explicitly, thus making the code more maintainable. This use closely parallels the use of *super* in other programming languages.

The second use case is to support cooperative multiple

inheritance in a dynamic execution environment. This use case is unique to Python and is not found in statically compiled languages or languages that only support single inheritance. This makes it possible to implement “diamond diagrams” where multiple base classes implement the same method. Good design dictates that such implementations have the same calling signature in every case (because the order of calls is determined at runtime, because that order adapts to changes in the class hierarchy, and because that order can include sibling classes that are unknown prior to runtime).

For both use cases, a typical superclass call looks like this:

```
class C(B):
    def method(self, arg):
        super().method(arg)     # This does the same
                                # super(C, self).met
```

In addition to method lookups, **`super()`** also works for attribute lookups. One possible use case for this is calling descriptors in a parent or sibling class.

Note that **`super()`** is implemented as part of the binding process for explicit dotted attribute lookups such as `super().__getitem__(name)`. It does so by implementing its own **`__getattribute__()`** method for searching classes in a predictable order that supports cooperative multiple inheritance. Accordingly, **`super()`** is undefined for implicit lookups using statements or operators such as `super()[name]`.

Also note that, aside from the zero argument form, **`super()`** is not limited to use inside methods. The two argument form specifies the arguments exactly and makes the appropriate references. The zero argument form only works inside a class definition, as the compiler fills in the necessary details to correctly retrieve the class being defined, as well as accessing the current instance for ordinary methods.

For practical suggestions on how to design cooperative classes using **`super()`**, see guide to using super() [https://

rhettinger.wordpress.com/2011/05/26/super-considered-super/].

class tuple
class tuple(*iterable*)

Rather than being a function, **tuple** is actually an immutable sequence type, as documented in Tuples and Sequence Types — list, tuple, range.

class type(*object*)
class type(*name*, *bases*, *dict*, ***kwds*)

With one argument, return the type of an *object*. The return value is a type object and generally the same object as returned by **object.__class__**.

The **isinstance()** built-in function is recommended for testing the type of an object, because it takes subclasses into account.

With three arguments, return a new type object. This is essentially a dynamic form of the **class** statement. The *name* string is the class name and becomes the **__name__** attribute. The *bases* tuple contains the base classes and becomes the **__bases__** attribute; if empty, **object**, the ultimate base of all classes, is added. The *dict* dictionary contains attribute and method definitions for the class body; it may be copied or wrapped before becoming the **__dict__** attribute. The following two statements create identical **type** objects:

```
>>> class X:
...     a = 1
...
>>> X = type('X', (), dict(a=1))
```

See also Type Objects.

Keyword arguments provided to the three argument form are passed to the appropriate metaclass machinery (usually **__init_subclass__()**) in the same way that keywords in

a class definition (besides *metaclass*) would.

See also Customizing class creation.

Changed in version 3.6: Subclasses of **type** which don't override `type.__new__` may no longer use the one-argument form to get the type of an object.

vars()
vars(*object*)

Return the **__dict__** attribute for a module, class, instance, or any other object with a **__dict__** attribute.

Objects such as modules and instances have an updateable **__dict__** attribute; however, other objects may have write restrictions on their **__dict__** attributes (for example, classes use a **types.MappingProxyType** to prevent direct dictionary updates).

Without an argument, **vars()** acts like **locals()**. Note, the locals dictionary is only useful for reads since updates to the locals dictionary are ignored.

A **TypeError** exception is raised if an object is specified but it doesn't have a **__dict__** attribute (for example, if its class defines the **__slots__** attribute).

zip(**iterables*, *strict=False*)

Iterate over several iterables in parallel, producing tuples with an item from each one.

Example:

```
>>> for item in zip([1, 2, 3], ['sugar', 'spice', '
...     print(item)
...
(1, 'sugar')
(2, 'spice')
(3, 'everything nice')
```

More formally: **`zip()`** returns an iterator of tuples, where the *i*-th tuple contains the *i*-th element from each of the argument iterables.

Another way to think of **`zip()`** is that it turns rows into columns, and columns into rows. This is similar to transposing a matrix [https://en.wikipedia.org/wiki/Transpose].

`zip()` is lazy: The elements won't be processed until the iterable is iterated on, e.g. by a **`for`** loop or by wrapping in a **`list`**.

One thing to consider is that the iterables passed to **`zip()`** could have different lengths; sometimes by design, and sometimes because of a bug in the code that prepared these iterables. Python offers three different approaches to dealing with this issue:

- By default, **`zip()`** stops when the shortest iterable is exhausted. It will ignore the remaining items in the longer iterables, cutting off the result to the length of the shortest iterable:

  ```
  >>> list(zip(range(3), ['fee', 'fi', 'fo', 'fum
  [(0, 'fee'), (1, 'fi'), (2, 'fo')]
  ```

- **`zip()`** is often used in cases where the iterables are assumed to be of equal length. In such cases, it's recommended to use the `strict=True` option. Its output is the same as regular **`zip()`**:

  ```
  >>> list(zip(('a', 'b', 'c'), (1, 2, 3), strict
  [('a', 1), ('b', 2), ('c', 3)]
  ```

  Unlike the default behavior, it checks that the lengths of iterables are identical, raising a **`ValueError`** if they aren't:

  ```
  >>> list(zip(range(3), ['fee', 'fi', 'fo', 'fum
  Traceback (most recent call last):
    ...
  ```

```
ValueError: zip() argument 2 is longer than arg
```

Without the `strict=True` argument, any bug that results in iterables of different lengths will be silenced, possibly manifesting as a hard-to-find bug in another part of the program.

- Shorter iterables can be padded with a constant value to make all the iterables have the same length. This is done by **`itertools.zip_longest()`**.

Edge cases: With a single iterable argument, **`zip()`** returns an iterator of 1-tuples. With no arguments, it returns an empty iterator.

Tips and tricks:

- The left-to-right evaluation order of the iterables is guaranteed. This makes possible an idiom for clustering a data series into n-length groups using `zip(*[iter(s)]*n, strict=True)`. This repeats the *same* iterator `n` times so that each output tuple has the result of `n` calls to the iterator. This has the effect of dividing the input into n-length chunks.

- **`zip()`** in conjunction with the `*` operator can be used to unzip a list:

```
>>> x = [1, 2, 3]
>>> y = [4, 5, 6]
>>> list(zip(x, y))
[(1, 4), (2, 5), (3, 6)]
>>> x2, y2 = zip(*zip(x, y))
>>> x == list(x2) and y == list(y2)
True
```

Changed in version 3.10: Added the `strict` argument.

import(*name*, *globals*=*None*, *locals*=*None*, *fromlist*=*()*, *level*=*0*)

Note

This is an advanced function that is not needed in everyday Python programming, unlike **`importlib.import_module()`**.

This function is invoked by the **`import`** statement. It can be replaced (by importing the **`builtins`** module and assigning to `builtins.__import__`) in order to change semantics of the **`import`** statement, but doing so is **strongly** discouraged as it is usually simpler to use import hooks (see **PEP 302** [https://peps.python.org/pep-0302/]) to attain the same goals and does not cause issues with code which assumes the default import implementation is in use. Direct use of **`__import__()`** is also discouraged in favor of **`importlib.import_module()`**.

The function imports the module *name*, potentially using the given *globals* and *locals* to determine how to interpret the name in a package context. The *fromlist* gives the names of objects or submodules that should be imported from the module given by *name*. The standard implementation does not use its *locals* argument at all and uses its *globals* only to determine the package context of the **`import`** statement.

level specifies whether to use absolute or relative imports. `0` (the default) means only perform absolute imports. Positive values for *level* indicate the number of parent directories to search relative to the directory of the module calling **`__import__()`** (see **PEP 328** [https://peps.python.org/pep-0328/] for the details).

When the *name* variable is of the form `package.module`, normally, the top-level package (the name up till the first dot) is returned, *not* the module named by *name*. However, when a non-empty *fromlist* argument is given, the module named by *name* is returned.

For example, the statement `import spam` results in bytecode resembling the following code:

```
spam = __import__('spam', globals(), locals(), [],
```

The statement `import spam.ham` results in this call:

```
spam = __import__('spam.ham', globals(), locals(),
```

Note how **`__import__()`** returns the toplevel module here because this is the object that is bound to a name by the **`import`** statement.

On the other hand, the statement `from spam.ham import eggs, sausage as saus` results in

```
_temp = __import__('spam.ham', globals(), locals(),
eggs = _temp.eggs
saus = _temp.sausage
```

Here, the `spam.ham` module is returned from **`__import__()`**. From this object, the names to import are retrieved and assigned to their respective names.

If you simply want to import a module (potentially within a package) by name, use **`importlib.import_module()`**.

Changed in version 3.3: Negative values for *level* are no longer supported (which also changes the default value to 0).

Changed in version 3.9: When the command line options **`-E`** or **`-I`** are being used, the environment variable **`PYTHONCASEOK`** is now ignored.

Footnotes

1

Note that the parser only accepts the Unix-style end of line convention. If you are reading the code from a file, make sure to use newline conversion mode to convert Windows or Mac-style newlines.

Built-in Constants

A small number of constants live in the built-in namespace. They are:

False

The false value of the **bool** type. Assignments to `False` are illegal and raise a **SyntaxError**.

True

The true value of the **bool** type. Assignments to `True` are illegal and raise a **SyntaxError**.

None

An object frequently used to represent the absence of a value, as when default arguments are not passed to a function. Assignments to `None` are illegal and raise a **SyntaxError**. `None` is the sole instance of the **NoneType** type.

NotImplemented

A special value which should be returned by the binary special methods (e.g. **__eq__()**, **__lt__()**, **__add__()**, **__rsub__()**, etc.) to indicate that the operation is not implemented with respect to the other type; may be returned by the in-place binary special methods (e.g. **__imul__()**, **__iand__()**, etc.) for the same purpose. It should not be evaluated in a boolean context. `NotImplemented` is the sole instance of the **types.NotImplementedType** type.

Note

When a binary (or in-place) method returns `NotImplemented` the interpreter will try the reflected operation on the other type (or some other fallback, depending on the operator). If all attempts return

`NotImplemented`, the interpreter will raise an appropriate exception. Incorrectly returning `NotImplemented` will result in a misleading error message or the `NotImplemented` value being returned to Python code.

See Implementing the arithmetic operations for examples.

Note

`NotImplementedError` and `NotImplemented` are not interchangeable, even though they have similar names and purposes. See **`NotImplementedError`** for details on when to use it.

Changed in version 3.9: Evaluating `NotImplemented` in a boolean context is deprecated. While it currently evaluates as true, it will emit a **`DeprecationWarning`**. It will raise a **`TypeError`** in a future version of Python.

Ellipsis

The same as the ellipsis literal "`...`". Special value used mostly in conjunction with extended slicing syntax for user-defined container data types. `Ellipsis` is the sole instance of the **`types.EllipsisType`** type.

debug

This constant is true if Python was not started with an **`-O`** option. See also the **`assert`** statement.

Note

The names **`None`**, **`False`**, **`True`** and **`__debug__`** cannot be reassigned (assignments to them, even as an attribute name, raise **`SyntaxError`**), so they can be considered "true" constants.

Constants added by the `site` module

The `site` module (which is imported automatically during startup, except if the `-S` command-line option is given) adds several constants to the built-in namespace. They are useful for the interactive interpreter shell and should not be used in programs.

quit(*code*=*None*)
exit(*code*=*None*)

Objects that when printed, print a message like “Use quit() or Ctrl-D (i.e. EOF) to exit”, and when called, raise `SystemExit` with the specified exit code.

copyright
credits

Objects that when printed or called, print the text of copyright or credits, respectively.

license

Object that when printed, prints the message “Type license() to see the full license text”, and when called, displays the full license text in a pager-like fashion (one screen at a time).

Built-in Types

The following sections describe the standard types that are built into the interpreter.

The principal built-in types are numerics, sequences, mappings, classes, instances and exceptions.

Some collection classes are mutable. The methods that add, subtract, or rearrange their members in place, and don't return a specific item, never return the collection instance itself but `None`.

Some operations are supported by several object types; in particular, practically all objects can be compared for equality, tested for truth value, and converted to a string (with the **`repr()`** function or the slightly different **`str()`** function). The latter function is implicitly used when an object is written by the **`print()`** function.

Truth Value Testing

Any object can be tested for truth value, for use in an **`if`** or **`while`** condition or as operand of the Boolean operations below.

By default, an object is considered true unless its class defines either a **`__bool__()`** method that returns `False` or a **`__len__()`** method that returns zero, when called with the object. 1 Here are most of the built-in objects considered false:

- constants defined to be false: `None` and `False`.
- zero of any numeric type: `0`, `0.0`, `0j`, `Decimal(0)`, `Fraction(0, 1)`
- empty sequences and collections: `''`, `()`, `[]`, `{}`, `set()`, `range(0)`

Operations and built-in functions that have a Boolean result always return `0` or `False` for false and `1` or `True` for true, unless otherwise stated. (Important exception: the Boolean operations `or` and `and` always return one of their operands.)

Boolean Operations — `and, or, not`

These are the Boolean operations, ordered by ascending priority:

Operation	Result	Notes
`x or y`	if *x* is false, then *y*, else *x*	(1)
`x and y`	if *x* is false, then *x*, else *y*	(2)
`not x`	if *x* is false, then `True`, else `False`	(3)

Notes:

1. This is a short-circuit operator, so it only evaluates the second argument if the first one is false.
2. This is a short-circuit operator, so it only evaluates the second argument if the first one is true.
3. `not` has a lower priority than non-Boolean operators, so `not a == b` is interpreted as `not (a == b)`, and `a == not b` is a syntax error.

Comparisons

There are eight comparison operations in Python. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily; for example, `x < y <= z` is equivalent to `x < y and y <= z`, except that *y* is evaluated only once (but in both cases *z* is not evaluated at all when `x < y` is found to be false).

This table summarizes the comparison operations:

Operation	Meaning
`<`	strictly less than
`<=`	less than or equal
`>`	strictly greater than
`>=`	greater than or equal

`==`	equal
`!=`	not equal
`is`	object identity
`is not`	negated object identity

Objects of different types, except different numeric types, never compare equal. The `==` operator is always defined but for some object types (for example, class objects) is equivalent to `is`. The `<`, `<=`, `>` and `>=` operators are only defined where they make sense; for example, they raise a `TypeError` exception when one of the arguments is a complex number.

Non-identical instances of a class normally compare as non-equal unless the class defines the `__eq__()` method.

Instances of a class cannot be ordered with respect to other instances of the same class, or other types of object, unless the class defines enough of the methods `__lt__()`, `__le__()`, `__gt__()`, and `__ge__()` (in general, `__lt__()` and `__eq__()` are sufficient, if you want the conventional meanings of the comparison operators).

The behavior of the `is` and `is not` operators cannot be customized; also they can be applied to any two objects and never raise an exception.

Two more operations with the same syntactic priority, `in` and `not in`, are supported by types that are iterable or implement the `__contains__()` method.

Numeric Types — `int`, `float`, `complex`

There are three distinct numeric types: *integers*, *floating point numbers*, and *complex numbers*. In addition, Booleans are a subtype of integers. Integers have unlimited precision. Floating point numbers are usually implemented using double in C; information about the precision and internal representation of floating point numbers for the machine on which your program is running is available in `sys.float_info`. Complex numbers have a real and imaginary part, which are each a floating point number. To extract

these parts from a complex number *z*, use `z.real` and `z.imag`. (The standard library includes the additional numeric types **`fractions.Fraction`**, for rationals, and **`decimal.Decimal`**, for floating-point numbers with user-definable precision.)

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex, octal and binary numbers) yield integers. Numeric literals containing a decimal point or an exponent sign yield floating point numbers. Appending `'j'` or `'J'` to a numeric literal yields an imaginary number (a complex number with a zero real part) which you can add to an integer or float to get a complex number with real and imaginary parts.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the "narrower" type is widened to that of the other, where integer is narrower than floating point, which is narrower than complex. A comparison between numbers of different types behaves as though the exact values of those numbers were being compared. [2]

The constructors **`int()`**, **`float()`**, and **`complex()`** can be used to produce numbers of a specific type.

All numeric types (except complex) support the following operations (for priorities of the operations, see Operator precedence):

Operation	Result	Notes	Full documentation
`x + y`	sum of *x* and *y*		
`x - y`	difference of *x* and *y*		
`x * y`	product of *x* and *y*		
`x / y`	quotient of *x* and *y*		
`x // y`	floored quotient of *x* and *y*	(2)	
`x % y`	remainder of `x / y`	(2)	
`-x`	*x* negated		
`+x`	*x* unchanged		
`abs()``(x)`	absolute value or magnitude of *x*		
`int()``(x)`	*x* converted to integer	(3)(6)	
`float()``(x)`	*x* converted to floating point	(4)(6)	
`complex()``(re, im)`	complex number with real part *re*, imaginary part *im*. *im*	(6)	

defaults to zero.

Operation	Result
`conjugate()`	conjugate of the complex number c
`divmod(x, y)`	`(x // y, x % y)`
`pow(x, y)`	x to the power y
`x ** y`	x to the power y

Notes:

1. Also referred to as integer division. The resultant value is a whole integer, though the result's type is not necessarily int. The result is always rounded towards minus infinity: `1//2` is `0`, `(-1)//2` is `-1`, `1//(-2)` is `-1`, and `(-1)//(-2)` is `0`.

2. Not for complex numbers. Instead convert to floats using **`abs()`** if appropriate.

3. Conversion from floating point to integer may round or truncate as in C; see functions **`math.floor()`** and **`math.ceil()`** for well-defined conversions.

4. float also accepts the strings "nan" and "inf" with an optional prefix "+" or "-" for Not a Number (NaN) and positive or negative infinity.

5. Python defines `pow(0, 0)` and `0 ** 0` to be `1`, as is common for programming languages.

6. The numeric literals accepted include the digits `0` to `9` or any Unicode equivalent (code points with the `Nd` property).

   See https://www.unicode.org/Public/14.0.0/ucd/extracted/DerivedNumericType.txt for a complete list of code points with the `Nd` property.

All **`numbers.Real`** types (**`int`** and **`float`**) also include the following operations:

Operation	Result
`math.trunc(x)`	x truncated to `Integral`
`round(x[, n])`	x rounded to n digits, rounding half to even. If n is omitted, it defaults to 0.
`math.floor(x)`	the greatest `Integral` $<= x$

the least `Integral` $>= x$	

For additional numeric operations see the `math` and `cmath` modules.

Bitwise Operations on Integer Types

Bitwise operations only make sense for integers. The result of bitwise operations is calculated as though carried out in two's complement with an infinite number of sign bits.

The priorities of the binary bitwise operations are all lower than the numeric operations and higher than the comparisons; the unary operation `~` has the same priority as the other unary numeric operations (`+` and `-`).

This table lists the bitwise operations sorted in ascending priority:

Operation	Result	Notes
$x \mid y$	bitwise *or* of x and y	(4)
$x \hat{} y$	bitwise *exclusive or* of x and y	(4)
$x \& y$	bitwise *and* of x and y	(4)
$x << n$	x shifted left by n bits	(1)(2)
$x >> n$	x shifted right by n bits	(1)(3)
$\sim x$	the bits of x inverted	

Notes:

1. Negative shift counts are illegal and cause a `ValueError` to be raised.
2. A left shift by *n* bits is equivalent to multiplication by `pow(2, n)`.
3. A right shift by *n* bits is equivalent to floor division by `pow(2, n)`.
4. Performing these calculations with at least one extra sign extension bit in a finite two's complement representation (a working bit-width of `1 + max(x.bit_length(), y.bit_length())` or more) is sufficient to get the same result as if there were an infinite number of sign bits.

Additional Methods on Integer Types

The int type implements the **numbers.Integral** abstract base class. In addition, it provides a few more methods:

int.bit_length()

Return the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros:

```
>>> n = -37
>>> bin(n)
'-0b100101'
>>> n.bit_length()
6
```

More precisely, if `x` is nonzero, then `x.bit_length()` is the unique positive integer `k` such that `2**(k-1) <= abs(x) < 2**k`. Equivalently, when `abs(x)` is small enough to have a correctly rounded logarithm, then `k = 1 + int(log(abs(x), 2))`. If `x` is zero, then `x.bit_length()` returns `0`.

Equivalent to:

```
def bit_length(self):
    s = bin(self)       # binary representation:  b
    s = s.lstrip('-0b') # remove leading zeros and
    return len(s)       # len('100101') --> 6
```

New in version 3.1.

int.bit_count()

Return the number of ones in the binary representation of the absolute value of the integer. This is also known as the population count. Example:

```
>>> n = 19
>>> bin(n)
'0b10011'
>>> n.bit_count()
3
>>> (-n).bit_count()
```

```
3
```

Equivalent to:

```
def bit_count(self):
    return bin(self).count("1")
```

New in version 3.10.

int.to_bytes(*length=1*, *byteorder='big'*, ***, *signed=False*)

Return an array of bytes representing an integer.

```
>>> (1024).to_bytes(2, byteorder='big')
b'\x04\x00'
>>> (1024).to_bytes(10, byteorder='big')
b'\x00\x00\x00\x00\x00\x00\x00\x00\x04\x00'
>>> (-1024).to_bytes(10, byteorder='big', signed=Tr
b'\xff\xff\xff\xff\xff\xff\xff\xff\xfc\x00'
>>> x = 1000
>>> x.to_bytes((x.bit_length() + 7) // 8, byteorder
b'\xe8\x03'
```

The integer is represented using *length* bytes, and defaults to 1. An **`OverflowError`** is raised if the integer is not representable with the given number of bytes.

The *byteorder* argument determines the byte order used to represent the integer, and defaults to `"big"`. If *byteorder* is `"big"`, the most significant byte is at the beginning of the byte array. If *byteorder* is `"little"`, the most significant byte is at the end of the byte array.

The *signed* argument determines whether two's complement is used to represent the integer. If *signed* is `False` and a negative integer is given, an **`OverflowError`** is raised. The default value for *signed* is `False`.

The default values can be used to conveniently turn an integer into a single byte object. However, when using the default arguments, don't try to convert a value greater than

255 or you'll get an **OverflowError**:

```
>>> (65).to_bytes()
b'A'
```

Equivalent to:

```
def to_bytes(n, length=1, byteorder='big', signed=F
    if byteorder == 'little':
        order = range(length)
    elif byteorder == 'big':
        order = reversed(range(length))
    else:
        raise ValueError("byteorder must be either

    return bytes((n >> i*8) & 0xff for i in order)
```

New in version 3.2.

Changed in version 3.11: Added default argument values for `length` and `byteorder`.

classmethod int.from_bytes(*bytes*, *byteorder='big'*, ***, *signed=False*)

Return the integer represented by the given array of bytes.

```
>>> int.from_bytes(b'\x00\x10', byteorder='big')
16
>>> int.from_bytes(b'\x00\x10', byteorder='little')
4096
>>> int.from_bytes(b'\xfc\x00', byteorder='big', si
-1024
>>> int.from_bytes(b'\xfc\x00', byteorder='big', si
64512
>>> int.from_bytes([255, 0, 0], byteorder='big')
16711680
```

The argument *bytes* must either be a bytes-like object or an iterable producing bytes.

The *byteorder* argument determines the byte order used to

represent the integer, and defaults to `"big"`. If *byteorder* is `"big"`, the most significant byte is at the beginning of the byte array. If *byteorder* is `"little"`, the most significant byte is at the end of the byte array. To request the native byte order of the host system, use **`sys.byteorder`** as the byte order value.

The *signed* argument indicates whether two's complement is used to represent the integer.

Equivalent to:

```
def from_bytes(bytes, byteorder='big', signed=False
    if byteorder == 'little':
        little_ordered = list(bytes)
    elif byteorder == 'big':
        little_ordered = list(reversed(bytes))
    else:
        raise ValueError("byteorder must be either

    n = sum(b << i*8 for i, b in enumerate(little_o
    if signed and little_ordered and (little_ordere
        n -= 1 << 8*len(little_ordered)

    return n
```

New in version 3.2.

Changed in version 3.11: Added default argument value for `byteorder`.

int.as_integer_ratio()

Return a pair of integers whose ratio is exactly equal to the original integer and with a positive denominator. The integer ratio of integers (whole numbers) is always the integer as the numerator and `1` as the denominator.

New in version 3.8.

Additional Methods on Float

The float type implements the **numbers.Real** abstract base class. float also has the following additional methods.

float.as_integer_ratio()

Return a pair of integers whose ratio is exactly equal to the original float and with a positive denominator. Raises **OverflowError** on infinities and a **ValueError** on NaNs.

float.is_integer()

Return `True` if the float instance is finite with integral value, and `False` otherwise:

```
>>> (-2.0).is_integer()
True
>>> (3.2).is_integer()
False
```

Two methods support conversion to and from hexadecimal strings. Since Python's floats are stored internally as binary numbers, converting a float to or from a *decimal* string usually involves a small rounding error. In contrast, hexadecimal strings allow exact representation and specification of floating-point numbers. This can be useful when debugging, and in numerical work.

float.hex()

Return a representation of a floating-point number as a hexadecimal string. For finite floating-point numbers, this representation will always include a leading `0x` and a trailing `p` and exponent.

classmethod float.fromhex(*s*)

Class method to return the float represented by a hexadecimal string *s*. The string *s* may have leading and trailing whitespace.

Note that **float.hex()** is an instance method, while **float.fromhex()** is a class method.

A hexadecimal string takes the form:

```
[sign] ['0x'] integer ['.' fraction] ['p' exponent]
```

where the optional `sign` may by either `+` or `-`, `integer` and `fraction` are strings of hexadecimal digits, and `exponent` is a decimal integer with an optional leading sign. Case is not significant, and there must be at least one hexadecimal digit in either the integer or the fraction. This syntax is similar to the syntax specified in section 6.4.4.2 of the C99 standard, and also to the syntax used in Java 1.5 onwards. In particular, the output of **`float.hex()`** is usable as a hexadecimal floating-point literal in C or Java code, and hexadecimal strings produced by C's `%a` format character or Java's `Double.toHexString` are accepted by **`float.fromhex()`**.

Note that the exponent is written in decimal rather than hexadecimal, and that it gives the power of 2 by which to multiply the coefficient. For example, the hexadecimal string `0x3.a7p10` represents the floating-point number `(3 + 10./16 + 7./16**2) * 2.0**10`, or `3740.0`:

```
>>> float.fromhex('0x3.a7p10')
3740.0
```

Applying the reverse conversion to `3740.0` gives a different hexadecimal string representing the same number:

```
>>> float.hex(3740.0)
'0x1.d380000000000p+11'
```

Hashing of numeric types

For numbers `x` and `y`, possibly of different types, it's a requirement that `hash(x) == hash(y)` whenever `x == y` (see the **`__hash__()`** method documentation for more details). For ease of implementation and efficiency across a variety of numeric types (including **`int`**, **`float`**, **`decimal.Decimal`** and **`fractions.Fraction`**) Python's hash for numeric types is based on a single mathematical function that's defined for any rational number, and hence applies to all instances of **`int`** and

fractions.Fraction, and all finite instances of **float** and **decimal.Decimal**. Essentially, this function is given by reduction modulo `P` for a fixed prime `P`. The value of `P` is made available to Python as the **modulus** attribute of **sys.hash_info**.

CPython implementation detail: Currently, the prime used is `P = 2**31 - 1` on machines with 32-bit C longs and `P = 2**61 - 1` on machines with 64-bit C longs.

Here are the rules in detail:

- If `x = m / n` is a nonnegative rational number and `n` is not divisible by `P`, define `hash(x)` as `m * invmod(n, P) % P`, where `invmod(n, P)` gives the inverse of `n` modulo `P`.
- If `x = m / n` is a nonnegative rational number and `n` is divisible by `P` (but `m` is not) then `n` has no inverse modulo `P` and the rule above doesn't apply; in this case define `hash(x)` to be the constant value `sys.hash_info.inf`.
- If `x = m / n` is a negative rational number define `hash(x)` as `-hash(-x)`. If the resulting hash is `-1`, replace it with `-2`.
- The particular values `sys.hash_info.inf` and `-sys.hash_info.inf` are used as hash values for positive infinity or negative infinity (respectively).
- For a **complex** number `z`, the hash values of the real and imaginary parts are combined by computing `hash(z.real) + sys.hash_info.imag * hash(z.imag)`, reduced modulo `2**sys.hash_info.width` so that it lies in `range(-2**(sys.hash_info.width - 1), 2**(sys.hash_info.width - 1))`. Again, if the result is `-1`, it's replaced with `-2`.

To clarify the above rules, here's some example Python code, equivalent to the built-in hash, for computing the hash of a rational number, **float**, or **complex**:

```
import sys, math

def hash_fraction(m, n):
    """Compute the hash of a rational number m / n.
```

```
    Assumes m and n are integers, with n positive.
    Equivalent to hash(fractions.Fraction(m, n)).

    """
    P = sys.hash_info.modulus
    # Remove common factors of P.  (Unnecessary if m and
    while m % P == n % P == 0:
        m, n = m // P, n // P

    if n % P == 0:
        hash_value = sys.hash_info.inf
    else:
        # Fermat's Little Theorem: pow(n, P-1, P) is 1,
        # pow(n, P-2, P) gives the inverse of n modulo P
        hash_value = (abs(m) % P) * pow(n, P - 2, P) % P
    if m < 0:
        hash_value = -hash_value
    if hash_value == -1:
        hash_value = -2
    return hash_value

def hash_float(x):
    """Compute the hash of a float x."""

    if math.isnan(x):
        return object.__hash__(x)
    elif math.isinf(x):
        return sys.hash_info.inf if x > 0 else -sys.hash
    else:
        return hash_fraction(*x.as_integer_ratio())

def hash_complex(z):
    """Compute the hash of a complex number z."""

    hash_value = hash_float(z.real) + sys.hash_info.imag
    # do a signed reduction modulo 2**sys.hash_info.widt
    M = 2**(sys.hash_info.width - 1)
    hash_value = (hash_value & (M - 1)) - (hash_value &
```

```
    if hash_value == -1:
        hash_value = -2
    return hash_value
```

Iterator Types

Python supports a concept of iteration over containers. This is implemented using two distinct methods; these are used to allow user-defined classes to support iteration. Sequences, described below in more detail, always support the iteration methods.

One method needs to be defined for container objects to provide iterable support:

container.__iter__()

> Return an iterator object. The object is required to support the iterator protocol described below. If a container supports different types of iteration, additional methods can be provided to specifically request iterators for those iteration types. (An example of an object supporting multiple forms of iteration would be a tree structure which supports both breadth-first and depth-first traversal.) This method corresponds to the **`tp_iter`** slot of the type structure for Python objects in the Python/C API.

The iterator objects themselves are required to support the following two methods, which together form the *iterator protocol*:

iterator.__iter__()

> Return the iterator object itself. This is required to allow both containers and iterators to be used with the **`for`** and **`in`** statements. This method corresponds to the **`tp_iter`** slot of the type structure for Python objects in the Python/C API.

iterator.__next__()

> Return the next item from the iterator. If there are no further items, raise the **`StopIteration`** exception. This method corresponds to the **`tp_iternext`** slot of the type structure

for Python objects in the Python/C API.

Python defines several iterator objects to support iteration over general and specific sequence types, dictionaries, and other more specialized forms. The specific types are not important beyond their implementation of the iterator protocol.

Once an iterator's **`__next__()`** method raises **`StopIteration`**, it must continue to do so on subsequent calls. Implementations that do not obey this property are deemed broken.

Generator Types

Python's generators provide a convenient way to implement the iterator protocol. If a container object's **`__iter__()`** method is implemented as a generator, it will automatically return an iterator object (technically, a generator object) supplying the **`__iter__()`** and **`__next__()`** methods. More information about generators can be found in the documentation for the yield expression.

Sequence Types — **`list`**, **`tuple`**, **`range`**

There are three basic sequence types: lists, tuples, and range objects. Additional sequence types tailored for processing of binary data and text strings are described in dedicated sections.

Common Sequence Operations

The operations in the following table are supported by most sequence types, both mutable and immutable. The **`collections.abc.Sequence`** ABC is provided to make it easier to correctly implement these operations on custom sequence types.

This table lists the sequence operations sorted in ascending priority. In the table, *s* and *t* are sequences of the same type, *n*, *i*, *j* and *k* are integers and *x* is an arbitrary object that meets any type and value restrictions imposed by *s*.

The `in` and `not in` operations have the same priorities as the comparison operations. The `+` (concatenation) and `*` (repetition)

operations have the same priority as the corresponding numeric operations. 3

Operation	Result	Notes
(1) `x in s`	`True` if an item of *s* is equal to *x*, else `False`	
(1) `x not in s`	`False` if an item of *s* is equal to *x*, else `True`	
(2) `s + t`	the concatenation of *s* and *t*	(6)(7)
(2) `s * n` or `n * s`	equivalent to adding *s* to itself *n* times	(2)
(3) `s[i]`	*i*th item of *s*, origin 0	(3)
(4) `s[i:j]`	slice of *s* from *i* to *j*	(3)(4)
(5) `s[i:j:k]`	slice of *s* from *i* to *j* with step *k*	(3)(5)
`len(s)`	length of *s*	
`min(s)`	smallest item of *s*	
`max(s)`	largest item of *s*	
`s.index(x[, i[, j]])`	index of the first occurrence of *x* in *s* (at or after index *i* and before index *j*)	(8)
`s.count(x)`	total number of occurrences of *x* in *s*	

Sequences of the same type also support comparisons. In particular, tuples and lists are compared lexicographically by comparing corresponding elements. This means that to compare equal, every element must compare equal and the two sequences must be of the same type and have the same length. (For full details see Comparisons in the language reference.)

Forward and reversed iterators over mutable sequences access values using an index. That index will continue to march forward (or backward) even if the underlying sequence is mutated. The iterator terminates only when an **`IndexError`** or a **`StopIteration`** is encountered (or when the index drops below zero).

Notes:

1. While the `in` and `not in` operations are used only for simple containment testing in the general case, some specialised sequences (such as **`str`**, **`bytes`** and **`bytearray`**) also use them for subsequence testing:

   ```
   >>> "gg" in "eggs"
   True
   ```

2. Values of *n* less than `0` are treated as `0` (which yields an empty sequence of the same type as *s*). Note that items in the sequence *s* are not copied; they are referenced multiple times. This often haunts new Python programmers; consider:

   ```
   >>> lists = [[]] * 3
   >>> lists
   [[], [], []]
   >>> lists[0].append(3)
   >>> lists
   [[3], [3], [3]]
   ```

   What has happened is that `[[]]` is a one-element list containing an empty list, so all three elements of `[[]] * 3` are references to this single empty list. Modifying any of the elements of `lists` modifies this single list. You can create a list of different lists this way:

   ```
   >>> lists = [[] for i in range(3)]
   >>> lists[0].append(3)
   >>> lists[1].append(5)
   >>> lists[2].append(7)
   >>> lists
   [[3], [5], [7]]
   ```

   Further explanation is available in the FAQ entry How do I create a multidimensional list?.

3. If *i* or *j* is negative, the index is relative to the end of sequence *s*: `len(s) + i` or `len(s) + j` is substituted. But note that `-0` is still `0`.

4. The slice of *s* from *i* to *j* is defined as the sequence of items with index *k* such that `i <= k < j`. If *i* or *j* is greater than `len(s)`, use `len(s)`. If *i* is omitted or `None`, use `0`. If *j* is omitted or `None`, use `len(s)`. If *i* is greater than or equal to *j*, the slice is empty.

5. The slice of *s* from *i* to *j* with step *k* is defined as the sequence of items with index `x = i + n*k` such that `0 <= n < (j-i)/k`. In other words, the indices are `i`, `i+k`, `i+2*k`, `i`

`+3*k` and so on, stopping when *j* is reached (but never including *j*). When *k* is positive, *i* and *j* are reduced to `len(s)` if they are greater. When *k* is negative, *i* and *j* are reduced to `len(s) - 1` if they are greater. If *i* or *j* are omitted or `None`, they become "end" values (which end depends on the sign of *k*). Note, *k* cannot be zero. If *k* is `None`, it is treated like `1`.

6. Concatenating immutable sequences always results in a new object. This means that building up a sequence by repeated concatenation will have a quadratic runtime cost in the total sequence length. To get a linear runtime cost, you must switch to one of the alternatives below:

    - if concatenating **`str`** objects, you can build a list and use **`str.join()`** at the end or else write to an **`io.StringIO`** instance and retrieve its value when complete
    - if concatenating **`bytes`** objects, you can similarly use **`bytes.join()`** or **`io.BytesIO`**, or you can do in-place concatenation with a **`bytearray`** object. **`bytearray`** objects are mutable and have an efficient overallocation mechanism
    - if concatenating **`tuple`** objects, extend a **`list`** instead
    - for other types, investigate the relevant class documentation

11. Some sequence types (such as **`range`**) only support item sequences that follow specific patterns, and hence don't support sequence concatenation or repetition.

12. `index` raises **`ValueError`** when *x* is not found in *s*. Not all implementations support passing the additional arguments *i* and *j*. These arguments allow efficient searching of subsections of the sequence. Passing the extra arguments is roughly equivalent to using `s[i:j].index(x)`, only without copying any data and with the returned index being relative to the start of the sequence rather than the start of the slice.

Immutable Sequence Types

The only operation that immutable sequence types generally implement that is not also implemented by mutable sequence types is support for the **`hash()`** built-in.

This support allows immutable sequences, such as **`tuple`** instances, to be used as **`dict`** keys and stored in **`set`** and **`frozenset`** instances.

Attempting to hash an immutable sequence that contains unhashable values will result in **`TypeError`**.

Mutable Sequence Types

The operations in the following table are defined on mutable sequence types. The **`collections.abc.MutableSequence`** ABC is provided to make it easier to correctly implement these operations on custom sequence types.

In the table *s* is an instance of a mutable sequence type, *t* is any iterable object and *x* is an arbitrary object that meets any type and value restrictions imposed by *s* (for example, **`bytearray`** only accepts integers that meet the value restriction `0 <= x <= 255`).

Operation	Result	Notes
`s[i] = x`	item *i* of *s* is replaced by *x*	
`s[i:j] = t`	slice of *s* from *i* to *j* is replaced by the contents of the iterable *t*	
`del s[i:j]`	same as `s[i:j] = []`	
`s[i:j:k] = t`	the elements of `s[i:j:k]` are replaced by those of *t*	(1)
`del s[i:j:k]`	removes the elements of `s[i:j:k]` from the list	
`s.append(x)`	appends *x* to the end of the sequence (same as `s[len(s):len(s)] = [x]`)	
`s.clear()`	removes all items from *s* (same as `del s[:]`)	(5)
`s.copy()`	creates a shallow copy of *s* (same as `s[:]`)	(5)
`s.extend(t)` or `s += t`	extends *s* with the contents of *t* (for the most part the same as `s[len(s):len(s)] = t`)	
`s *= n`	updates *s* with its contents repeated *n* times	(6)
`s.insert(i, x)`	inserts *x* into *s* at the index given by *i* (same as `s[i:i] = [x]`)	
`s.pop()` or `s.pop(i)`	retrieves the item at *i* and also removes it from *s*	(2)

s.remove(x)	remove the first item from *s* where `s[i]` is equal to *x*
s.reverse()	reverses the items of *s* in place

Notes:

1. *t* must have the same length as the slice it is replacing.

2. The optional argument *i* defaults to `-1`, so that by default the last item is removed and returned.

3. **`remove()`** raises **`ValueError`** when *x* is not found in *s*.

4. The **`reverse()`** method modifies the sequence in place for economy of space when reversing a large sequence. To remind users that it operates by side effect, it does not return the reversed sequence.

5. **`clear()`** and **`copy()`** are included for consistency with the interfaces of mutable containers that don't support slicing operations (such as **`dict`** and **`set`**). **`copy()`** is not part of the **`collections.abc.MutableSequence`** ABC, but most concrete mutable sequence classes provide it.

   New in version 3.3: **`clear()`** and **`copy()`** methods.

6. The value *n* is an integer, or an object implementing **`__index__()`**. Zero and negative values of *n* clear the sequence. Items in the sequence are not copied; they are referenced multiple times, as explained for `s * n` under Common Sequence Operations.

Lists

Lists are mutable sequences, typically used to store collections of homogeneous items (where the precise degree of similarity will vary by application).

class list([*iterable*])

Lists may be constructed in several ways:

- Using a pair of square brackets to denote the empty list:

`[]`

- Using square brackets, separating items with commas: `[a]`, `[a, b, c]`
- Using a list comprehension: `[x for x in iterable]`
- Using the type constructor: `list()` or `list(iterable)`

The constructor builds a list whose items are the same and in the same order as *iterable*'s items. *iterable* may be either a sequence, a container that supports iteration, or an iterator object. If *iterable* is already a list, a copy is made and returned, similar to `iterable[:]`. For example, `list('abc')` returns `['a', 'b', 'c']` and `list( (1, 2, 3) )` returns `[1, 2, 3]`. If no argument is given, the constructor creates a new empty list, `[]`.

Many other operations also produce lists, including the **`sorted()`** built-in.

Lists implement all of the common and mutable sequence operations. Lists also provide the following additional method:

sort(*, *key*=*None*, *reverse*=*False*)

This method sorts the list in place, using only `<` comparisons between items. Exceptions are not suppressed - if any comparison operations fail, the entire sort operation will fail (and the list will likely be left in a partially modified state).

`sort()` accepts two arguments that can only be passed by keyword (keyword-only arguments):

key specifies a function of one argument that is used to extract a comparison key from each list element (for example, `key=str.lower`). The key corresponding to each item in the list is calculated once and then used for the entire sorting process. The default value of `None` means that list items are sorted directly without calculating a separate key value.

The **functools.cmp_to_key()** utility is available to convert a 2.x style *cmp* function to a *key* function.

reverse is a boolean value. If set to `True`, then the list elements are sorted as if each comparison were reversed.

This method modifies the sequence in place for economy of space when sorting a large sequence. To remind users that it operates by side effect, it does not return the sorted sequence (use **sorted()** to explicitly request a new sorted list instance).

The **sort()** method is guaranteed to be stable. A sort is stable if it guarantees not to change the relative order of elements that compare equal — this is helpful for sorting in multiple passes (for example, sort by department, then by salary grade).

For sorting examples and a brief sorting tutorial, see Sorting HOW TO.

CPython implementation detail: While a list is being sorted, the effect of attempting to mutate, or even inspect, the list is undefined. The C implementation of Python makes the list appear empty for the duration, and raises **ValueError** if it can detect that the list has been mutated during a sort.

Tuples

Tuples are immutable sequences, typically used to store collections of heterogeneous data (such as the 2-tuples produced by the **enumerate()** built-in). Tuples are also used for cases where an immutable sequence of homogeneous data is needed (such as allowing storage in a **set** or **dict** instance).

class tuple([*iterable*])

Tuples may be constructed in a number of ways:

- Using a pair of parentheses to denote the empty tuple: `()`
- Using a trailing comma for a singleton tuple: `a,` or `(a,)`
- Separating items with commas: `a, b, c` or `(a, b, c)`
- Using the **`tuple()`** built-in: `tuple()` or `tuple(iterable)`

The constructor builds a tuple whose items are the same and in the same order as *iterable*'s items. *iterable* may be either a sequence, a container that supports iteration, or an iterator object. If *iterable* is already a tuple, it is returned unchanged. For example, `tuple('abc')` returns `('a', 'b', 'c')` and `tuple( [1, 2, 3] )` returns `(1, 2, 3)`. If no argument is given, the constructor creates a new empty tuple, `()`.

Note that it is actually the comma which makes a tuple, not the parentheses. The parentheses are optional, except in the empty tuple case, or when they are needed to avoid syntactic ambiguity. For example, `f(a, b, c)` is a function call with three arguments, while `f((a, b, c))` is a function call with a 3-tuple as the sole argument.

Tuples implement all of the common sequence operations.

For heterogeneous collections of data where access by name is clearer than access by index, **`collections.namedtuple()`** may be a more appropriate choice than a simple tuple object.

Ranges

The **`range`** type represents an immutable sequence of numbers and is commonly used for looping a specific number of times in **`for`** loops.

class range(*stop*)
class range(*start*, *stop*[, *step*])

The arguments to the range constructor must be integers

(either built-in **`int`** or any object that implements the **`__index__()`** special method). If the *step* argument is omitted, it defaults to `1`. If the *start* argument is omitted, it defaults to `0`. If *step* is zero, **`ValueError`** is raised.

For a positive *step*, the contents of a range `r` are determined by the formula `r[i] = start + step*i` where `i >= 0` and `r[i] < stop`.

For a negative *step*, the contents of the range are still determined by the formula `r[i] = start + step*i`, but the constraints are `i >= 0` and `r[i] > stop`.

A range object will be empty if `r[0]` does not meet the value constraint. Ranges do support negative indices, but these are interpreted as indexing from the end of the sequence determined by the positive indices.

Ranges containing absolute values larger than **`sys.maxsize`** are permitted but some features (such as **`len()`**) may raise **`OverflowError`**.

Range examples:

```
>>> list(range(10))
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> list(range(1, 11))
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> list(range(0, 30, 5))
[0, 5, 10, 15, 20, 25]
>>> list(range(0, 10, 3))
[0, 3, 6, 9]
>>> list(range(0, -10, -1))
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
>>> list(range(0))
[]
>>> list(range(1, 0))
[]
```

Ranges implement all of the common sequence operations except concatenation and repetition (due to the fact that

range objects can only represent sequences that follow a strict pattern and repetition and concatenation will usually violate that pattern).

start

The value of the *start* parameter (or `0` if the parameter was not supplied)

stop

The value of the *stop* parameter

step

The value of the *step* parameter (or `1` if the parameter was not supplied)

The advantage of the **`range`** type over a regular **`list`** or **`tuple`** is that a **`range`** object will always take the same (small) amount of memory, no matter the size of the range it represents (as it only stores the `start`, `stop` and `step` values, calculating individual items and subranges as needed).

Range objects implement the **`collections.abc.Sequence`** ABC, and provide features such as containment tests, element index lookup, slicing and support for negative indices (see Sequence Types — list, tuple, range):

```
>>> r = range(0, 20, 2)
>>> r
range(0, 20, 2)
>>> 11 in r
False
>>> 10 in r
True
>>> r.index(10)
5
>>> r[5]
10
>>> r[:5]
range(0, 10, 2)
```

```
>>> r[-1]
18
```

Testing range objects for equality with `==` and `!=` compares them as sequences. That is, two range objects are considered equal if they represent the same sequence of values. (Note that two range objects that compare equal might have different **`start`**, **`stop`** and **`step`** attributes, for example `range(0) == range(2, 1, 3)` or `range(0, 3, 2) == range(0, 4, 2)`.)

Changed in version 3.2: Implement the Sequence ABC. Support slicing and negative indices. Test **`int`** objects for membership in constant time instead of iterating through all items.

Changed in version 3.3: Define '==' and '!=' to compare range objects based on the sequence of values they define (instead of comparing based on object identity).

New in version 3.3: The **`start`**, **`stop`** and **`step`** attributes.

See also

- The linspace recipe [https://code.activestate.com/recipes/579000/] shows how to implement a lazy version of range suitable for floating point applications.

Text Sequence Type — **`str`**

Textual data in Python is handled with **`str`** objects, or *strings*. Strings are immutable sequences of Unicode code points. String literals are written in a variety of ways:

- Single quotes: `'allows embedded "double" quotes'`
- Double quotes: `"allows embedded 'single' quotes"`
- Triple quoted: `'''Three single quotes'''`, `"""Three double quotes"""`

Triple quoted strings may span multiple lines - all associated whitespace will be included in the string literal.

String literals that are part of a single expression and have only whitespace between them will be implicitly converted to a single string literal. That is, `("spam " "eggs") == "spam eggs"`.

See String and Bytes literals for more about the various forms of string literal, including supported escape sequences, and the `r` ("raw") prefix that disables most escape sequence processing.

Strings may also be created from other objects using the **`str`** constructor.

Since there is no separate "character" type, indexing a string produces strings of length 1. That is, for a non-empty string *s*, `s[0] == s[0:1]`.

There is also no mutable string type, but **`str.join()`** or **`io.StringIO`** can be used to efficiently construct strings from multiple fragments.

Changed in version 3.3: For backwards compatibility with the Python 2 series, the `u` prefix is once again permitted on string literals. It has no effect on the meaning of string literals and cannot be combined with the `r` prefix.

class str(*object*='')
class str(*object*=b'', *encoding*='utf-8', *errors*='strict')

Return a string version of *object*. If *object* is not provided, returns the empty string. Otherwise, the behavior of `str()` depends on whether *encoding* or *errors* is given, as follows.

If neither *encoding* nor *errors* is given, `str(object)` returns **`type(object).__str__(object)`**, which is the "informal" or nicely printable string representation of *object*. For string objects, this is the string itself. If *object* does not have a **`__str__()`** method, then **`str()`** falls back to returning **`repr(object)`**.

If at least one of *encoding* or *errors* is given, *object* should be a bytes-like object (e.g. **`bytes`** or **`bytearray`**). In this case, if *object* is a **`bytes`** (or **`bytearray`**) object, then `str(bytes, encoding, errors)` is equivalent to

bytes.decode(encoding, errors). Otherwise, the bytes object underlying the buffer object is obtained before calling **bytes.decode()**. See Binary Sequence Types — bytes, bytearray, memoryview and Buffer Protocol for information on buffer objects.

Passing a **bytes** object to **str()** without the *encoding* or *errors* arguments falls under the first case of returning the informal string representation (see also the **-b** command-line option to Python). For example:

```
>>> str(b'Zoot!')
"b'Zoot!'"
```

For more information on the `str` class and its methods, see Text Sequence Type — str and the String Methods section below. To output formatted strings, see the Formatted string literals and Format String Syntax sections. In addition, see the Text Processing Services section.

String Methods

Strings implement all of the common sequence operations, along with the additional methods described below.

Strings also support two styles of string formatting, one providing a large degree of flexibility and customization (see **str.format()**, Format String Syntax and Custom String Formatting) and the other based on C `printf` style formatting that handles a narrower range of types and is slightly harder to use correctly, but is often faster for the cases it can handle (printf-style String Formatting).

The Text Processing Services section of the standard library covers a number of other modules that provide various text related utilities (including regular expression support in the **re** module).

str.capitalize()

Return a copy of the string with its first character capitalized and the rest lowercased.

Changed in version 3.8: The first character is now put into titlecase rather than uppercase. This means that characters like digraphs will only have their first letter capitalized, instead of the full character.

str.casefold()

Return a casefolded copy of the string. Casefolded strings may be used for caseless matching.

Casefolding is similar to lowercasing but more aggressive because it is intended to remove all case distinctions in a string. For example, the German lowercase letter `'ß'` is equivalent to `"ss"`. Since it is already lowercase, **`lower()`** would do nothing to `'ß'`; **`casefold()`** converts it to `"ss"`.

The casefolding algorithm is described in section 3.13 of the Unicode Standard.

New in version 3.3.

str.center(*width*[, *fillchar*])

Return centered in a string of length *width*. Padding is done using the specified *fillchar* (default is an ASCII space). The original string is returned if *width* is less than or equal to `len(s)`.

str.count(*sub*[, *start*[, *end*]])

Return the number of non-overlapping occurrences of substring *sub* in the range [*start*, *end*]. Optional arguments *start* and *end* are interpreted as in slice notation.

If *sub* is empty, returns the number of empty strings between characters which is the length of the string plus one.

str.encode(*encoding='utf-8'*, *errors='strict'*)

Return an encoded version of the string as a bytes object. Default encoding is `'utf-8'`. *errors* may be given to set a

different error handling scheme. The default for *errors* is `'strict'`, meaning that encoding errors raise a **`UnicodeError`**. Other possible values are `'ignore'`, `'replace'`, `'xmlcharrefreplace'`, `'backslashreplace'` and any other name registered via **`codecs.register_error()`**, see section Error Handlers. For a list of possible encodings, see section Standard Encodings.

By default, the *errors* argument is not checked for best performances, but only used at the first encoding error. Enable the Python Development Mode, or use a debug build to check *errors*.

Changed in version 3.1: Support for keyword arguments added.

Changed in version 3.9: The *errors* is now checked in development mode and in debug mode.

str.endswith(*suffix*[, *start*[, *end*]])

Return `True` if the string ends with the specified *suffix*, otherwise return `False`. *suffix* can also be a tuple of suffixes to look for. With optional *start*, test beginning at that position. With optional *end*, stop comparing at that position.

str.expandtabs(*tabsize*=*8*)

Return a copy of the string where all tab characters are replaced by one or more spaces, depending on the current column and the given tab size. Tab positions occur every *tabsize* characters (default is 8, giving tab positions at columns 0, 8, 16 and so on). To expand the string, the current column is set to zero and the string is examined character by character. If the character is a tab (`\t`), one or more space characters are inserted in the result until the current column is equal to the next tab position. (The tab character itself is not copied.) If the character is a newline (`\n`) or return (`\r`), it is copied and the current column is reset to zero. Any other character is copied unchanged and the current column is incremented by one regardless of how the character is

represented when printed.

```
>>> '01\t012\t0123\t01234'.expandtabs()
'01      012     0123    01234'
>>> '01\t012\t0123\t01234'.expandtabs(4)
'01  012 0123    01234'
```

str.find(*sub*[, *start*[, *end*]])

Return the lowest index in the string where substring *sub* is found within the slice `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` if *sub* is not found.

Note

The **`find()`** method should be used only if you need to know the position of *sub*. To check if *sub* is a substring or not, use the **`in`** operator:

```
>>> 'Py' in 'Python'
True
```

str.format(**args*, ***kwargs*)

Perform a string formatting operation. The string on which this method is called can contain literal text or replacement fields delimited by braces `{}`. Each replacement field contains either the numeric index of a positional argument, or the name of a keyword argument. Returns a copy of the string where each replacement field is replaced with the string value of the corresponding argument.

```
>>> "The sum of 1 + 2 is {0}".format(1+2)
'The sum of 1 + 2 is 3'
```

See Format String Syntax for a description of the various formatting options that can be specified in format strings.

Note

When formatting a number (**int**, **float**, **complex**, **decimal.Decimal** and subclasses) with the `n` type (ex: `'{:n}'.format(1234)`), the function temporarily sets the `LC_CTYPE` locale to the `LC_NUMERIC` locale to decode `decimal_point` and `thousands_sep` fields of **localeconv()** if they are non-ASCII or longer than 1 byte, and the `LC_NUMERIC` locale is different than the `LC_CTYPE` locale. This temporary change affects other threads.

Changed in version 3.7: When formatting a number with the `n` type, the function sets temporarily the `LC_CTYPE` locale to the `LC_NUMERIC` locale in some cases.

str.format_map(*mapping*)

Similar to `str.format(**mapping)`, except that `mapping` is used directly and not copied to a **dict**. This is useful if for example `mapping` is a dict subclass:

```
>>> class Default(dict):
...     def __missing__(self, key):
...         return key
...
>>> '{name} was born in {country}'.format_map(Defau
'Guido was born in country'
```

New in version 3.2.

str.index(*sub*[, *start*[, *end*]])

Like **find()**, but raise **ValueError** when the substring is not found.

str.isalnum()

Return `True` if all characters in the string are alphanumeric and there is at least one character, `False` otherwise. A character `c` is alphanumeric if one of the following returns `True`: `c.isalpha()`, `c.isdecimal()`, `c.isdigit()`, or `c.isnumeric()`.

str.isalpha()

Return `True` if all characters in the string are alphabetic and there is at least one character, `False` otherwise. Alphabetic characters are those characters defined in the Unicode character database as “Letter”, i.e., those with general category property being one of “Lm”, “Lt”, “Lu”, “Ll”, or “Lo”. Note that this is different from the “Alphabetic” property defined in the Unicode Standard.

str.isascii()

Return `True` if the string is empty or all characters in the string are ASCII, `False` otherwise. ASCII characters have code points in the range U+0000-U+007F.

New in version 3.7.

str.isdecimal()

Return `True` if all characters in the string are decimal characters and there is at least one character, `False` otherwise. Decimal characters are those that can be used to form numbers in base 10, e.g. U+0660, ARABIC-INDIC DIGIT ZERO. Formally a decimal character is a character in the Unicode General Category “Nd”.

str.isdigit()

Return `True` if all characters in the string are digits and there is at least one character, `False` otherwise. Digits include decimal characters and digits that need special handling, such as the compatibility superscript digits. This covers digits which cannot be used to form numbers in base 10, like the Kharosthi numbers. Formally, a digit is a character that has the property value Numeric_Type=Digit or Numeric_Type=Decimal.

str.isidentifier()

Return `True` if the string is a valid identifier according to the language definition, section Identifiers and keywords.

Call **keyword.iskeyword()** to test whether string s is a reserved identifier, such as **def** and **class**.

Example:

```
>>> from keyword import iskeyword

>>> 'hello'.isidentifier(), iskeyword('hello')
(True, False)
>>> 'def'.isidentifier(), iskeyword('def')
(True, True)
```

str.islower()

Return True if all cased characters 4 in the string are lowercase and there is at least one cased character, False otherwise.

str.isnumeric()

Return True if all characters in the string are numeric characters, and there is at least one character, False otherwise. Numeric characters include digit characters, and all characters that have the Unicode numeric value property, e.g. U+2155, VULGAR FRACTION ONE FIFTH. Formally, numeric characters are those with the property value Numeric_Type=Digit, Numeric_Type=Decimal or Numeric_Type=Numeric.

str.isprintable()

Return True if all characters in the string are printable or the string is empty, False otherwise. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when **repr()** is invoked on a string. It has no bearing on the handling of strings written to **sys.stdout** or **sys.stderr**.)

str.isspace()

Return `True` if there are only whitespace characters in the string and there is at least one character, `False` otherwise.

A character is *whitespace* if in the Unicode character database (see **`unicodedata`**), either its general category is `Zs` ("Separator, space"), or its bidirectional class is one of `WS`, `B`, or `S`.

str.istitle()

Return `True` if the string is a titlecased string and there is at least one character, for example uppercase characters may only follow uncased characters and lowercase characters only cased ones. Return `False` otherwise.

str.isupper()

Return `True` if all cased characters 4 in the string are uppercase and there is at least one cased character, `False` otherwise.

```
>>> 'BANANA'.isupper()
True
>>> 'banana'.isupper()
False
>>> 'baNana'.isupper()
False
>>> ' '.isupper()
False
```

str.join(*iterable*)

Return a string which is the concatenation of the strings in *iterable*. A **`TypeError`** will be raised if there are any non-string values in *iterable*, including **`bytes`** objects. The separator between elements is the string providing this method.

str.ljust(*width*[, *fillchar*])

Return the string left justified in a string of length *width*. Padding is done using the specified *fillchar* (default is an ASCII space). The original string is returned if *width* is less than or equal to `len(s)`.

str.lower()

Return a copy of the string with all the cased characters [4] converted to lowercase.

The lowercasing algorithm used is described in section 3.13 of the Unicode Standard.

str.lstrip([*chars*])

Return a copy of the string with leading characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a prefix; rather, all combinations of its values are stripped:

```
>>> '   spacious   '.lstrip()
'spacious   '
>>> 'www.example.com'.lstrip('cmowz.')
'example.com'
```

See **`str.removeprefix()`** for a method that will remove a single prefix string rather than all of a set of characters. For example:

```
>>> 'Arthur: three!'.lstrip('Arthur: ')
'ee!'
>>> 'Arthur: three!'.removeprefix('Arthur: ')
'three!'
```

static str.maketrans(*x*[, *y*[, *z*]])

This static method returns a translation table usable for **`str.translate()`**.

If there is only one argument, it must be a dictionary mapping Unicode ordinals (integers) or characters (strings of

length 1) to Unicode ordinals, strings (of arbitrary lengths) or `None`. Character keys will then be converted to ordinals.

If there are two arguments, they must be strings of equal length, and in the resulting dictionary, each character in x will be mapped to the character at the same position in y. If there is a third argument, it must be a string, whose characters will be mapped to `None` in the result.

str.partition(*sep*)

Split the string at the first occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.

str.removeprefix(*prefix*, */*)

If the string starts with the *prefix* string, return `string[len(prefix):]`. Otherwise, return a copy of the original string:

```
>>> 'TestHook'.removeprefix('Test')
'Hook'
>>> 'BaseTestCase'.removeprefix('Test')
'BaseTestCase'
```

New in version 3.9.

str.removesuffix(*suffix*, */*)

If the string ends with the *suffix* string and that *suffix* is not empty, return `string[:-len(suffix)]`. Otherwise, return a copy of the original string:

```
>>> 'MiscTests'.removesuffix('Tests')
'Misc'
>>> 'TmpDirMixin'.removesuffix('Tests')
'TmpDirMixin'
```

New in version 3.9.

str.replace(*old*, *new*[, *count*])

Return a copy of the string with all occurrences of substring *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

str.rfind(*sub*[, *start*[, *end*]])

Return the highest index in the string where substring *sub* is found, such that *sub* is contained within `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` on failure.

str.rindex(*sub*[, *start*[, *end*]])

Like **`rfind()`** but raises **`ValueError`** when the substring *sub* is not found.

str.rjust(*width*[, *fillchar*])

Return the string right justified in a string of length *width*. Padding is done using the specified *fillchar* (default is an ASCII space). The original string is returned if *width* is less than or equal to `len(s)`.

str.rpartition(*sep*)

Split the string at the last occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.

str.rsplit(*sep*=*None*, *maxsplit*=*-1*)

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done, the *rightmost* ones. If *sep* is not specified or `None`, any whitespace string is a separator. Except for splitting from the right, **`rsplit()`** behaves like **`split()`** which is described in detail below.

str.rstrip([*chars*])

Return a copy of the string with trailing characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a suffix; rather, all combinations of its values are stripped:

```
>>> '   spacious   '.rstrip()
'   spacious'
>>> 'mississippi'.rstrip('ipz')
'mississ'
```

See **`str.removesuffix()`** for a method that will remove a single suffix string rather than all of a set of characters. For example:

```
>>> 'Monty Python'.rstrip(' Python')
'M'
>>> 'Monty Python'.removesuffix(' Python')
'Monty'
```

str.split(*sep=None*, *maxsplit=-1*)

Return a list of the words in the string, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done (thus, the list will have at most `maxsplit+1` elements). If *maxsplit* is not specified or `-1`, then there is no limit on the number of splits (all possible splits are made).

If *sep* is given, consecutive delimiters are not grouped together and are deemed to delimit empty strings (for example, `'1,,2'.split(',')` returns `['1', '', '2']`). The *sep* argument may consist of multiple characters (for example, `'1<>2<>3'.split('<>')` returns `['1', '2', '3']`). Splitting an empty string with a specified separator returns `['']`.

For example:

```
>>> '1,2,3'.split(',')
```

```
['1', '2', '3']
>>> '1,2,3'.split(',', maxsplit=1)
['1', '2,3']
>>> '1,2,,3,'.split(',')
['1', '2', '', '3', '']
```

If *sep* is not specified or is `None`, a different splitting algorithm is applied: runs of consecutive whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the string has leading or trailing whitespace. Consequently, splitting an empty string or a string consisting of just whitespace with a `None` separator returns `[]`.

For example:

```
>>> '1 2 3'.split()
['1', '2', '3']
>>> '1 2 3'.split(maxsplit=1)
['1', '2 3']
>>> '   1   2   3   '.split()
['1', '2', '3']
```

str.splitlines(*keepends=False*)

Return a list of the lines in the string, breaking at line boundaries. Line breaks are not included in the resulting list unless *keepends* is given and true.

This method splits on the following line boundaries. In particular, the boundaries are a superset of universal newlines.

Representation	Description
`\n`	Line Feed
`\r`	Carriage Return
`\r\n`	Carriage Return + Line Feed
`\v` or `\x0b`	Line Tabulation
`\f` or `\x0c`	Form Feed
`\x1c`	File Separator
`\x1d`	Group Separator

\x1e	Record Separator
\x85	Next Line (C1 Control Code)
\u2028	Line Separator
\u2029	Paragraph Separator

Changed in version 3.2: `\v` and `\f` added to list of line boundaries.

For example:

```
>>> 'ab c\n\nde fg\rkl\r\n'.splitlines()
['ab c', '', 'de fg', 'kl']
>>> 'ab c\n\nde fg\rkl\r\n'.splitlines(keepends=Tru
['ab c\n', '\n', 'de fg\r', 'kl\r\n']
```

Unlike **`split()`** when a delimiter string *sep* is given, this method returns an empty list for the empty string, and a terminal line break does not result in an extra line:

```
>>> "".splitlines()
[]
>>> "One line\n".splitlines()
['One line']
```

For comparison, `split('\n')` gives:

```
>>> ''.split('\n')
['']
>>> 'Two lines\n'.split('\n')
['Two lines', '']
```

str.startswith(*prefix*[, *start*[, *end*]])

Return `True` if string starts with the *prefix*, otherwise return `False`. *prefix* can also be a tuple of prefixes to look for. With optional *start*, test string beginning at that position. With optional *end*, stop comparing string at that position.

str.strip([*chars*])

Return a copy of the string with the leading and trailing

characters removed. The *chars* argument is a string specifying the set of characters to be removed. If omitted or `None`, the *chars* argument defaults to removing whitespace. The *chars* argument is not a prefix or suffix; rather, all combinations of its values are stripped:

```
>>> '   spacious   '.strip()
'spacious'
>>> 'www.example.com'.strip('cmowz.')
'example'
```

The outermost leading and trailing *chars* argument values are stripped from the string. Characters are removed from the leading end until reaching a string character that is not contained in the set of characters in *chars*. A similar action takes place on the trailing end. For example:

```
>>> comment_string = '#....... Section 3.2.1 Issue
>>> comment_string.strip('.#! ')
'Section 3.2.1 Issue #32'
```

str.swapcase()

Return a copy of the string with uppercase characters converted to lowercase and vice versa. Note that it is not necessarily true that `s.swapcase().swapcase() == s`.

str.title()

Return a titlecased version of the string where words start with an uppercase character and the remaining characters are lowercase.

For example:

```
>>> 'Hello world'.title()
'Hello World'
```

The algorithm uses a simple language-independent definition of a word as groups of consecutive letters. The definition works in many contexts but it means that apostrophes in

contractions and possessives form word boundaries, which may not be the desired result:

```
>>> "they're bill's friends from the UK".title()
"They'Re Bill'S Friends From The Uk"
```

The **string.capwords()** function does not have this problem, as it splits words on spaces only.

Alternatively, a workaround for apostrophes can be constructed using regular expressions:

```
>>> import re
>>> def titlecase(s):
...     return re.sub(r"[A-Za-z]+('[A-Za-z]+)?",
...                   lambda mo: mo.group(0).capita
...                   s)
...
>>> titlecase("they're bill's friends.")
"They're Bill's Friends."
```

str.translate(*table*)

Return a copy of the string in which each character has been mapped through the given translation table. The table must be an object that implements indexing via **__getitem__()**, typically a mapping or sequence. When indexed by a Unicode ordinal (an integer), the table object can do any of the following: return a Unicode ordinal or a string, to map the character to one or more other characters; return `None`, to delete the character from the return string; or raise a **LookupError** exception, to map the character to itself.

You can use **str.maketrans()** to create a translation map from character-to-character mappings in different formats.

See also the **codecs** module for a more flexible approach to custom character mappings.

str.upper()

Return a copy of the string with all the cased characters [4] converted to uppercase. Note that `s.upper().isupper()` might be `False` if `s` contains uncased characters or if the Unicode category of the resulting character(s) is not “Lu” (Letter, uppercase), but e.g. “Lt” (Letter, titlecase).

The uppercasing algorithm used is described in section 3.13 of the Unicode Standard.

str.zfill(*width*)

Return a copy of the string left filled with ASCII `'0'` digits to make a string of length *width*. A leading sign prefix (`'+'`/`'-'`) is handled by inserting the padding *after* the sign character rather than before. The original string is returned if *width* is less than or equal to `len(s)`.

For example:

```
>>> "42".zfill(5)
'00042'
>>> "-42".zfill(5)
'-0042'
```

`printf`-style String Formatting

Note

The formatting operations described here exhibit a variety of quirks that lead to a number of common errors (such as failing to display tuples and dictionaries correctly). Using the newer formatted string literals, the **`str.format()`** interface, or template strings may help avoid these errors. Each of these alternatives provides their own trade-offs and benefits of simplicity, flexibility, and/or extensibility.

String objects have one unique built-in operation: the `%` operator (modulo). This is also known as the string *formatting* or *interpolation* operator. Given `format % values` (where *format* is a string), `%` conversion specifications in *format* are replaced with zero or more

elements of *values*. The effect is similar to using the **`sprintf()`** in the C language.

If *format* requires a single argument, *values* may be a single non-tuple object. 5 Otherwise, *values* must be a tuple with exactly the number of items specified by the format string, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The `'%'` character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, `(somename)`).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an `'*'` (asterisk), the actual width is read from the next element of the tuple in *values*, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a `'.'` (dot) followed by the precision. If specified as `'*'` (an asterisk), the actual precision is read from the next element of the tuple in *values*, and the value to convert comes after the precision.
6. Length modifier (optional).
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the string *must* include a parenthesised mapping key into that dictionary inserted immediately after the `'%'` character. The mapping key selects the value to be formatted from the mapping. For example:

```
>>> print('%(language)s has %(number)03d quote types.' %
...       {'language': "Python", "number": 2})
Python has 002 quote types.
```

In this case no `*` specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

Flag	Meaning
`'#'`	The value conversion will use the “alternate form” (where defined below).
`'0'`	The conversion will be zero padded for numeric values.
`'-'`	The converted value is left adjusted (overrides the `'0'` conversion if both are given).
`' '`	(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.
`'+'`	A sign character (`'+'` or `'-'`) will precede the conversion (overrides a “space” flag).

A length modifier (`h`, `l`, or `L`) may be present, but is ignored as it is not necessary for Python – so e.g. `%ld` is identical to `%d`.

The conversion types are:

Conversion	Meaning	Notes
`'d'`	Signed integer decimal.	
`'i'`	Signed integer decimal.	
`'o'`	Signed octal value.	(1)
`'u'`	Obsolete type – it is identical to `'d'`.	(8)
`'x'`	Signed hexadecimal (lowercase).	(2)
`'X'`	Signed hexadecimal (uppercase).	(2)
`'e'`	Floating point exponential format (lowercase).	(3)
`'E'`	Floating point exponential format (uppercase).	(3)
`'f'`	Floating point decimal format.	(3)
`'F'`	Floating point decimal format.	(3)
`'g'`	Floating point format. Uses lowercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.	(4)
`'G'`	Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.	(4)
`'c'`	Single character (accepts integer or single character string).	
`'r'`	String (converts any Python object using **`repr()`**).	(5)
`'s'`	String (converts any Python object using **`str()`**).	(5)
`'a'`	String (converts any Python object using **`ascii()`**).	(5)
`'%'`	No argument is converted, results in a `'%'` character in the result.	

Notes:

1. The alternate form causes a leading octal specifier (`'0o'`) to be inserted before the first digit.

2. The alternate form causes a leading `'0x'` or `'0X'` (depending on whether the `'x'` or `'X'` format was used) to be inserted before the first digit.

3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

   The precision determines the number of digits after the decimal point and defaults to 6.

4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

   The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. If precision is `N`, the output is truncated to `N` characters.

6. See **PEP 237** [https://peps.python.org/pep-0237/].

Since Python strings have an explicit length, `%s` conversions do not assume that `'\0'` is the end of the string.

Changed in version 3.1: `%f` conversions for numbers whose absolute value is over 1e50 are no longer replaced by `%g` conversions.

Binary Sequence Types — `bytes`, `bytearray`, `memoryview`

The core built-in types for manipulating binary data are **`bytes`** and **`bytearray`**. They are supported by **`memoryview`** which uses the buffer protocol to access the memory of other binary objects without needing to make a copy.

The **`array`** module supports efficient storage of basic data types like 32-bit integers and IEEE754 double-precision floating values.

Bytes Objects

Bytes objects are immutable sequences of single bytes. Since many major binary protocols are based on the ASCII text encoding, bytes objects offer several methods that are only valid when working with ASCII compatible data and are closely related to string objects in a variety of other ways.

class bytes([*source*[, *encoding*[, *errors*]]])

Firstly, the syntax for bytes literals is largely the same as that for string literals, except that a `b` prefix is added:

- Single quotes: `b'still allows embedded "double" quotes'`
- Double quotes: `b"still allows embedded 'single' quotes"`
- Triple quoted: `b'''3 single quotes'''`, `b"""3 double quotes"""`

Only ASCII characters are permitted in bytes literals (regardless of the declared source code encoding). Any binary values over 127 must be entered into bytes literals using the appropriate escape sequence.

As with string literals, bytes literals may also use a `r` prefix to disable processing of escape sequences. See String and Bytes literals for more about the various forms of bytes literal, including supported escape sequences.

While bytes literals and representations are based on ASCII text, bytes objects actually behave like immutable sequences of integers, with each value in the sequence restricted such that `0 <= x < 256` (attempts to violate this restriction will trigger **`ValueError`**). This is done deliberately to emphasise that while many binary formats include ASCII based elements and can be usefully manipulated with some text-oriented algorithms, this is not generally the case for arbitrary binary data (blindly applying text processing algorithms to binary data formats that are not ASCII compatible will usually lead to data corruption).

In addition to the literal forms, bytes objects can be created in a number of other ways:

- A zero-filled bytes object of a specified length: `bytes(10)`
- From an iterable of integers: `bytes(range(20))`
- Copying existing binary data via the buffer protocol: `bytes(obj)`

Also see the bytes built-in.

Since 2 hexadecimal digits correspond precisely to a single byte, hexadecimal numbers are a commonly used format for describing binary data. Accordingly, the bytes type has an additional class method to read data in that format:

classmethod fromhex(*string*)

This **`bytes`** class method returns a bytes object, decoding the given string object. The string must contain two hexadecimal digits per byte, with ASCII whitespace being ignored.

```
>>> bytes.fromhex('2Ef0 F1f2  ')
b'.\xf0\xf1\xf2'
```

Changed in version 3.7: **`bytes.fromhex()`** now skips all ASCII whitespace in the string, not just spaces.

A reverse conversion function exists to transform a bytes object into its hexadecimal representation.

hex([*sep*[, *bytes_per_sep*]])

Return a string object containing two hexadecimal digits for each byte in the instance.

```
>>> b'\xf0\xf1\xf2'.hex()
'f0f1f2'
```

If you want to make the hex string easier to read, you can specify a single character separator *sep* parameter

to include in the output. By default, this separator will be included between each byte. A second optional *bytes_per_sep* parameter controls the spacing. Positive values calculate the separator position from the right, negative values from the left.

```
>>> value = b'\xf0\xf1\xf2'
>>> value.hex('-')
'f0-f1-f2'
>>> value.hex('_', 2)
'f0_f1f2'
>>> b'UUDDLRLRAB'.hex(' ', -4)
'55554444 4c524c52 4142'
```

New in version 3.5.

Changed in version 3.8: **`bytes.hex()`** now supports optional *sep* and *bytes_per_sep* parameters to insert separators between bytes in the hex output.

Since bytes objects are sequences of integers (akin to a tuple), for a bytes object *b*, `b[0]` will be an integer, while `b[0:1]` will be a bytes object of length 1. (This contrasts with text strings, where both indexing and slicing will produce a string of length 1)

The representation of bytes objects uses the literal format (`b'...'`) since it is often more useful than e.g. `bytes([46, 46, 46])`. You can always convert a bytes object into a list of integers using `list(b)`.

Bytearray Objects

`bytearray` objects are a mutable counterpart to **`bytes`** objects.

class bytearray([*source*[, *encoding*[, *errors*]]])

There is no dedicated literal syntax for bytearray objects, instead they are always created by calling the constructor:

- Creating an empty instance: `bytearray()`
- Creating a zero-filled instance with a given length:

`bytearray(10)`
- From an iterable of integers:
  `bytearray(range(20))`
- Copying existing binary data via the buffer protocol:
  `bytearray(b'Hi!')`

As bytearray objects are mutable, they support the mutable sequence operations in addition to the common bytes and bytearray operations described in Bytes and Bytearray Operations.

Also see the bytearray built-in.

Since 2 hexadecimal digits correspond precisely to a single byte, hexadecimal numbers are a commonly used format for describing binary data. Accordingly, the bytearray type has an additional class method to read data in that format:

classmethod fromhex(*string*)

This **bytearray** class method returns bytearray object, decoding the given string object. The string must contain two hexadecimal digits per byte, with ASCII whitespace being ignored.

```
>>> bytearray.fromhex('2Ef0 F1f2  ')
bytearray(b'.\xf0\xf1\xf2')
```

Changed in version 3.7: **bytearray.fromhex()** now skips all ASCII whitespace in the string, not just spaces.

A reverse conversion function exists to transform a bytearray object into its hexadecimal representation.

hex([*sep*[, *bytes_per_sep*]])

Return a string object containing two hexadecimal digits for each byte in the instance.

```
>>> bytearray(b'\xf0\xf1\xf2').hex()
'f0f1f2'
```

New in version 3.5.

Changed in version 3.8: Similar to `bytes.hex()`, `bytearray.hex()` now supports optional *sep* and *bytes_per_sep* parameters to insert separators between bytes in the hex output.

Since bytearray objects are sequences of integers (akin to a list), for a bytearray object *b*, `b[0]` will be an integer, while `b[0:1]` will be a bytearray object of length 1. (This contrasts with text strings, where both indexing and slicing will produce a string of length 1)

The representation of bytearray objects uses the bytes literal format (`bytearray(b'...')`) since it is often more useful than e.g. `bytearray([46, 46, 46])`. You can always convert a bytearray object into a list of integers using `list(b)`.

Bytes and Bytearray Operations

Both bytes and bytearray objects support the common sequence operations. They interoperate not just with operands of the same type, but with any bytes-like object. Due to this flexibility, they can be freely mixed in operations without causing errors. However, the return type of the result may depend on the order of operands.

Note

The methods on bytes and bytearray objects don't accept strings as their arguments, just as the methods on strings don't accept bytes as their arguments. For example, you have to write:

```
a = "abc"
b = a.replace("a", "f")
```

and:

```
a = b"abc"
b = a.replace(b"a", b"f")
```

Some bytes and bytearray operations assume the use of ASCII

compatible binary formats, and hence should be avoided when working with arbitrary binary data. These restrictions are covered below.

Note

Using these ASCII based operations to manipulate binary data that is not stored in an ASCII based format may lead to data corruption.

The following methods on bytes and bytearray objects can be used with arbitrary binary data.

bytes.count(*sub*[, *start*[, *end*]])
bytearray.count(*sub*[, *start*[, *end*]])

Return the number of non-overlapping occurrences of subsequence *sub* in the range [*start*, *end*]. Optional arguments *start* and *end* are interpreted as in slice notation.

The subsequence to search for may be any bytes-like object or an integer in the range 0 to 255.

If *sub* is empty, returns the number of empty slices between characters which is the length of the bytes object plus one.

Changed in version 3.3: Also accept an integer in the range 0 to 255 as the subsequence.

bytes.removeprefix(*prefix*, /)
bytearray.removeprefix(*prefix*, /)

If the binary data starts with the *prefix* string, return `bytes[len(prefix):]`. Otherwise, return a copy of the original binary data:

```
>>> b'TestHook'.removeprefix(b'Test')
b'Hook'
>>> b'BaseTestCase'.removeprefix(b'Test')
b'BaseTestCase'
```

The *prefix* may be any bytes-like object.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

New in version 3.9.

bytes.removesuffix(*suffix*, */*)
bytearray.removesuffix(*suffix*, */*)

If the binary data ends with the *suffix* string and that *suffix* is not empty, return `bytes[:-len(suffix)]`. Otherwise, return a copy of the original binary data:

```
>>> b'MiscTests'.removesuffix(b'Tests')
b'Misc'
>>> b'TmpDirMixin'.removesuffix(b'Tests')
b'TmpDirMixin'
```

The *suffix* may be any bytes-like object.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

New in version 3.9.

bytes.decode(*encoding='utf-8'*, *errors='strict'*)
bytearray.decode(*encoding='utf-8'*, *errors='strict'*)

Return a string decoded from the given bytes. Default encoding is `'utf-8'`. *errors* may be given to set a different error handling scheme. The default for *errors* is `'strict'`, meaning that encoding errors raise a **`UnicodeError`**. Other possible values are `'ignore'`, `'replace'` and any other

name registered via `codecs.register_error()`, see section Error Handlers. For a list of possible encodings, see section Standard Encodings.

By default, the *errors* argument is not checked for best performances, but only used at the first decoding error. Enable the Python Development Mode, or use a debug build to check *errors*.

Note

Passing the *encoding* argument to `str` allows decoding any bytes-like object directly, without needing to make a temporary bytes or bytearray object.

Changed in version 3.1: Added support for keyword arguments.

Changed in version 3.9: The *errors* is now checked in development mode and in debug mode.

bytes.endswith(*suffix*[, *start*[, *end*]])
bytearray.endswith(*suffix*[, *start*[, *end*]])

Return `True` if the binary data ends with the specified *suffix*, otherwise return `False`. *suffix* can also be a tuple of suffixes to look for. With optional *start*, test beginning at that position. With optional *end*, stop comparing at that position.

The suffix(es) to search for may be any bytes-like object.

bytes.find(*sub*[, *start*[, *end*]])
bytearray.find(*sub*[, *start*[, *end*]])

Return the lowest index in the data where the subsequence *sub* is found, such that *sub* is contained in the slice `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` if *sub* is not found.

The subsequence to search for may be any bytes-like object or an integer in the range 0 to 255.

Note

The `find()` method should be used only if you need to know the position of *sub*. To check if *sub* is a substring or not, use the `in` operator:

```
>>> b'Py' in b'Python'
True
```

Changed in version 3.3: Also accept an integer in the range 0 to 255 as the subsequence.

bytes.index(*sub*[, *start*[, *end*]])
bytearray.index(*sub*[, *start*[, *end*]])

Like `find()`, but raise `ValueError` when the subsequence is not found.

The subsequence to search for may be any bytes-like object or an integer in the range 0 to 255.

Changed in version 3.3: Also accept an integer in the range 0 to 255 as the subsequence.

bytes.join(*iterable*)
bytearray.join(*iterable*)

Return a bytes or bytearray object which is the concatenation of the binary data sequences in *iterable*. A `TypeError` will be raised if there are any values in *iterable* that are not bytes-like objects, including `str` objects. The separator between elements is the contents of the bytes or bytearray object providing this method.

static bytes.maketrans(*from*, *to*)
static bytearray.maketrans(*from*, *to*)

This static method returns a translation table usable for `bytes.translate()` that will map each character in *from* into the character at the same position in *to*; *from* and *to* must both be bytes-like objects and have the same length.

New in version 3.1.

bytes.partition(*sep*)
bytearray.partition(*sep*)

Split the sequence at the first occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself or its bytearray copy, and the part after the separator. If the separator is not found, return a 3-tuple containing a copy of the original sequence, followed by two empty bytes or bytearray objects.

The separator to search for may be any bytes-like object.

bytes.replace(*old*, *new*[, *count*])
bytearray.replace(*old*, *new*[, *count*])

Return a copy of the sequence with all occurrences of subsequence *old* replaced by *new*. If the optional argument *count* is given, only the first *count* occurrences are replaced.

The subsequence to search for and its replacement may be any bytes-like object.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.rfind(*sub*[, *start*[, *end*]])
bytearray.rfind(*sub*[, *start*[, *end*]])

Return the highest index in the sequence where the subsequence *sub* is found, such that *sub* is contained within `s[start:end]`. Optional arguments *start* and *end* are interpreted as in slice notation. Return `-1` on failure.

The subsequence to search for may be any bytes-like object or an integer in the range 0 to 255.

Changed in version 3.3: Also accept an integer in the range 0 to 255 as the subsequence.

bytes.rindex(*sub*[, *start*[, *end*]])
bytearray.rindex(*sub*[, *start*[, *end*]])

Like **`rfind()`** but raises **`ValueError`** when the subsequence *sub* is not found.

The subsequence to search for may be any bytes-like object or an integer in the range 0 to 255.

Changed in version 3.3: Also accept an integer in the range 0 to 255 as the subsequence.

bytes.rpartition(*sep*)
bytearray.rpartition(*sep*)

Split the sequence at the last occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself or its bytearray copy, and the part after the separator. If the separator is not found, return a 3-tuple containing two empty bytes or bytearray objects, followed by a copy of the original sequence.

The separator to search for may be any bytes-like object.

bytes.startswith(*prefix*[, *start*[, *end*]])
bytearray.startswith(*prefix*[, *start*[, *end*]])

Return `True` if the binary data starts with the specified *prefix*, otherwise return `False`. *prefix* can also be a tuple of prefixes to look for. With optional *start*, test beginning at that position. With optional *end*, stop comparing at that position.

The prefix(es) to search for may be any bytes-like object.

bytes.translate(*table*, */*, *delete*=*b''*)
bytearray.translate(*table*, */*, *delete*=*b''*)

Return a copy of the bytes or bytearray object where all bytes

occurring in the optional argument *delete* are removed, and the remaining bytes have been mapped through the given translation table, which must be a bytes object of length 256.

You can use the **`bytes.maketrans()`** method to create a translation table.

Set the *table* argument to `None` for translations that only delete characters:

```
>>> b'read this short text'.translate(None, b'aeiou
b'rd ths shrt txt'
```

Changed in version 3.6: delete is now supported as a keyword argument.

The following methods on bytes and bytearray objects have default behaviours that assume the use of ASCII compatible binary formats, but can still be used with arbitrary binary data by passing appropriate arguments. Note that all of the bytearray methods in this section do *not* operate in place, and instead produce new objects.

bytes.center(*width*[, *fillbyte*])
bytearray.center(*width*[, *fillbyte*])

Return a copy of the object centered in a sequence of length *width*. Padding is done using the specified *fillbyte* (default is an ASCII space). For **`bytes`** objects, the original sequence is returned if *width* is less than or equal to `len(s)`.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.ljust(*width*[, *fillbyte*])
bytearray.ljust(*width*[, *fillbyte*])

Return a copy of the object left justified in a sequence of length *width*. Padding is done using the specified *fillbyte* (default is an ASCII space). For **bytes** objects, the original sequence is returned if *width* is less than or equal to `len(s)`.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.lstrip([*chars*])

bytearray.lstrip([*chars*])

Return a copy of the sequence with specified leading bytes removed. The *chars* argument is a binary sequence specifying the set of byte values to be removed - the name refers to the fact this method is usually used with ASCII characters. If omitted or `None`, the *chars* argument defaults to removing ASCII whitespace. The *chars* argument is not a prefix; rather, all combinations of its values are stripped:

```
>>> b'   spacious   '.lstrip()
b'spacious   '
>>> b'www.example.com'.lstrip(b'cmowz.')
b'example.com'
```

The binary sequence of byte values to remove may be any bytes-like object. See **removeprefix()** for a method that will remove a single prefix string rather than all of a set of characters. For example:

```
>>> b'Arthur: three!'.lstrip(b'Arthur: ')
b'ee!'
>>> b'Arthur: three!'.removeprefix(b'Arthur: ')
b'three!'
```

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.rjust(*width*[, *fillbyte*])

bytearray.rjust(*width*[, *fillbyte*])

Return a copy of the object right justified in a sequence of length *width*. Padding is done using the specified *fillbyte* (default is an ASCII space). For **`bytes`** objects, the original sequence is returned if *width* is less than or equal to `len(s)`.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.rsplit(*sep*=*None*, *maxsplit*=*-1*)

bytearray.rsplit(*sep*=*None*, *maxsplit*=*-1*)

Split the binary sequence into subsequences of the same type, using *sep* as the delimiter string. If *maxsplit* is given, at most *maxsplit* splits are done, the *rightmost* ones. If *sep* is not specified or `None`, any subsequence consisting solely of ASCII whitespace is a separator. Except for splitting from the right, **`rsplit()`** behaves like **`split()`** which is described in detail below.

bytes.rstrip([*chars*])

bytearray.rstrip([*chars*])

Return a copy of the sequence with specified trailing bytes removed. The *chars* argument is a binary sequence specifying the set of byte values to be removed - the name refers to the fact this method is usually used with ASCII characters. If omitted or `None`, the *chars* argument defaults to removing ASCII whitespace. The *chars* argument is not a suffix; rather,

all combinations of its values are stripped:

```
>>> b'   spacious   '.rstrip()
b'   spacious'
>>> b'mississippi'.rstrip(b'ipz')
b'mississ'
```

The binary sequence of byte values to remove may be any bytes-like object. See **`removesuffix()`** for a method that will remove a single suffix string rather than all of a set of characters. For example:

```
>>> b'Monty Python'.rstrip(b' Python')
b'M'
>>> b'Monty Python'.removesuffix(b' Python')
b'Monty'
```

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.split(*sep* = *None*, *maxsplit* = *- 1*)
bytearray.split(*sep* = *None*, *maxsplit* = *- 1*)

Split the binary sequence into subsequences of the same type, using *sep* as the delimiter string. If *maxsplit* is given and non-negative, at most *maxsplit* splits are done (thus, the list will have at most `maxsplit+1` elements). If *maxsplit* is not specified or is `-1`, then there is no limit on the number of splits (all possible splits are made).

If *sep* is given, consecutive delimiters are not grouped together and are deemed to delimit empty subsequences (for example, `b'1,,2'.split(b',')` returns `[b'1', b'', b'2']`). The *sep* argument may consist of a multibyte sequence (for example, `b'1<>2<>3'.split(b'<>')` returns `[b'1', b'2', b'3']`). Splitting an empty

sequence with a specified separator returns `[b'']` or `[bytearray(b'')]` depending on the type of object being split. The *sep* argument may be any bytes-like object.

For example:

```
>>> b'1,2,3'.split(b',')
[b'1', b'2', b'3']
>>> b'1,2,3'.split(b',', maxsplit=1)
[b'1', b'2,3']
>>> b'1,2,,3,'.split(b',')
[b'1', b'2', b'', b'3', b'']
```

If *sep* is not specified or is `None`, a different splitting algorithm is applied: runs of consecutive ASCII whitespace are regarded as a single separator, and the result will contain no empty strings at the start or end if the sequence has leading or trailing whitespace. Consequently, splitting an empty sequence or a sequence consisting solely of ASCII whitespace without a specified separator returns `[]`.

For example:

```
>>> b'1 2 3'.split()
[b'1', b'2', b'3']
>>> b'1 2 3'.split(maxsplit=1)
[b'1', b'2 3']
>>> b'   1   2   3   '.split()
[b'1', b'2', b'3']
```

bytes.strip([*chars*])

bytearray.strip([*chars*])

Return a copy of the sequence with specified leading and trailing bytes removed. The *chars* argument is a binary sequence specifying the set of byte values to be removed - the name refers to the fact this method is usually used with ASCII characters. If omitted or `None`, the *chars* argument defaults to removing ASCII whitespace. The *chars* argument is not a prefix or suffix; rather, all combinations of its values are

stripped:

```
>>> b'   spacious   '.strip()
b'spacious'
>>> b'www.example.com'.strip(b'cmowz.')
b'example'
```

The binary sequence of byte values to remove may be any bytes-like object.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

The following methods on bytes and bytearray objects assume the use of ASCII compatible binary formats and should not be applied to arbitrary binary data. Note that all of the bytearray methods in this section do *not* operate in place, and instead produce new objects.

bytes.capitalize()
bytearray.capitalize()

Return a copy of the sequence with each byte interpreted as an ASCII character, and the first byte capitalized and the rest lowercased. Non-ASCII byte values are passed through unchanged.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.expandtabs(*tabsize*=*8*)
bytearray.expandtabs(*tabsize*=*8*)

Return a copy of the sequence where all ASCII tab characters are replaced by one or more ASCII spaces, depending on the current column and the given tab size. Tab positions occur every *tabsize* bytes (default is 8, giving tab positions at columns 0, 8, 16 and so on). To expand the sequence, the current column is set to zero and the sequence is examined byte by byte. If the byte is an ASCII tab character (`b'\t'`), one or more space characters are inserted in the result until the current column is equal to the next tab position. (The tab character itself is not copied.) If the current byte is an ASCII newline (`b'\n'`) or carriage return (`b'\r'`), it is copied and the current column is reset to zero. Any other byte value is copied unchanged and the current column is incremented by one regardless of how the byte value is represented when printed:

```
>>> b'01\t012\t0123\t01234'.expandtabs()
b'01      012     0123    01234'
>>> b'01\t012\t0123\t01234'.expandtabs(4)
b'01  012 0123    01234'
```

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.isalnum()
bytearray.isalnum()

Return `True` if all bytes in the sequence are alphabetical ASCII characters or ASCII decimal digits and the sequence is not empty, `False` otherwise. Alphabetic ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVW`. ASCII decimal digits are those byte values in the sequence `b'0123456789'`.

For example:

```
>>> b'ABCabc1'.isalnum()
True
>>> b'ABC abc1'.isalnum()
False
```

bytes.isalpha()

bytearray.isalpha()

Return `True` if all bytes in the sequence are alphabetic ASCII characters and the sequence is not empty, `False` otherwise. Alphabetic ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVW`

For example:

```
>>> b'ABCabc'.isalpha()
True
>>> b'ABCabc1'.isalpha()
False
```

bytes.isascii()

bytearray.isascii()

Return `True` if the sequence is empty or all bytes in the sequence are ASCII, `False` otherwise. ASCII bytes are in the range 0-0x7F.

New in version 3.7.

bytes.isdigit()

bytearray.isdigit()

Return `True` if all bytes in the sequence are ASCII decimal digits and the sequence is not empty, `False` otherwise. ASCII decimal digits are those byte values in the sequence `b'0123456789'`.

For example:

```
>>> b'1234'.isdigit()
```

```
True
>>> b'1.23'.isdigit()
False
```

bytes.islower()
bytearray.islower()

Return `True` if there is at least one lowercase ASCII character in the sequence and no uppercase ASCII characters, `False` otherwise.

For example:

```
>>> b'hello world'.islower()
True
>>> b'Hello world'.islower()
False
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`.

bytes.isspace()
bytearray.isspace()

Return `True` if all bytes in the sequence are ASCII whitespace and the sequence is not empty, `False` otherwise. ASCII whitespace characters are those byte values in the sequence `b' \t\n\r\x0b\f'` (space, tab, newline, carriage return, vertical tab, form feed).

bytes.istitle()
bytearray.istitle()

Return `True` if the sequence is ASCII titlecase and the sequence is not empty, `False` otherwise. See **`bytes.title()`** for more details on the definition of "titlecase".

For example:

```
>>> b'Hello World'.istitle()
True
>>> b'Hello world'.istitle()
False
```

bytes.isupper()
bytearray.isupper()

Return `True` if there is at least one uppercase alphabetic ASCII character in the sequence and no lowercase ASCII characters, `False` otherwise.

For example:

```
>>> b'HELLO WORLD'.isupper()
True
>>> b'Hello world'.isupper()
False
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`.

bytes.lower()
bytearray.lower()

Return a copy of the sequence with all the uppercase ASCII characters converted to their corresponding lowercase counterpart.

For example:

```
>>> b'Hello World'.lower()
b'hello world'
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.splitlines(*keepends*=*False*)
bytearray.splitlines(*keepends*=*False*)

Return a list of the lines in the binary sequence, breaking at ASCII line boundaries. This method uses the universal newlines approach to splitting lines. Line breaks are not included in the resulting list unless *keepends* is given and true.

For example:

```
>>> b'ab c\n\nde fg\rkl\r\n'.splitlines()
[b'ab c', b'', b'de fg', b'kl']
>>> b'ab c\n\nde fg\rkl\r\n'.splitlines(keepends=Tr
[b'ab c\n', b'\n', b'de fg\r', b'kl\r\n']
```

Unlike **`split()`** when a delimiter string *sep* is given, this method returns an empty list for the empty string, and a terminal line break does not result in an extra line:

```
>>> b"".split(b'\n'), b"Two lines\n".split(b'\n')
([b''], [b'Two lines', b''])
>>> b"".splitlines(), b"One line\n".splitlines()
([], [b'One line'])
```

bytes.swapcase()
bytearray.swapcase()

Return a copy of the sequence with all the lowercase ASCII characters converted to their corresponding uppercase counterpart and vice-versa.

For example:

```
>>> b'Hello World'.swapcase()
```

```
b'hELLO wORLD'
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`.

Unlike **`str.swapcase()`**, it is always the case that `bin.swapcase().swapcase() == bin` for the binary versions. Case conversions are symmetrical in ASCII, even though that is not generally true for arbitrary Unicode code points.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.title()
bytearray.title()

Return a titlecased version of the binary sequence where words start with an uppercase ASCII character and the remaining characters are lowercase. Uncased byte values are left unmodified.

For example:

```
>>> b'Hello world'.title()
b'Hello World'
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`. All other byte values are uncased.

The algorithm uses a simple language-independent definition of a word as groups of consecutive letters. The definition

works in many contexts but it means that apostrophes in contractions and possessives form word boundaries, which may not be the desired result:

```
>>> b"they're bill's friends from the UK".title()
b"They're Bill'S Friends From The Uk"
```

A workaround for apostrophes can be constructed using regular expressions:

```
>>> import re
>>> def titlecase(s):
...     return re.sub(rb"[A-Za-z]+('[A-Za-z]+)?",
...                   lambda mo: mo.group(0)[0:1].u
...                              mo.group(0)[1:].lo
...                   s)
...
>>> titlecase(b"they're bill's friends.")
b"They're Bill's Friends."
```

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.upper()
bytearray.upper()

Return a copy of the sequence with all the lowercase ASCII characters converted to their corresponding uppercase counterpart.

For example:

```
>>> b'Hello World'.upper()
b'HELLO WORLD'
```

Lowercase ASCII characters are those byte values in the sequence `b'abcdefghijklmnopqrstuvwxyz'`. Uppercase

ASCII characters are those byte values in the sequence `b'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`.

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

bytes.zfill(*width*)
bytearray.zfill(*width*)

Return a copy of the sequence left filled with ASCII `b'0'` digits to make a sequence of length *width*. A leading sign prefix (`b'+'/ b'-'`) is handled by inserting the padding *after* the sign character rather than before. For **`bytes`** objects, the original sequence is returned if *width* is less than or equal to `len(seq)`.

For example:

```
>>> b"42".zfill(5)
b'00042'
>>> b"-42".zfill(5)
b'-0042'
```

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

`printf`-style Bytes Formatting

Note

The formatting operations described here exhibit a variety of quirks that lead to a number of common errors (such as failing to

display tuples and dictionaries correctly). If the value being printed may be a tuple or dictionary, wrap it in a tuple.

Bytes objects (`bytes/bytearray`) have one unique built-in operation: the `%` operator (modulo). This is also known as the bytes *formatting* or *interpolation* operator. Given `format % values` (where *format* is a bytes object), `%` conversion specifications in *format* are replaced with zero or more elements of *values*. The effect is similar to using the **`sprintf()`** in the C language.

If *format* requires a single argument, *values* may be a single non-tuple object. 5 Otherwise, *values* must be a tuple with exactly the number of items specified by the format bytes object, or a single mapping object (for example, a dictionary).

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The `'%'` character, which marks the start of the specifier.
2. Mapping key (optional), consisting of a parenthesised sequence of characters (for example, `(somename)`).
3. Conversion flags (optional), which affect the result of some conversion types.
4. Minimum field width (optional). If specified as an `'*'` (asterisk), the actual width is read from the next element of the tuple in *values*, and the object to convert comes after the minimum field width and optional precision.
5. Precision (optional), given as a `'.'` (dot) followed by the precision. If specified as `'*'` (an asterisk), the actual precision is read from the next element of the tuple in *values*, and the value to convert comes after the precision.
6. Length modifier (optional).
7. Conversion type.

When the right argument is a dictionary (or other mapping type), then the formats in the bytes object *must* include a parenthesised mapping key into that dictionary inserted immediately after the `'%'` character. The mapping key selects the value to be formatted from the mapping. For example:

```
>>> print(b'%(language)s has %(number)03d quote types.'
...       {b'language': b"Python", b"number": 2})
b'Python has 002 quote types.'
```

In this case no `*` specifiers may occur in a format (since they require a sequential parameter list).

The conversion flag characters are:

Flag	Meaning
`'#'`	The value conversion will use the “alternate form” (where defined below).
`'0'`	The conversion will be zero padded for numeric values.
`'-'`	The converted value is left adjusted (overrides the `'0'` conversion if both are given).
`' '`	(a space) A blank should be left before a positive number (or empty string) produced by a signed conversion.
`'+'`	A sign character (`'+'` or `'-'`) will precede the conversion (overrides a “space” flag).

A length modifier (`h`, `l`, or `L`) may be present, but is ignored as it is not necessary for Python – so e.g. `%ld` is identical to `%d`.

The conversion types are:

Conversion	Meaning	Notes
`'d'`	Signed integer decimal.	
`'i'`	Signed integer decimal.	
`'o'`	Signed octal value.	(1)
`'u'`	Obsolete type – it is identical to `'d'`.	(8)
`'x'`	Signed hexadecimal (lowercase).	(2)
`'X'`	Signed hexadecimal (uppercase).	(2)
`'e'`	Floating point exponential format (lowercase).	(3)
`'E'`	Floating point exponential format (uppercase).	(3)
`'f'`	Floating point decimal format.	(3)
`'F'`	Floating point decimal format.	(3)
`'g'`	Floating point format. Uses lowercase exponential format if exponent is less than -4 or not less than precision, decimal format otherwise.	(4)
`'G'`	Floating point format. Uses uppercase exponential format if exponent is less than -4 or not less than precision, decimal format	(4)

otherwise.

`'c'`	Single byte (accepts integer or single byte objects).
`'b'`	Bytes (any object that follows the buffer protocol or has `__bytes__()`).
`'B'`	`'b'` is an alias for `'b'` and should only be used for Python2/3 code bases.
`'a'`	Bytes (converts any Python object using `repr(obj).encode('ascii', 'backslashreplace')`).
`'A'`	`'a'` is an alias for `'a'` and should only be used for Python2/3 code bases.
`'%'`	No argument is converted, results in a `'%'` character in the result.

Notes:

1. The alternate form causes a leading octal specifier (`'0o'`) to be inserted before the first digit.

2. The alternate form causes a leading `'0x'` or `'0X'` (depending on whether the `'x'` or `'X'` format was used) to be inserted before the first digit.

3. The alternate form causes the result to always contain a decimal point, even if no digits follow it.

   The precision determines the number of digits after the decimal point and defaults to 6.

4. The alternate form causes the result to always contain a decimal point, and trailing zeroes are not removed as they would otherwise be.

   The precision determines the number of significant digits before and after the decimal point and defaults to 6.

5. If precision is `N`, the output is truncated to `N` characters.

6. `b'%s'` is deprecated, but will not be removed during the 3.x series.

7. `b'%r'` is deprecated, but will not be removed during the 3.x series.

8. See **PEP 237** [https://peps.python.org/pep-0237/].

Note

The bytearray version of this method does *not* operate in place - it always produces a new object, even if no changes were made.

See also

PEP 461 [https://peps.python.org/pep-0461/] - Adding % formatting to bytes and bytearray

New in version 3.5.

Memory Views

memoryview objects allow Python code to access the internal data of an object that supports the buffer protocol without copying.

class memoryview(*object*)

Create a **memoryview** that references *object*. *object* must support the buffer protocol. Built-in objects that support the buffer protocol include **bytes** and **bytearray**.

A **memoryview** has the notion of an *element*, which is the atomic memory unit handled by the originating *object*. For many simple types such as **bytes** and **bytearray**, an element is a single byte, but other types such as **array.array** may have bigger elements.

`len(view)` is equal to the length of **tolist**. If `view.ndim = 0`, the length is 1. If `view.ndim = 1`, the length is equal to the number of elements in the view. For higher dimensions, the length is equal to the length of the nested list representation of the view. The **itemsize** attribute will give you the number of bytes in a single element.

A **memoryview** supports slicing and indexing to expose its

data. One-dimensional slicing will result in a subview:

```
>>> v = memoryview(b'abcefg')
>>> v[1]
98
>>> v[-1]
103
>>> v[1:4]
<memory at 0x7f3ddc9f4350>
>>> bytes(v[1:4])
b'bce'
```

If **format** is one of the native format specifiers from the **struct** module, indexing with an integer or a tuple of integers is also supported and returns a single *element* with the correct type. One-dimensional memoryviews can be indexed with an integer or a one-integer tuple. Multi-dimensional memoryviews can be indexed with tuples of exactly *ndim* integers where *ndim* is the number of dimensions. Zero-dimensional memoryviews can be indexed with the empty tuple.

Here is an example with a non-byte format:

```
>>> import array
>>> a = array.array('l', [-11111111, 22222222, -333
>>> m = memoryview(a)
>>> m[0]
-11111111
>>> m[-1]
44444444
>>> m[::2].tolist()
[-11111111, -33333333]
```

If the underlying object is writable, the memoryview supports one-dimensional slice assignment. Resizing is not allowed:

```
>>> data = bytearray(b'abcefg')
>>> v = memoryview(data)
>>> v.readonly
```

```
False
>>> v[0] = ord(b'z')
>>> data
bytearray(b'zbcefg')
>>> v[1:4] = b'123'
>>> data
bytearray(b'z123fg')
>>> v[2:3] = b'spam'
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: memoryview assignment: lvalue and rvalu
>>> v[2:6] = b'spam'
>>> data
bytearray(b'z1spam')
```

One-dimensional memoryviews of hashable (read-only) types with formats 'B', 'b' or 'c' are also hashable. The hash is defined as `hash(m) == hash(m.tobytes())`:

```
>>> v = memoryview(b'abcefg')
>>> hash(v) == hash(b'abcefg')
True
>>> hash(v[2:4]) == hash(b'ce')
True
>>> hash(v[::-2]) == hash(b'abcefg'[::-2])
True
```

Changed in version 3.3: One-dimensional memoryviews can now be sliced. One-dimensional memoryviews with formats 'B', 'b' or 'c' are now hashable.

Changed in version 3.4: memoryview is now registered automatically with **`collections.abc.Sequence`**

Changed in version 3.5: memoryviews can now be indexed with tuple of integers.

`memoryview` has several methods:

_eq_(*exporter*)

A memoryview and a **PEP 3118** [https://peps.python.org/pep-3118/] exporter are equal if their shapes are equivalent and if all corresponding values are equal when the operands' respective format codes are interpreted using **`struct`** syntax.

For the subset of **`struct`** format strings currently supported by **`tolist()`**, `v` and `w` are equal if `v.tolist() == w.tolist()`:

```
>>> import array
>>> a = array.array('I', [1, 2, 3, 4, 5])
>>> b = array.array('d', [1.0, 2.0, 3.0, 4.0, 5
>>> c = array.array('b', [5, 3, 1])
>>> x = memoryview(a)
>>> y = memoryview(b)
>>> x == a == y == b
True
>>> x.tolist() == a.tolist() == y.tolist() == b
True
>>> z = y[::-2]
>>> z == c
True
>>> z.tolist() == c.tolist()
True
```

If either format string is not supported by the **`struct`** module, then the objects will always compare as unequal (even if the format strings and buffer contents are identical):

```
>>> from ctypes import BigEndianStructure, c_lo
>>> class BEPoint(BigEndianStructure):
...     _fields_ = [("x", c_long), ("y", c_long
...
>>> point = BEPoint(100, 200)
>>> a = memoryview(point)
>>> b = memoryview(point)
>>> a == point
False
```

```
>>> a == b
False
```

Note that, as with floating point numbers, `v is w` does *not* imply `v == w` for memoryview objects.

Changed in version 3.3: Previous versions compared the raw memory disregarding the item format and the logical array structure.

tobytes(*order='C'*)

Return the data in the buffer as a bytestring. This is equivalent to calling the **bytes** constructor on the memoryview.

```
>>> m = memoryview(b"abc")
>>> m.tobytes()
b'abc'
>>> bytes(m)
b'abc'
```

For non-contiguous arrays the result is equal to the flattened list representation with all elements converted to bytes. **tobytes()** supports all format strings, including those that are not in **struct** module syntax.

New in version 3.8: order can be {'C', 'F', 'A'}. When *order* is 'C' or 'F', the data of the original array is converted to C or Fortran order. For contiguous views, 'A' returns an exact copy of the physical memory. In particular, in-memory Fortran order is preserved. For non-contiguous views, the data is converted to C first. *order=None* is the same as *order='C'*.

hex([*sep*[, *bytes_per_sep*]])

Return a string object containing two hexadecimal digits for each byte in the buffer.

```
>>> m = memoryview(b"abc")
```

```
>>> m.hex()
'616263'
```

New in version 3.5.

Changed in version 3.8: Similar to **bytes.hex()**, **memoryview.hex()** now supports optional *sep* and *bytes_per_sep* parameters to insert separators between bytes in the hex output.

tolist()

Return the data in the buffer as a list of elements.

```
>>> memoryview(b'abc').tolist()
[97, 98, 99]
>>> import array
>>> a = array.array('d', [1.1, 2.2, 3.3])
>>> m = memoryview(a)
>>> m.tolist()
[1.1, 2.2, 3.3]
```

Changed in version 3.3: **tolist()** now supports all single character native formats in **struct** module syntax as well as multi-dimensional representations.

toreadonly()

Return a readonly version of the memoryview object. The original memoryview object is unchanged.

```
>>> m = memoryview(bytearray(b'abc'))
>>> mm = m.toreadonly()
>>> mm.tolist()
[89, 98, 99]
>>> mm[0] = 42
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot modify read-only memory
>>> m[0] = 43
>>> mm.tolist()
```

```
[43, 98, 99]
```

New in version 3.8.

release()

Release the underlying buffer exposed by the memoryview object. Many objects take special actions when a view is held on them (for example, a **bytearray** would temporarily forbid resizing); therefore, calling release() is handy to remove these restrictions (and free any dangling resources) as soon as possible.

After this method has been called, any further operation on the view raises a **ValueError** (except **release()** itself which can be called multiple times):

```
>>> m = memoryview(b'abc')
>>> m.release()
>>> m[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: operation forbidden on released mem
```

The context management protocol can be used for a similar effect, using the `with` statement:

```
>>> with memoryview(b'abc') as m:
...     m[0]
...
97
>>> m[0]
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: operation forbidden on released mem
```

New in version 3.2.

cast(*format*[, *shape*])

Cast a memoryview to a new format or shape. *shape* defaults to `[byte_length//new_itemsize]`, which means that the result view will be one-dimensional. The return value is a new memoryview, but the buffer itself is not copied. Supported casts are 1D -> C-contiguous and C-contiguous -> 1D.

The destination format is restricted to a single element native format in **`struct`** syntax. One of the formats must be a byte format ('B', 'b' or 'c'). The byte length of the result must be the same as the original length.

Cast 1D/long to 1D/unsigned bytes:

```
>>> import array
>>> a = array.array('l', [1,2,3])
>>> x = memoryview(a)
>>> x.format
'l'
>>> x.itemsize
8
>>> len(x)
3
>>> x.nbytes
24
>>> y = x.cast('B')
>>> y.format
'B'
>>> y.itemsize
1
>>> len(y)
24
>>> y.nbytes
24
```

Cast 1D/unsigned bytes to 1D/char:

```
>>> b = bytearray(b'zyz')
>>> x = memoryview(b)
>>> x[0] = b'a'
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: memoryview: invalid value for forma
>>> y = x.cast('c')
>>> y[0] = b'a'
>>> b
bytearray(b'ayz')
```

Cast 1D/bytes to 3D/ints to 1D/signed char:

```
>>> import struct
>>> buf = struct.pack("i"*12, *list(range(12)))
>>> x = memoryview(buf)
>>> y = x.cast('i', shape=[2,2,3])
>>> y.tolist()
[[[0, 1, 2], [3, 4, 5]], [[6, 7, 8], [9, 10, 11
>>> y.format
'i'
>>> y.itemsize
4
>>> len(y)
2
>>> y.nbytes
48
>>> z = y.cast('b')
>>> z.format
'b'
>>> z.itemsize
1
>>> len(z)
48
>>> z.nbytes
48
```

Cast 1D/unsigned long to 2D/unsigned long:

```
>>> buf = struct.pack("L"*6, *list(range(6)))
>>> x = memoryview(buf)
>>> y = x.cast('L', shape=[2,3])
```

```
>>> len(y)
2
>>> y.nbytes
48
>>> y.tolist()
[[0, 1, 2], [3, 4, 5]]
```

New in version 3.3.

Changed in version 3.5: The source format is no longer restricted when casting to a byte view.

There are also several readonly attributes available:

obj

The underlying object of the memoryview:

```
>>> b  = bytearray(b'xyz')
>>> m = memoryview(b)
>>> m.obj is b
True
```

New in version 3.3.

nbytes

`nbytes == product(shape) * itemsize == len(m.tobytes())`. This is the amount of space in bytes that the array would use in a contiguous representation. It is not necessarily equal to `len(m)`:

```
>>> import array
>>> a = array.array('i', [1,2,3,4,5])
>>> m = memoryview(a)
>>> len(m)
5
>>> m.nbytes
20
>>> y = m[::2]
>>> len(y)
```

```
3
>>> y.nbytes
12
>>> len(y.tobytes())
12
```

Multi-dimensional arrays:

```
>>> import struct
>>> buf = struct.pack("d"*12, *[1.5*x for x in
>>> x = memoryview(buf)
>>> y = x.cast('d', shape=[3,4])
>>> y.tolist()
[[0.0, 1.5, 3.0, 4.5], [6.0, 7.5, 9.0, 10.5], |
>>> len(y)
3
>>> y.nbytes
96
```

New in version 3.3.

readonly

A bool indicating whether the memory is read only.

format

A string containing the format (in **`struct`** module style) for each element in the view. A memoryview can be created from exporters with arbitrary format strings, but some methods (e.g. **`tolist()`**) are restricted to native single element formats.

Changed in version 3.3: format `'B'` is now handled according to the struct module syntax. This means that `memoryview(b'abc')[0] == b'abc'[0] == 97`.

itemsize

The size in bytes of each element of the memoryview:

```
>>> import array, struct
```

```
>>> m = memoryview(array.array('H', [32000, 320
>>> m.itemsize
2
>>> m[0]
32000
>>> struct.calcsize('H') == m.itemsize
True
```

ndim

An integer indicating how many dimensions of a multi-dimensional array the memory represents.

shape

A tuple of integers the length of **ndim** giving the shape of the memory as an N-dimensional array.

Changed in version 3.3: An empty tuple instead of `None` when ndim = 0.

strides

A tuple of integers the length of **ndim** giving the size in bytes to access each element for each dimension of the array.

Changed in version 3.3: An empty tuple instead of `None` when ndim = 0.

suboffsets

Used internally for PIL-style arrays. The value is informational only.

c_contiguous

A bool indicating whether the memory is C-contiguous.

New in version 3.3.

f_contiguous

A bool indicating whether the memory is Fortran

contiguous.

New in version 3.3.

contiguous
: A bool indicating whether the memory is contiguous.

  New in version 3.3.

Set Types — `set`, `frozenset`

A *set* object is an unordered collection of distinct hashable objects. Common uses include membership testing, removing duplicates from a sequence, and computing mathematical operations such as intersection, union, difference, and symmetric difference. (For other containers see the built-in `dict`, `list`, and `tuple` classes, and the `collections` module.)

Like other collections, sets support `x in set`, `len(set)`, and `for x in set`. Being an unordered collection, sets do not record element position or order of insertion. Accordingly, sets do not support indexing, slicing, or other sequence-like behavior.

There are currently two built-in set types, `set` and `frozenset`. The `set` type is mutable — the contents can be changed using methods like `add()` and `remove()`. Since it is mutable, it has no hash value and cannot be used as either a dictionary key or as an element of another set. The `frozenset` type is immutable and hashable — its contents cannot be altered after it is created; it can therefore be used as a dictionary key or as an element of another set.

Non-empty sets (not frozensets) can be created by placing a comma-separated list of elements within braces, for example: `{'jack', 'sjoerd'}`, in addition to the `set` constructor.

The constructors for both classes work the same:

class set([*iterable*])

class frozenset([*iterable*])

Return a new set or frozenset object whose elements are taken from *iterable*. The elements of a set must be hashable. To represent sets of sets, the inner sets must be **`frozenset`** objects. If *iterable* is not specified, a new empty set is returned.

Sets can be created by several means:

- Use a comma-separated list of elements within braces: `{'jack', 'sjoerd'}`
- Use a set comprehension: `{c for c in 'abracadabra' if c not in 'abc'}`
- Use the type constructor: `set()`, `set('foobar')`, `set(['a', 'b', 'foo'])`

Instances of **`set`** and **`frozenset`** provide the following operations:

len(s)

Return the number of elements in set *s* (cardinality of *s*).

x in s

Test *x* for membership in *s*.

x not in s

Test *x* for non-membership in *s*.

isdisjoint(*other*)

Return `True` if the set has no elements in common with *other*. Sets are disjoint if and only if their intersection is the empty set.

issubset(*other*)
set <= other

Test whether every element in the set is in *other*.

set < other

Test whether the set is a proper subset of *other*, that is, `set <= other and set != other`.

issuperset(*other*)
set >= other

Test whether every element in *other* is in the set.

set > other

Test whether the set is a proper superset of *other*, that is, `set >= other and set != other`.

union(**others*)
set | other | ...

Return a new set with elements from the set and all others.

intersection(**others*)
set & other & ...

Return a new set with elements common to the set and all others.

difference(**others*)
set - other - ...

Return a new set with elements in the set that are not in the others.

symmetric_difference(*other*)
set ^ other

Return a new set with elements in either the set or *other* but not both.

copy()

Return a shallow copy of the set.

Note, the non-operator versions of **`union()`**,

`intersection()`, **`difference()`**, **`symmetric_difference()`**, **`issubset()`**, and **`issuperset()`** methods will accept any iterable as an argument. In contrast, their operator based counterparts require their arguments to be sets. This precludes error-prone constructions like `set('abc') & 'cbs'` in favor of the more readable `set('abc').intersection('cbs')`.

Both **`set`** and **`frozenset`** support set to set comparisons. Two sets are equal if and only if every element of each set is contained in the other (each is a subset of the other). A set is less than another set if and only if the first set is a proper subset of the second set (is a subset, but is not equal). A set is greater than another set if and only if the first set is a proper superset of the second set (is a superset, but is not equal).

Instances of **`set`** are compared to instances of **`frozenset`** based on their members. For example, `set('abc') == frozenset('abc')` returns `True` and so does `set('abc') in set([frozenset('abc')])`.

The subset and equality comparisons do not generalize to a total ordering function. For example, any two nonempty disjoint sets are not equal and are not subsets of each other, so *all* of the following return `False`: `a<b`, `a==b`, or `a>b`.

Since sets only define partial ordering (subset relationships), the output of the **`list.sort()`** method is undefined for lists of sets.

Set elements, like dictionary keys, must be hashable.

Binary operations that mix **`set`** instances with **`frozenset`** return the type of the first operand. For example: `frozenset('ab') | set('bc')` returns an instance of **`frozenset`**.

The following table lists operations available for **`set`** that do not apply to immutable instances of **`frozenset`**:

update(**others*)

set |= other | ...

Update the set, adding elements from all others.

intersection_update(*others)
set &= other & ...

Update the set, keeping only elements found in it and all others.

difference_update(*others)
set -= other | ...

Update the set, removing elements found in others.

symmetric_difference_update(*other*)
set ^= other

Update the set, keeping only elements found in either set, but not in both.

add(*elem*)

Add element *elem* to the set.

remove(*elem*)

Remove element *elem* from the set. Raises `KeyError` if *elem* is not contained in the set.

discard(*elem*)

Remove element *elem* from the set if it is present.

pop()

Remove and return an arbitrary element from the set. Raises `KeyError` if the set is empty.

clear()

Remove all elements from the set.

Note, the non-operator versions of the `update()`,

intersection_update(), **difference_update()**, and **symmetric_difference_update()** methods will accept any iterable as an argument.

Note, the *elem* argument to the **__contains__()**, **remove()**, and **discard()** methods may be a set. To support searching for an equivalent frozenset, a temporary one is created from *elem*.

Mapping Types — dict

A mapping object maps hashable values to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the *dictionary*. (For other containers see the built-in **list**, **set**, and **tuple** classes, and the **collections** module.)

A dictionary's keys are *almost* arbitrary values. Values that are not hashable, that is, values containing lists, dictionaries or other mutable types (that are compared by value rather than by object identity) may not be used as keys. Values that compare equal (such as `1`, `1.0`, and `True`) can be used interchangeably to index the same dictionary entry.

class dict(***kwargs*)
class dict(*mapping*, ***kwargs*)
class dict(*iterable*, ***kwargs*)

Return a new dictionary initialized from an optional positional argument and a possibly empty set of keyword arguments.

Dictionaries can be created by several means:

- Use a comma-separated list of `key: value` pairs within braces: `{'jack': 4098, 'sjoerd': 4127}` or `{4098: 'jack', 4127: 'sjoerd'}`
- Use a dict comprehension: `{}`, `{x: x ** 2 for x in range(10)}`
- Use the type constructor: `dict()`, `dict([('foo', 100), ('bar', 200)])`, `dict(foo=100,`

```
    bar=200)
```

If no positional argument is given, an empty dictionary is created. If a positional argument is given and it is a mapping object, a dictionary is created with the same key-value pairs as the mapping object. Otherwise, the positional argument must be an iterable object. Each item in the iterable must itself be an iterable with exactly two objects. The first object of each item becomes a key in the new dictionary, and the second object the corresponding value. If a key occurs more than once, the last value for that key becomes the corresponding value in the new dictionary.

If keyword arguments are given, the keyword arguments and their values are added to the dictionary created from the positional argument. If a key being added is already present, the value from the keyword argument replaces the value from the positional argument.

To illustrate, the following examples all return a dictionary equal to `{"one": 1, "two": 2, "three": 3}`:

```
>>> a = dict(one=1, two=2, three=3)
>>> b = {'one': 1, 'two': 2, 'three': 3}
>>> c = dict(zip(['one', 'two', 'three'], [1, 2, 3]))
>>> d = dict([('two', 2), ('one', 1), ('three', 3)])
>>> e = dict({'three': 3, 'one': 1, 'two': 2})
>>> f = dict({'one': 1, 'three': 3}, two=2)
>>> a == b == c == d == e == f
True
```

Providing keyword arguments as in the first example only works for keys that are valid Python identifiers. Otherwise, any valid keys can be used.

These are the operations that dictionaries support (and therefore, custom mapping types should support too):

list(d)

Return a list of all the keys used in the dictionary *d*.

len(d)

Return the number of items in the dictionary *d*.

d[key]

Return the item of *d* with key *key*. Raises a **KeyError** if *key* is not in the map.

If a subclass of dict defines a method **__missing__()** and *key* is not present, the `d[key]` operation calls that method with the key *key* as argument. The `d[key]` operation then returns or raises whatever is returned or raised by the `__missing__(key)` call. No other operations or methods invoke **__missing__()**. If **__missing__()** is not defined, **KeyError** is raised. **__missing__()** must be a method; it cannot be an instance variable:

```
>>> class Counter(dict):
...     def __missing__(self, key):
...         return 0
>>> c = Counter()
>>> c['red']
0
>>> c['red'] += 1
>>> c['red']
1
```

The example above shows part of the implementation of **collections.Counter**. A different `__missing__` method is used by **collections.defaultdict**.

d[key] = value

Set `d[key]` to *value*.

del d[key]

Remove `d[key]` from *d*. Raises a **KeyError** if *key* is not in the map.

key in d

Return `True` if *d* has a key *key*, else `False`.

key not in d

Equivalent to `not key in d`.

iter(d)

Return an iterator over the keys of the dictionary. This is a shortcut for `iter(d.keys())`.

clear()

Remove all items from the dictionary.

copy()

Return a shallow copy of the dictionary.

classmethod fromkeys(*iterable*[, *value*])

Create a new dictionary with keys from *iterable* and values set to *value*.

`fromkeys()` is a class method that returns a new dictionary. *value* defaults to `None`. All of the values refer to just a single instance, so it generally doesn't make sense for *value* to be a mutable object such as an empty list. To get distinct values, use a dict comprehension instead.

get(*key*[, *default*])

Return the value for *key* if *key* is in the dictionary, else *default*. If *default* is not given, it defaults to `None`, so that this method never raises a **`KeyError`**.

items()

Return a new view of the dictionary's items (`(key, value)` pairs). See the documentation of view objects.

keys()

Return a new view of the dictionary's keys. See the documentation of view objects.

pop(*key*[, *default*])

If *key* is in the dictionary, remove it and return its value, else return *default*. If *default* is not given and *key* is not in the dictionary, a **`KeyError`** is raised.

popitem()

Remove and return a `(key, value)` pair from the dictionary. Pairs are returned in LIFO order.

`popitem()` is useful to destructively iterate over a dictionary, as often used in set algorithms. If the dictionary is empty, calling **`popitem()`** raises a **`KeyError`**.

Changed in version 3.7: LIFO order is now guaranteed. In prior versions, **`popitem()`** would return an arbitrary key/value pair.

reversed(d)

Return a reverse iterator over the keys of the dictionary. This is a shortcut for `reversed(d.keys())`.

New in version 3.8.

setdefault(*key*[, *default*])

If *key* is in the dictionary, return its value. If not, insert *key* with a value of *default* and return *default*. *default* defaults to `None`.

update([*other*])

Update the dictionary with the key/value pairs from *other*, overwriting existing keys. Return `None`.

update() accepts either another dictionary object or an iterable of key/value pairs (as tuples or other iterables of length two). If keyword arguments are specified, the dictionary is then updated with those key/value pairs: `d.update(red=1, blue=2)`.

values()

Return a new view of the dictionary's values. See the documentation of view objects.

An equality comparison between one `dict.values()` view and another will always return `False`. This also applies when comparing `dict.values()` to itself:

```
>>> d = {'a': 1}
>>> d.values() == d.values()
False
```

d | other

Create a new dictionary with the merged keys and values of *d* and *other*, which must both be dictionaries. The values of *other* take priority when *d* and *other* share keys.

New in version 3.9.

d |= other

Update the dictionary *d* with keys and values from *other*, which may be either a mapping or an iterable of key/value pairs. The values of *other* take priority when *d* and *other* share keys.

New in version 3.9.

Dictionaries compare equal if and only if they have the same `(key, value)` pairs (regardless of ordering). Order comparisons ('<', '<=', '>=', '>') raise **TypeError**.

Dictionaries preserve insertion order. Note that updating a

key does not affect the order. Keys added after deletion are inserted at the end.

```
>>> d = {"one": 1, "two": 2, "three": 3, "four": 4}
>>> d
{'one': 1, 'two': 2, 'three': 3, 'four': 4}
>>> list(d)
['one', 'two', 'three', 'four']
>>> list(d.values())
[1, 2, 3, 4]
>>> d["one"] = 42
>>> d
{'one': 42, 'two': 2, 'three': 3, 'four': 4}
>>> del d["two"]
>>> d["two"] = None
>>> d
{'one': 42, 'three': 3, 'four': 4, 'two': None}
```

Changed in version 3.7: Dictionary order is guaranteed to be insertion order. This behavior was an implementation detail of CPython from 3.6.

Dictionaries and dictionary views are reversible.

```
>>> d = {"one": 1, "two": 2, "three": 3, "four": 4}
>>> d
{'one': 1, 'two': 2, 'three': 3, 'four': 4}
>>> list(reversed(d))
['four', 'three', 'two', 'one']
>>> list(reversed(d.values()))
[4, 3, 2, 1]
>>> list(reversed(d.items()))
[('four', 4), ('three', 3), ('two', 2), ('one', 1)]
```

Changed in version 3.8: Dictionaries are now reversible.

See also

types.MappingProxyType can be used to create a read-only

view of a **dict**.

Dictionary view objects

The objects returned by **dict.keys()**, **dict.values()** and **dict.items()** are *view objects*. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes.

Dictionary views can be iterated over to yield their respective data, and support membership tests:

len(dictview)

Return the number of entries in the dictionary.

iter(dictview)

Return an iterator over the keys, values or items (represented as tuples of `(key, value)`) in the dictionary.

Keys and values are iterated over in insertion order. This allows the creation of `(value, key)` pairs using **zip()**: `pairs = zip(d.values(), d.keys())`. Another way to create the same list is `pairs = [(v, k) for (k, v) in d.items()]`.

Iterating views while adding or deleting entries in the dictionary may raise a **RuntimeError** or fail to iterate over all entries.

Changed in version 3.7: Dictionary order is guaranteed to be insertion order.

x in dictview

Return `True` if *x* is in the underlying dictionary's keys, values or items (in the latter case, *x* should be a `(key, value)` tuple).

reversed(dictview)

Return a reverse iterator over the keys, values or items of the

dictionary. The view will be iterated in reverse order of the insertion.

Changed in version 3.8: Dictionary views are now reversible.

dictview.mapping

Return a **types.MappingProxyType** that wraps the original dictionary to which the view refers.

New in version 3.10.

Keys views are set-like since their entries are unique and hashable. If all values are hashable, so that `(key, value)` pairs are unique and hashable, then the items view is also set-like. (Values views are not treated as set-like since the entries are generally not unique.) For set-like views, all of the operations defined for the abstract base class **collections.abc.Set** are available (for example, `==`, `<`, or `^`).

An example of dictionary view usage:

```
>>> dishes = {'eggs': 2, 'sausage': 1, 'bacon': 1, 'spam
>>> keys = dishes.keys()
>>> values = dishes.values()

>>> # iteration
>>> n = 0
>>> for val in values:
...     n += val
>>> print(n)
504

>>> # keys and values are iterated over in the same orde
>>> list(keys)
['eggs', 'sausage', 'bacon', 'spam']
>>> list(values)
[2, 1, 1, 500]

>>> # view objects are dynamic and reflect dict changes
```

```
>>> del dishes['eggs']
>>> del dishes['sausage']
>>> list(keys)
['bacon', 'spam']

>>> # set operations
>>> keys & {'eggs', 'bacon', 'salad'}
{'bacon'}
>>> keys ^ {'sausage', 'juice'}
{'juice', 'sausage', 'bacon', 'spam'}

>>> # get back a read-only proxy for the original dictio
>>> values.mapping
mappingproxy({'bacon': 1, 'spam': 500})
>>> values.mapping['spam']
500
```

Context Manager Types

Python's **with** statement supports the concept of a runtime context defined by a context manager. This is implemented using a pair of methods that allow user-defined classes to define a runtime context that is entered before the statement body is executed and exited when the statement ends:

contextmanager._enter_()

> Enter the runtime context and return either this object or another object related to the runtime context. The value returned by this method is bound to the identifier in the **as** clause of **with** statements using this context manager.
>
> An example of a context manager that returns itself is a file object. File objects return themselves from _enter_() to allow **open()** to be used as the context expression in a **with** statement.
>
> An example of a context manager that returns a related object is the one returned by **decimal.localcontext()**. These managers set the active decimal context to a copy of the

original decimal context and then return the copy. This allows changes to be made to the current decimal context in the body of the **with** statement without affecting code outside the **with** statement.

contextmanager.__exit__(*exc_type*, *exc_val*, *exc_tb*)

Exit the runtime context and return a Boolean flag indicating if any exception that occurred should be suppressed. If an exception occurred while executing the body of the **with** statement, the arguments contain the exception type, value and traceback information. Otherwise, all three arguments are `None`.

Returning a true value from this method will cause the **with** statement to suppress the exception and continue execution with the statement immediately following the **with** statement. Otherwise the exception continues propagating after this method has finished executing. Exceptions that occur during execution of this method will replace any exception that occurred in the body of the **with** statement.

The exception passed in should never be reraised explicitly - instead, this method should return a false value to indicate that the method completed successfully and does not want to suppress the raised exception. This allows context management code to easily detect whether or not an **__exit__()** method has actually failed.

Python defines several context managers to support easy thread synchronisation, prompt closure of files or other objects, and simpler manipulation of the active decimal arithmetic context. The specific types are not treated specially beyond their implementation of the context management protocol. See the **contextlib** module for some examples.

Python's generators and the **contextlib.contextmanager** decorator provide a convenient way to implement these protocols. If a generator function is decorated with the **contextlib.contextmanager** decorator, it will return a context manager implementing the necessary **__enter__()** and

`__exit__()` methods, rather than the iterator produced by an undecorated generator function.

Note that there is no specific slot for any of these methods in the type structure for Python objects in the Python/C API. Extension types wanting to define these methods must provide them as a normal Python accessible method. Compared to the overhead of setting up the runtime context, the overhead of a single class dictionary lookup is negligible.

Type Annotation Types — Generic Alias, Union

The core built-in types for type annotations are Generic Alias and Union.

Generic Alias Type

`GenericAlias` objects are generally created by subscripting a class. They are most often used with container classes, such as **`list`** or **`dict`**. For example, `list[int]` is a `GenericAlias` object created by subscripting the `list` class with the argument **`int`**. `GenericAlias` objects are intended primarily for use with type annotations.

> **Note**
>
> It is generally only possible to subscript a class if the class implements the special method **`__class_getitem__()`**.

A `GenericAlias` object acts as a proxy for a generic type, implementing *parameterized generics*.

For a container class, the argument(s) supplied to a subscription of the class may indicate the type(s) of the elements an object contains. For example, `set[bytes]` can be used in type annotations to signify a **`set`** in which all the elements are of type **`bytes`**.

For a class which defines **`__class_getitem__()`** but is not a container, the argument(s) supplied to a subscription of the class will often indicate the return type(s) of one or more methods defined on an object. For example, **regular expressions** can be used on both the **`str`** data type and the **`bytes`** data type:

- If `x = re.search('foo', 'foo')`, `x` will be a re.Match object where the return values of `x.group(0)` and `x[0]` will both be of type **`str`**. We can represent this kind of object in type annotations with the `GenericAlias` `re.Match[str]`.
- If `y = re.search(b'bar', b'bar')`, (note the `b` for **`bytes`**), `y` will also be an instance of `re.Match`, but the return values of `y.group(0)` and `y[0]` will both be of type **`bytes`**. In type annotations, we would represent this variety of re.Match objects with `re.Match[bytes]`.

`GenericAlias` objects are instances of the class **`types.GenericAlias`**, which can also be used to create `GenericAlias` objects directly.

T[X, Y, ...]

Creates a `GenericAlias` representing a type `T` parameterized by types *X*, *Y*, and more depending on the `T` used. For example, a function expecting a **`list`** containing **`float`** elements:

```
def average(values: list[float]) -> float:
    return sum(values) / len(values)
```

Another example for mapping objects, using a **`dict`**, which is a generic type expecting two type parameters representing the key type and the value type. In this example, the function expects a `dict` with keys of type **`str`** and values of type **`int`**:

```
def send_post_request(url: str, body: dict[str, int
    ...
```

The builtin functions **`isinstance()`** and **`issubclass()`** do not

accept `GenericAlias` types for their second argument:

```
>>> isinstance([1, 2], list[str])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: isinstance() argument 2 cannot be a parameter
```

The Python runtime does not enforce type annotations. This extends to generic types and their type parameters. When creating a container object from a `GenericAlias`, the elements in the container are not checked against their type. For example, the following code is discouraged, but will run without errors:

```
>>> t = list[str]
>>> t([1, 2, 3])
[1, 2, 3]
```

Furthermore, parameterized generics erase type parameters during object creation:

```
>>> t = list[str]
>>> type(t)
<class 'types.GenericAlias'>

>>> l = t()
>>> type(l)
<class 'list'>
```

Calling **`repr()`** or **`str()`** on a generic shows the parameterized type:

```
>>> repr(list[int])
'list[int]'

>>> str(list[int])
'list[int]'
```

The **`__getitem__()`** method of generic containers will raise an exception to disallow mistakes like `dict[str][str]`:

```
>>> dict[str][str]
```

```
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: There are no type variables left in dict[str]
```

However, such expressions are valid when type variables are used. The index must have as many elements as there are type variable items in the `GenericAlias` object's **`__args__`**.

```
>>> from typing import TypeVar
>>> Y = TypeVar('Y')
>>> dict[str, Y][int]
dict[str, int]
```

Standard Generic Classes

The following standard library classes support parameterized generics. This list is non-exhaustive.

- **`tuple`**
- **`list`**
- **`dict`**
- **`set`**
- **`frozenset`**
- **`type`**
- **`collections.deque`**
- **`collections.defaultdict`**
- **`collections.OrderedDict`**
- **`collections.Counter`**
- **`collections.ChainMap`**
- **`collections.abc.Awaitable`**
- **`collections.abc.Coroutine`**
- **`collections.abc.AsyncIterable`**
- **`collections.abc.AsyncIterator`**
- **`collections.abc.AsyncGenerator`**
- **`collections.abc.Iterable`**
- **`collections.abc.Iterator`**
- **`collections.abc.Generator`**
- **`collections.abc.Reversible`**
- **`collections.abc.Container`**
- **`collections.abc.Collection`**

- collections.abc.Callable
- collections.abc.Set
- collections.abc.MutableSet
- collections.abc.Mapping
- collections.abc.MutableMapping
- collections.abc.Sequence
- collections.abc.MutableSequence
- collections.abc.ByteString
- collections.abc.MappingView
- collections.abc.KeysView
- collections.abc.ItemsView
- collections.abc.ValuesView
- contextlib.AbstractContextManager
- contextlib.AbstractAsyncContextManager
- dataclasses.Field
- functools.cached_property
- functools.partialmethod
- os.PathLike
- queue.LifoQueue
- queue.Queue
- queue.PriorityQueue
- queue.SimpleQueue
- re.Pattern
- re.Match
- shelve.BsdDbShelf
- shelve.DbfilenameShelf
- shelve.Shelf
- types.MappingProxyType
- weakref.WeakKeyDictionary
- weakref.WeakMethod
- weakref.WeakSet
- weakref.WeakValueDictionary

Special Attributes of `GenericAlias` objects

All parameterized generics implement special read-only attributes.

genericalias.__origin__

This attribute points at the non-parameterized generic class:

```
>>> list[int].__origin__
<class 'list'>
```

genericalias._args_

This attribute is a **tuple** (possibly of length 1) of generic types passed to the original **__class_getitem__()** of the generic class:

```
>>> dict[str, list[int]].__args__
(<class 'str'>, list[int])
```

genericalias._parameters_

This attribute is a lazily computed tuple (possibly empty) of unique type variables found in `__args__`:

```
>>> from typing import TypeVar

>>> T = TypeVar('T')
>>> list[T].__parameters__
(~T,)
```

Note

A `GenericAlias` object with **typing.ParamSpec** parameters may not have correct `__parameters__` after substitution because **typing.ParamSpec** is intended primarily for static type checking.

genericalias._unpacked_

A boolean that is true if the alias has been unpacked using the `*` operator (see **TypeVarTuple**).

New in version 3.11.

Introducing Python's framework for type annotations.

PEP 585 **[https://peps.python.org/pep-0585/]** **- Type Hinting Generics In Standard Collections**
Introducing the ability to natively parameterize standard-library classes, provided they implement the special class method `__class_getitem__()`.

Generics, user-defined generics and `typing.Generic`
Documentation on how to implement generic classes that can be parameterized at runtime and understood by static type-checkers.

New in version 3.9.

Union Type

A union object holds the value of the `|` (bitwise or) operation on multiple type objects. These types are intended primarily for type annotations. The union type expression enables cleaner type hinting syntax compared to `typing.Union`.

X | Y | ...
Defines a union object which holds types *X*, *Y*, and so forth. `X | Y` means either X or Y. It is equivalent to `typing.Union[X, Y]`. For example, the following function expects an argument of type `int` or `float`:

```
def square(number: int | float) -> int | float:
    return number ** 2
```

union_object == other
Union objects can be tested for equality with other union objects. Details:

- Unions of unions are flattened:

  ```
  (int | str) | float == int | str | float
  ```

- Redundant types are removed:

```
int | str | int == int | str
```

- When comparing unions, the order is ignored:

  ```
  int | str == str | int
  ```

- It is compatible with **`typing.Union`**:

  ```
  int | str == typing.Union[int, str]
  ```

- Optional types can be spelled as a union with `None`:

  ```
  str | None == typing.Optional[str]
  ```

isinstance(obj, union_object)

issubclass(obj, union_object)

Calls to **`isinstance()`** and **`issubclass()`** are also supported with a union object:

```
>>> isinstance("", int | str)
True
```

However, union objects containing parameterized generics cannot be used:

```
>>> isinstance(1, int | list[int])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: isinstance() argument 2 cannot contain a
```

The user-exposed type for the union object can be accessed from **`types.UnionType`** and used for **`isinstance()`** checks. An object cannot be instantiated from the type:

```
>>> import types
>>> isinstance(int | str, types.UnionType)
True
>>> types.UnionType()
Traceback (most recent call last):
```

```
  File "<stdin>", line 1, in <module>
TypeError: cannot create 'types.UnionType' instances
```

Note

The **__or__()** method for type objects was added to support the syntax `X | Y`. If a metaclass implements **__or__()**, the Union may override it:

```
>>> class M(type):
...     def __or__(self, other):
...         return "Hello"
...
>>> class C(metaclass=M):
...     pass
...
>>> C | int
'Hello'
>>> int | C
int | __main__.C
```

See also

PEP 604 [https://peps.python.org/pep-0604/] – PEP proposing the `X | Y` syntax and the Union type.

New in version 3.10.

Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

Modules

The only special operation on a module is attribute access: `m.name`, where *m* is a module and *name* accesses a name defined in *m*'s symbol table. Module attributes can be assigned to. (Note that

the **`import`** statement is not, strictly speaking, an operation on a module object; `import foo` does not require a module object named *foo* to exist, rather it requires an (external) *definition* for a module named *foo* somewhere.)

A special attribute of every module is **`__dict__`**. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the **`__dict__`** attribute is not possible (you can write `m.__dict__['a'] = 1`, which defines `m.a` to be `1`, but you can't write `m.__dict__ = {}`). Modifying **`__dict__`** directly is not recommended.

Modules built into the interpreter are written like this: `<module 'sys' (built-in)>`. If loaded from a file, they are written as `<module 'os' from '/usr/local/lib/pythonX.Y/os.pyc'>`.

Classes and Class Instances

See Objects, values and types and Class definitions for these.

Functions

Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

See Function definitions for more information.

Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as **`append()`** on lists) and class instance methods. Built-in methods are described

with the types that support them.

If you access a method (a function defined in a class namespace) through an instance, you get a special object: a *bound method* (also called *instance method*) object. When called, it will add the `self` argument to the argument list. Bound methods have two special read-only attributes: `m.__self__` is the object on which the method operates, and `m.__func__` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.__func__(m.__self__, arg-1, arg-2, ..., arg-n)`.

Like function objects, bound method objects support getting arbitrary attributes. However, since method attributes are actually stored on the underlying function object (`meth.__func__`), setting method attributes on bound methods is disallowed. Attempting to set an attribute on a method results in an **`AttributeError`** being raised. In order to set a method attribute, you need to explicitly set it on the underlying function object:

```
>>> class C:
...     def method(self):
...         pass
...
>>> c = C()
>>> c.method.whoami = 'my name is method'  # can't set c
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
AttributeError: 'method' object has no attribute 'whoami
>>> c.method.__func__.whoami = 'my name is method'
>>> c.method.whoami
'my name is method'
```

See The standard type hierarchy for more information.

Code Objects

Code objects are used by the implementation to represent “pseudo-compiled” executable Python code such as a function body. They differ from function objects because they don’t contain a reference

to their global execution environment. Code objects are returned by the built-in **`compile()`** function and can be extracted from function objects through their **`__code__`** attribute. See also the **`code`** module.

Accessing `__code__` raises an auditing event `object.__getattr__` with arguments `obj` and `"__code__"`.

A code object can be executed or evaluated by passing it (instead of a source string) to the **`exec()`** or **`eval()`** built-in functions.

See The standard type hierarchy for more information.

Type Objects

Type objects represent the various object types. An object's type is accessed by the built-in function **`type()`**. There are no special operations on types. The standard module **`types`** defines names for all standard built-in types.

Types are written like this: `<class 'int'>`.

The Null Object

This object is returned by functions that don't explicitly return a value. It supports no special operations. There is exactly one null object, named `None` (a built-in name). `type(None)()` produces the same singleton.

It is written as `None`.

The Ellipsis Object

This object is commonly used by slicing (see Slicings). It supports no special operations. There is exactly one ellipsis object, named **`Ellipsis`** (a built-in name). `type(Ellipsis)()` produces the **`Ellipsis`** singleton.

It is written as `Ellipsis` or `...`.

The NotImplemented Object

This object is returned from comparisons and binary operations when they are asked to operate on types they don't support. See Comparisons for more information. There is exactly one `NotImplemented` object. `type(NotImplemented)()` produces the singleton instance.

It is written as `NotImplemented`.

Boolean Values

Boolean values are the two constant objects `False` and `True`. They are used to represent truth values (although other values can also be considered false or true). In numeric contexts (for example when used as the argument to an arithmetic operator), they behave like the integers 0 and 1, respectively. The built-in function **`bool()`** can be used to convert any value to a Boolean, if the value can be interpreted as a truth value (see section Truth Value Testing above).

They are written as `False` and `True`, respectively.

Internal Objects

See The standard type hierarchy for this information. It describes stack frame objects, traceback objects, and slice objects.

Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant. Some of these are not reported by the **`dir()`** built-in function.

object._dict_

> A dictionary or other mapping object used to store an object's (writable) attributes.

instance._class_

The class to which a class instance belongs.

class.__bases__
: The tuple of base classes of a class object.

definition.__name__
: The name of the class, function, method, descriptor, or generator instance.

definition.__qualname__
: The qualified name of the class, function, method, descriptor, or generator instance.

  New in version 3.3.

class.__mro__
: This attribute is a tuple of classes that are considered when looking for base classes during method resolution.

class.mro()
: This method can be overridden by a metaclass to customize the method resolution order for its instances. It is called at class instantiation, and its result is stored in **__mro__**.

class.__subclasses__()
: Each class keeps a list of weak references to its immediate subclasses. This method returns a list of all those references still alive. The list is in definition order. Example:

```
>>> int.__subclasses__()
[<class 'bool'>]
```

Integer string conversion length limitation

CPython has a global limit for converting between **int** and **str** to

mitigate denial of service attacks. This limit *only* applies to decimal or other non-power-of-two number bases. Hexadecimal, octal, and binary conversions are unlimited. The limit can be configured.

The **`int`** type in CPython is an abitrary length number stored in binary form (commonly known as a "bignum"). There exists no algorithm that can convert a string to a binary integer or a binary integer to a string in linear time, *unless* the base is a power of 2. Even the best known algorithms for base 10 have sub-quadratic complexity. Converting a large value such as `int('1' * 500_000)` can take over a second on a fast CPU.

Limiting conversion size offers a practical way to avoid CVE-2020-10735 [https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2020-10735].

The limit is applied to the number of digit characters in the input or output string when a non-linear conversion algorithm would be involved. Underscores and the sign are not counted towards the limit.

When an operation would exceed the limit, a **`ValueError`** is raised:

```
>>> import sys
>>> sys.set_int_max_str_digits(4300)  # Illustrative, th
>>> _ = int('2' * 5432)
Traceback (most recent call last):
...
ValueError: Exceeds the limit (4300 digits) for integer
>>> i = int('2' * 4300)
>>> len(str(i))
4300
>>> i_squared = i*i
>>> len(str(i_squared))
Traceback (most recent call last):
...
ValueError: Exceeds the limit (4300 digits) for integer
>>> len(hex(i_squared))
7144
```

```
>>> assert int(hex(i_squared), base=16) == i*i  # Hexade
```

The default limit is 4300 digits as provided in **`sys.int_info.default_max_str_digits`**. The lowest limit that can be configured is 640 digits as provided in **`sys.int_info.str_digits_check_threshold`**.

Verification:

```
>>> import sys
>>> assert sys.int_info.default_max_str_digits == 4300,
>>> assert sys.int_info.str_digits_check_threshold == 64
>>> msg = int('578966293710682886880994035146873798396720
...           '92529255143839154833338127435805497794361
...           '571186405732').to_bytes(53, 'big')
...
```

New in version 3.11.

Affected APIs

The limitation only applies to potentially slow conversions between **`int`** and **`str`** or **`bytes`**:

- `int(string)` with default base 10.
- `int(string, base)` for all bases that are not a power of 2.
- `str(integer)`.
- `repr(integer)`
- any other string conversion to base 10, for example `f"{integer}"`, `"{}".format(integer)`, or `b"%d" % integer`.

The limitations do not apply to functions with a linear algorithm:

- `int(string, base)` with base 2, 4, 8, 16, or 32.
- **`int.from_bytes()`** and **`int.to_bytes()`**.
- **`hex()`**, **`oct()`**, **`bin()`**.
- Format Specification Mini-Language for hex, octal, and binary numbers.
- **`str`** to **`float`**.
- **`str`** to **`decimal.Decimal`**.

Configuring the limit

Before Python starts up you can use an environment variable or an interpreter command line flag to configure the limit:

- **PYTHONINTMAXSTRDIGITS**, e.g. `PYTHONINTMAXSTRDIGITS=640 python3` to set the limit to 640 or `PYTHONINTMAXSTRDIGITS=0 python3` to disable the limitation.
- **-X int_max_str_digits**, e.g. `python3 -X int_max_str_digits=640`
- **sys.flags.int_max_str_digits** contains the value of **PYTHONINTMAXSTRDIGITS** or **-X int_max_str_digits**. If both the env var and the `-X` option are set, the `-X` option takes precedence. A value of *-1* indicates that both were unset, thus a value of **sys.int_info.default_max_str_digits** was used during initilization.

From code, you can inspect the current limit and set a new one using these **sys** APIs:

- **sys.get_int_max_str_digits()** and **sys.set_int_max_str_digits()** are a getter and setter for the interpreter-wide limit. Subinterpreters have their own limit.

Information about the default and minimum can be found in **sys.int_info**:

- **sys.int_info.default_max_str_digits** is the compiled-in default limit.
- **sys.int_info.str_digits_check_threshold** is the lowest accepted value for the limit (other than 0 which disables it).

New in version 3.11.

Caution

Setting a low limit *can* lead to problems. While rare, code exists

that contains integer constants in decimal in their source that exceed the minimum threshold. A consequence of setting the limit is that Python source code containing decimal integer literals longer than the limit will encounter an error during parsing, usually at startup time or import time or even at installation time - anytime an up to date `.pyc` does not already exist for the code. A workaround for source that contains such large constants is to convert them to `0x` hexadecimal form as it has no limit.

Test your application thoroughly if you use a low limit. Ensure your tests run with the limit set early via the environment or flag so that it applies during startup and even during any installation step that may invoke Python to precompile `.py` sources to `.pyc` files.

Recommended configuration

The default **`sys.int_info.default_max_str_digits`** is expected to be reasonable for most applications. If your application requires a different limit, set it from your main entry point using Python version agnostic code as these APIs were added in security patch releases in versions before 3.11.

Example:

```
>>> import sys
>>> if hasattr(sys, "set_int_max_str_digits"):
...     upper_bound = 68000
...     lower_bound = 4004
...     current_limit = sys.get_int_max_str_digits()
...     if current_limit == 0 or current_limit > upper_b
...         sys.set_int_max_str_digits(upper_bound)
...     elif current_limit < lower_bound:
...         sys.set_int_max_str_digits(lower_bound)
```

If you need to disable it entirely, set it to `0`.

Footnotes

1

Additional information on these special methods may be found in the Python Reference Manual (Basic customization).

2

As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similarly for tuples.

3

They must have since the parser can't tell the type of the operands.

4(*1*,*2*,*3*,*4*)

Cased characters are those with general category property being one of "Lu" (Letter, uppercase), "Ll" (Letter, lowercase), or "Lt" (Letter, titlecase).

5(*1*,*2*)

To format only a tuple you should therefore provide a singleton tuple whose only element is the tuple to be formatted.

Built-in Exceptions

In Python, all exceptions must be instances of a class that derives from `BaseException`. In a `try` statement with an `except` clause that mentions a particular class, that clause also handles any exception classes derived from that class (but not exception classes from which *it* is derived). Two exception classes that are not related via subclassing are never equivalent, even if they have the same name.

The built-in exceptions listed below can be generated by the interpreter or built-in functions. Except where mentioned, they have an "associated value" indicating the detailed cause of the error. This may be a string or a tuple of several items of information (e.g., an error code and a string explaining the code). The associated value is usually passed as arguments to the exception class's constructor.

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition "just like" the situation in which the interpreter raises the same exception; but beware that there is nothing to prevent user code from raising an inappropriate error.

The built-in exception classes can be subclassed to define new exceptions; programmers are encouraged to derive new exceptions from the `Exception` class or one of its subclasses, and not from `BaseException`. More information on defining exceptions is available in the Python Tutorial under User-defined Exceptions.

Exception context

When raising a new exception while another exception is already being handled, the new exception's `__context__` attribute is automatically set to the handled exception. An exception may be handled when an `except` or `finally` clause, or a `with` statement, is used.

This implicit exception context can be supplemented with an explicit cause by using **`from`** with **`raise`**:

```
raise new_exc from original_exc
```

The expression following **`from`** must be an exception or `None`. It will be set as **`__cause__`** on the raised exception. Setting **`__cause__`** also implicitly sets the **`__suppress_context__`** attribute to `True`, so that using `raise new_exc from None` effectively replaces the old exception with the new one for display purposes (e.g. converting **`KeyError`** to **`AttributeError`**), while leaving the old exception available in **`__context__`** for introspection when debugging.

The default traceback display code shows these chained exceptions in addition to the traceback for the exception itself. An explicitly chained exception in **`__cause__`** is always shown when present. An implicitly chained exception in **`__context__`** is shown only if **`__cause__`** is **`None`** and **`__suppress_context__`** is false.

In either case, the exception itself is always shown after any chained exceptions so that the final line of the traceback always shows the last exception that was raised.

Inheriting from built-in exceptions

User code can create subclasses that inherit from an exception type. It's recommended to only subclass one exception type at a time to avoid any possible conflicts between how the bases handle the `args` attribute, as well as due to possible memory layout incompatibilities.

CPython implementation detail: Most built-in exceptions are implemented in C for efficiency, see: Objects/exceptions.c [https://github.com/python/cpython/tree/3.11/Objects/exceptions.c]. Some have custom memory layouts which makes it impossible to create a subclass that inherits from multiple exception types. The memory layout of a type is an implementation detail and might change between Python versions, leading to new conflicts in the future. Therefore, it's recommended to avoid subclassing multiple

exception types altogether.

Base classes

The following exceptions are used mostly as base classes for other exceptions.

exception BaseException

The base class for all built-in exceptions. It is not meant to be directly inherited by user-defined classes (for that, use **`Exception`**). If **`str()`** is called on an instance of this class, the representation of the argument(s) to the instance are returned, or the empty string when there were no arguments.

args

The tuple of arguments given to the exception constructor. Some built-in exceptions (like **`OSError`**) expect a certain number of arguments and assign a special meaning to the elements of this tuple, while others are usually called only with a single string giving an error message.

with_traceback(*tb*)

This method sets *tb* as the new traceback for the exception and returns the exception object. It was more commonly used before the exception chaining features of **PEP 3134** [https://peps.python.org/pep-3134/] became available. The following example shows how we can convert an instance of `SomeException` into an instance of `OtherException` while preserving the traceback. Once raised, the current frame is pushed onto the traceback of the `OtherException`, as would have happened to the traceback of the original `SomeException` had we allowed it to propagate to the caller.

```
try:
    ...
except SomeException:
```

```
tb = sys.exc_info()[2]
raise OtherException(...).with_traceback(tb
```

add_note(*note*)

Add the string `note` to the exception's notes which appear in the standard traceback after the exception string. A **`TypeError`** is raised if `note` is not a string.

New in version 3.11.

notes

A list of the notes of this exception, which were added with **`add_note()`**. This attribute is created when **`add_note()`** is called.

New in version 3.11.

exception Exception

All built-in, non-system-exiting exceptions are derived from this class. All user-defined exceptions should also be derived from this class.

exception ArithmeticError

The base class for those built-in exceptions that are raised for various arithmetic errors: **`OverflowError`**, **`ZeroDivisionError`**, **`FloatingPointError`**.

exception BufferError

Raised when a buffer related operation cannot be performed.

exception LookupError

The base class for the exceptions that are raised when a key or index used on a mapping or sequence is invalid: **`IndexError`**, **`KeyError`**. This can be raised directly by **`codecs.lookup()`**.

Concrete exceptions

The following exceptions are the exceptions that are usually raised.

exception AssertionError

Raised when an **`assert`** statement fails.

exception AttributeError

Raised when an attribute reference (see Attribute references) or assignment fails. (When an object does not support attribute references or attribute assignments at all, **`TypeError`** is raised.)

The **`name`** and **`obj`** attributes can be set using keyword-only arguments to the constructor. When set they represent the name of the attribute that was attempted to be accessed and the object that was accessed for said attribute, respectively.

Changed in version 3.10: Added the **`name`** and **`obj`** attributes.

exception EOFError

Raised when the **`input()`** function hits an end-of-file condition (EOF) without reading any data. (N.B.: the **`io.IOBase.read()`** and **`io.IOBase.readline()`** methods return an empty string when they hit EOF.)

exception FloatingPointError

Not currently used.

exception GeneratorExit

Raised when a generator or coroutine is closed; see **`generator.close()`** and **`coroutine.close()`**. It directly inherits from **`BaseException`** instead of **`Exception`** since it is technically not an error.

exception ImportError

Raised when the **`import`** statement has troubles trying to load a module. Also raised when the "from list" in `from ... import` has a name that cannot be found.

The **`name`** and **`path`** attributes can be set using keyword-

only arguments to the constructor. When set they represent the name of the module that was attempted to be imported and the path to any file which triggered the exception, respectively.

Changed in version 3.3: Added the **name** and **path** attributes.

exception ModuleNotFoundError

A subclass of **ImportError** which is raised by **import** when a module could not be located. It is also raised when `None` is found in **sys.modules**.

New in version 3.6.

exception IndexError

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not an integer, **TypeError** is raised.)

exception KeyError

Raised when a mapping (dictionary) key is not found in the set of existing keys.

exception KeyboardInterrupt

Raised when the user hits the interrupt key (normally `Control-C` or `Delete`). During execution, a check for interrupts is made regularly. The exception inherits from **BaseException** so as to not be accidentally caught by code that catches **Exception** and thus prevent the interpreter from exiting.

Note

Catching a **KeyboardInterrupt** requires special consideration. Because it can be raised at unpredictable points, it may, in some circumstances, leave the running program in an inconsistent state. It is generally best to allow **KeyboardInterrupt** to end the program as quickly as possible or avoid raising it entirely. (See Note

on Signal Handlers and Exceptions.)

exception MemoryError

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C's **`malloc()`** function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.

exception NameError

Raised when a local or global name is not found. This applies only to unqualified names. The associated value is an error message that includes the name that could not be found.

The **`name`** attribute can be set using a keyword-only argument to the constructor. When set it represent the name of the variable that was attempted to be accessed.

Changed in version 3.10: Added the **`name`** attribute.

exception NotImplementedError

This exception is derived from **`RuntimeError`**. In user defined base classes, abstract methods should raise this exception when they require derived classes to override the method, or while the class is being developed to indicate that the real implementation still needs to be added.

Note

It should not be used to indicate that an operator or method is not meant to be supported at all – in that case either leave the operator / method undefined or, if a subclass, set it to **`None`**.

Note

`NotImplementedError` and `NotImplemented` are not interchangeable, even though they have similar names and purposes. See **`NotImplemented`** for details on when to use it.

exception OSError([*arg*])
exception OSError(*errno*, *strerror*[, *filename*[, *winerror*[, *filename2*]]])

This exception is raised when a system function returns a system-related error, including I/O failures such as “file not found” or “disk full” (not for illegal argument types or other incidental errors).

The second form of the constructor sets the corresponding attributes, described below. The attributes default to **`None`** if not specified. For backwards compatibility, if three arguments are passed, the **`args`** attribute contains only a 2-tuple of the first two constructor arguments.

The constructor often actually returns a subclass of **`OSError`**, as described in OS exceptions below. The particular subclass depends on the final **`errno`** value. This behaviour only occurs when constructing **`OSError`** directly or via an alias, and is not inherited when subclassing.

errno

A numeric error code from the C variable **`errno`**.

winerror

Under Windows, this gives you the native Windows error code. The **`errno`** attribute is then an approximate translation, in POSIX terms, of that native error code.

Under Windows, if the *winerror* constructor argument is an integer, the **`errno`** attribute is determined from the

Windows error code, and the *errno* argument is ignored. On other platforms, the *winerror* argument is ignored, and the **winerror** attribute does not exist.

strerror

The corresponding error message, as provided by the operating system. It is formatted by the C functions **perror()** under POSIX, and **FormatMessage()** under Windows.

filename
filename2

For exceptions that involve a file system path (such as **open()** or **os.unlink()**), **filename** is the file name passed to the function. For functions that involve two file system paths (such as **os.rename()**), **filename2** corresponds to the second file name passed to the function.

Changed in version 3.3: **EnvironmentError**, **IOError**, **WindowsError**, **socket.error**, **select.error** and **mmap.error** have been merged into **OSError**, and the constructor may return a subclass.

Changed in version 3.4: The **filename** attribute is now the original file name passed to the function, instead of the name encoded to or decoded from the filesystem encoding and error handler. Also, the *filename2* constructor argument and attribute was added.

exception OverflowError

Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for integers (which would rather raise **MemoryError** than give up). However, for historical reasons, OverflowError is sometimes raised for integers that are outside a required range. Because of the lack of standardization of floating point exception handling in C, most floating point operations are not checked.

exception RecursionError

This exception is derived from **RuntimeError**. It is raised when the interpreter detects that the maximum recursion depth (see **sys.getrecursionlimit()**) is exceeded.

New in version 3.5: Previously, a plain **RuntimeError** was raised.

exception ReferenceError

This exception is raised when a weak reference proxy, created by the **weakref.proxy()** function, is used to access an attribute of the referent after it has been garbage collected. For more information on weak references, see the **weakref** module.

exception RuntimeError

Raised when an error is detected that doesn't fall in any of the other categories. The associated value is a string indicating what precisely went wrong.

exception StopIteration

Raised by built-in function **next()** and an iterator's **__next__()** method to signal that there are no further items produced by the iterator.

The exception object has a single attribute **value**, which is given as an argument when constructing the exception, and defaults to **None**.

When a generator or coroutine function returns, a new **StopIteration** instance is raised, and the value returned by the function is used as the **value** parameter to the constructor of the exception.

If a generator code directly or indirectly raises **StopIteration**, it is converted into a **RuntimeError** (retaining the **StopIteration** as the new exception's cause).

Changed in version 3.3: Added `value` attribute and the ability for generator functions to use it to return a value.

Changed in version 3.5: Introduced the RuntimeError transformation via `from __future__ import generator_stop`, see **PEP 479** [https://peps.python.org/pep-0479/].

Changed in version 3.7: Enable **PEP 479** [https://peps.python.org/pep-0479/] for all code by default: a **`StopIteration`** error raised in a generator is transformed into a **`RuntimeError`**.

exception StopAsyncIteration

Must be raised by **`__anext__()`** method of an asynchronous iterator object to stop the iteration.

New in version 3.5.

exception SyntaxError(*message*, *details*)

Raised when the parser encounters a syntax error. This may occur in an **`import`** statement, in a call to the built-in functions **`compile()`**, **`exec()`**, or **`eval()`**, or when reading the initial script or standard input (also interactively).

The **`str()`** of the exception instance returns only the error message. Details is a tuple whose members are also available as separate attributes.

filename

The name of the file the syntax error occurred in.

lineno

Which line number in the file the error occurred in. This is 1-indexed: the first line in the file has a `lineno` of 1.

offset

The column in the line where the error occurred. This is 1-indexed: the first character in the line has an

`offset` of 1.

text

The source code text involved in the error.

end_lineno

Which line number in the file the error occurred ends in. This is 1-indexed: the first line in the file has a `lineno` of 1.

end_offset

The column in the end line where the error occurred finishes. This is 1-indexed: the first character in the line has an `offset` of 1.

For errors in f-string fields, the message is prefixed by “f-string: ” and the offsets are offsets in a text constructed from the replacement expression. For example, compiling f’Bad {a b} field’ results in this args attribute: (‘f-string: …’, (‘’, 1, 2, ‘(a b)n’, 1, 5)).

Changed in version 3.10: Added the **`end_lineno`** and **`end_offset`** attributes.

exception IndentationError

Base class for syntax errors related to incorrect indentation. This is a subclass of **`SyntaxError`**.

exception TabError

Raised when indentation contains an inconsistent use of tabs and spaces. This is a subclass of **`IndentationError`**.

exception SystemError

Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version of the Python interpreter (`sys.version`; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

exception SystemExit

This exception is raised by the **`sys.exit()`** function. It inherits from **`BaseException`** instead of **`Exception`** so that it is not accidentally caught by code that catches **`Exception`**. This allows the exception to properly propagate up and cause the interpreter to exit. When it is not handled, the Python interpreter exits; no stack traceback is printed. The constructor accepts the same optional argument passed to **`sys.exit()`**. If the value is an integer, it specifies the system exit status (passed to C's **`exit()`** function); if it is `None`, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

A call to **`sys.exit()`** is translated into an exception so that clean-up handlers (**`finally`** clauses of **`try`** statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The **`os._exit()`** function can be used if it is absolutely positively necessary to exit immediately (for example, in the child process after a call to **`os.fork()`**).

code

The exit status or error message that is passed to the constructor. (Defaults to `None`.)

exception TypeError

Raised when an operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

This exception may be raised by user code to indicate that an attempted operation on an object is not supported, and is not

meant to be. If an object is meant to support a given operation but has not yet provided an implementation, **`NotImplementedError`** is the proper exception to raise.

Passing arguments of the wrong type (e.g. passing a **`list`** when an **`int`** is expected) should result in a **`TypeError`**, but passing arguments with the wrong value (e.g. a number outside expected boundaries) should result in a **`ValueError`**.

exception UnboundLocalError

Raised when a reference is made to a local variable in a function or method, but no value has been bound to that variable. This is a subclass of **`NameError`**.

exception UnicodeError

Raised when a Unicode-related encoding or decoding error occurs. It is a subclass of **`ValueError`**.

`UnicodeError` has attributes that describe the encoding or decoding error. For example, `err.object[err.start:err.end]` gives the particular invalid input that the codec failed on.

encoding

The name of the encoding that raised the error.

reason

A string describing the specific codec error.

object

The object the codec was attempting to encode or decode.

start

The first index of invalid data in **`object`**.

end

The index after the last invalid data in **`object`**.

exception UnicodeEncodeError

Raised when a Unicode-related error occurs during encoding. It is a subclass of **`UnicodeError`**.

exception UnicodeDecodeError

Raised when a Unicode-related error occurs during decoding. It is a subclass of **`UnicodeError`**.

exception UnicodeTranslateError

Raised when a Unicode-related error occurs during translating. It is a subclass of **`UnicodeError`**.

exception ValueError

Raised when an operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as **`IndexError`**.

exception ZeroDivisionError

Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

The following exceptions are kept for compatibility with previous versions; starting from Python 3.3, they are aliases of **`OSError`**.

exception EnvironmentError

exception IOError

exception WindowsError

Only available on Windows.

OS exceptions

The following exceptions are subclasses of **OSError**, they get raised depending on the system error code.

exception BlockingIOError

Raised when an operation would block on an object (e.g. socket) set for non-blocking operation. Corresponds to **errno** **EAGAIN**, **EALREADY**, **EWOULDBLOCK** and **EINPROGRESS**.

In addition to those of **OSError**, **BlockingIOError** can have one more attribute:

characters_written

An integer containing the number of characters written to the stream before it blocked. This attribute is available when using the buffered I/O classes from the **io** module.

exception ChildProcessError

Raised when an operation on a child process failed. Corresponds to **errno** **ECHILD**.

exception ConnectionError

A base class for connection-related issues.

Subclasses are **BrokenPipeError**, **ConnectionAbortedError**, **ConnectionRefusedError** and **ConnectionResetError**.

exception BrokenPipeError

A subclass of **ConnectionError**, raised when trying to write on a pipe while the other end has been closed, or trying to write on a socket which has been shutdown for writing. Corresponds to **errno** **EPIPE** and **ESHUTDOWN**.

exception ConnectionAbortedError

A subclass of **ConnectionError**, raised when a connection attempt is aborted by the peer. Corresponds to **errno** **ECONNABORTED**.

exception ConnectionRefusedError

A subclass of **ConnectionError**, raised when a connection attempt is refused by the peer. Corresponds to **errno ECONNREFUSED**.

exception ConnectionResetError

A subclass of **ConnectionError**, raised when a connection is reset by the peer. Corresponds to **errno ECONNRESET**.

exception FileExistsError

Raised when trying to create a file or directory which already exists. Corresponds to **errno EEXIST**.

exception FileNotFoundError

Raised when a file or directory is requested but doesn't exist. Corresponds to **errno ENOENT**.

exception InterruptedError

Raised when a system call is interrupted by an incoming signal. Corresponds to **errno EINTR**.

Changed in version 3.5: Python now retries system calls when a syscall is interrupted by a signal, except if the signal handler raises an exception (see **PEP 475** [https://peps.python.org/pep-0475/] for the rationale), instead of raising **InterruptedError**.

exception IsADirectoryError

Raised when a file operation (such as **os.remove()**) is requested on a directory. Corresponds to **errno EISDIR**.

exception NotADirectoryError

Raised when a directory operation (such as **os.listdir()**) is requested on something which is not a directory. On most POSIX platforms, it may also be raised if an operation attempts to open or traverse a non-directory file as if it were a directory. Corresponds to **errno ENOTDIR**.

exception PermissionError

Raised when trying to run an operation without the adequate access rights - for example filesystem permissions. Corresponds to **errno** **EACCES**, **EPERM**, and **ENOTCAPABLE**.

Changed in version 3.11.1: WASI's **ENOTCAPABLE** is now mapped to **PermissionError**.

exception ProcessLookupError

Raised when a given process doesn't exist. Corresponds to **errno** **ESRCH**.

exception TimeoutError

Raised when a system function timed out at the system level. Corresponds to **errno** **ETIMEDOUT**.

New in version 3.3: All the above **OSError** subclasses were added.

Warnings

The following exceptions are used as warning categories; see the Warning Categories documentation for more details.

exception Warning

Base class for warning categories.

exception UserWarning

Base class for warnings generated by user code.

exception DeprecationWarning

Base class for warnings about deprecated features when those

warnings are intended for other Python developers.

Ignored by the default warning filters, except in the `__main__` module (**PEP 565** [https://peps.python.org/pep-0565/]). Enabling the Python Development Mode shows this warning.

The deprecation policy is described in **PEP 387** [https://peps.python.org/pep-0387/].

exception PendingDeprecationWarning

Base class for warnings about features which are obsolete and expected to be deprecated in the future, but are not deprecated at the moment.

This class is rarely used as emitting a warning about a possible upcoming deprecation is unusual, and **`DeprecationWarning`** is preferred for already active deprecations.

Ignored by the default warning filters. Enabling the Python Development Mode shows this warning.

The deprecation policy is described in **PEP 387** [https://peps.python.org/pep-0387/].

exception SyntaxWarning

Base class for warnings about dubious syntax.

exception RuntimeWarning

Base class for warnings about dubious runtime behavior.

exception FutureWarning

Base class for warnings about deprecated features when those warnings are intended for end users of applications that are written in Python.

exception ImportWarning

Base class for warnings about probable mistakes in module imports.

Ignored by the default warning filters. Enabling the Python Development Mode shows this warning.

exception UnicodeWarning

Base class for warnings related to Unicode.

exception EncodingWarning

Base class for warnings related to encodings.

See Opt-in EncodingWarning for details.

New in version 3.10.

exception BytesWarning

Base class for warnings related to **`bytes`** and **`bytearray`**.

exception ResourceWarning

Base class for warnings related to resource usage.

Ignored by the default warning filters. Enabling the Python Development Mode shows this warning.

New in version 3.2.

Exception groups

The following are used when it is necessary to raise multiple unrelated exceptions. They are part of the exception hierarchy so they can be handled with **`except`** like all other exceptions. In addition, they are recognised by **`except*`**, which matches their subgroups based on the types of the contained exceptions.

exception ExceptionGroup(*msg*, *excs*)

exception BaseExceptionGroup(*msg*, *excs*)

Both of these exception types wrap the exceptions in the sequence `excs`. The `msg` parameter must be a string. The difference between the two classes is that

BaseExceptionGroup extends **BaseException** and it can wrap any exception, while **ExceptionGroup** extends **Exception** and it can only wrap subclasses of **Exception**. This design is so that `except Exception` catches an **ExceptionGroup** but not **BaseExceptionGroup**.

The **BaseExceptionGroup** constructor returns an **ExceptionGroup** rather than a **BaseExceptionGroup** if all contained exceptions are **Exception** instances, so it can be used to make the selection automatic. The **ExceptionGroup** constructor, on the other hand, raises a **TypeError** if any contained exception is not an **Exception** subclass.

message

> The `msg` argument to the constructor. This is a read-only attribute.

exceptions

> A tuple of the exceptions in the `excs` sequence given to the constructor. This is a read-only attribute.

subgroup(*condition*)

> Returns an exception group that contains only the exceptions from the current group that match *condition*, or `None` if the result is empty.
>
> The condition can be either a function that accepts an exception and returns true for those that should be in the subgroup, or it can be an exception type or a tuple of exception types, which is used to check for a match using the same check that is used in an `except` clause.
>
> The nesting structure of the current exception is preserved in the result, as are the values of its **message**, **__traceback__**, **__cause__**, **__context__** and **__notes__** fields. Empty nested groups are omitted from the result.
>
> The condition is checked for all exceptions in the

nested exception group, including the top-level and any nested exception groups. If the condition is true for such an exception group, it is included in the result in full.

split(*condition*)

Like **`subgroup()`**, but returns the pair `(match, rest)` where `match` is `subgroup(condition)` and `rest` is the remaining non-matching part.

derive(*excs*)

Returns an exception group with the same **`message`**, but which wraps the exceptions in `excs`.

This method is used by **`subgroup()`** and **`split()`**. A subclass needs to override it in order to make **`subgroup()`** and **`split()`** return instances of the subclass rather than **`ExceptionGroup`**.

`subgroup()` and **`split()`** copy the **`__traceback__`**, **`__cause__`**, **`__context__`** and **`__notes__`** fields from the original exception group to the one returned by **`derive()`**, so these fields do not need to be updated by **`derive()`**.

```
>>> class MyGroup(ExceptionGroup):
...     def derive(self, exc):
...         return MyGroup(self.message, exc)
...
>>> e = MyGroup("eg", [ValueError(1), TypeError
>>> e.add_note("a note")
>>> e.__context__ = Exception("context")
>>> e.__cause__ = Exception("cause")
>>> try:
...     raise e
... except Exception as e:
...     exc = e
...
>>> match, rest = exc.split(ValueError)
```

```
>>> exc, exc.__context__, exc.__cause__, exc.__
(MyGroup('eg', [ValueError(1), TypeError(2)]),
>>> match, match.__context__, match.__cause__,
(MyGroup('eg', [ValueError(1)]), Exception('cor
>>> rest, rest.__context__, rest.__cause__, res
(MyGroup('eg', [TypeError(2)]), Exception('cont
>>> exc.__traceback__ is match.__traceback__ is
True
```

Note that **BaseExceptionGroup** defines **__new__()**, so subclasses that need a different constructor signature need to override that rather than **__init__()**. For example, the following defines an exception group subclass which accepts an exit_code and and constructs the group's message from it.

```
class Errors(ExceptionGroup):
   def __new__(cls, errors, exit_code):
      self = super().__new__(Errors, f"exit code: {
      self.exit_code = exit_code
      return self

   def derive(self, excs):
      return Errors(excs, self.exit_code)
```

Like **ExceptionGroup**, any subclass of **BaseExceptionGroup** which is also a subclass of **Exception** can only wrap instances of **Exception**.

New in version 3.11.

Exception hierarchy

The class hierarchy for built-in exceptions is:

```
BaseException
     BaseExceptionGroup
     GeneratorExit
     KeyboardInterrupt
     SystemExit
```

```
Exception
     ArithmeticError
          FloatingPointError
          OverflowError
          ZeroDivisionError
     AssertionError
     AttributeError
     BufferError
     EOFError
     ExceptionGroup [BaseExceptionGroup]
     ImportError
          ModuleNotFoundError
     LookupError
          IndexError
          KeyError
     MemoryError
     NameError
          UnboundLocalError
     OSError
          BlockingIOError
          ChildProcessError
          ConnectionError
               BrokenPipeError
               ConnectionAbortedError
               ConnectionRefusedError
               ConnectionResetError
          FileExistsError
          FileNotFoundError
          InterruptedError
          IsADirectoryError
          NotADirectoryError
          PermissionError
          ProcessLookupError
          TimeoutError
     ReferenceError
     RuntimeError
          NotImplementedError
          RecursionError
```

```

```

Text Processing Services

The modules described in this chapter provide a wide range of string manipulation operations and other text processing services.

The **codecs** module described under Binary Data Services is also highly relevant to text processing. In addition, see the documentation for Python's built-in string type in Text Sequence Type — str.

Text Sequence Type — str

String Methods

String constants

The constants defined in this module are:

string.ascii_letters

The concatenation of the **`ascii_lowercase`** and **`ascii_uppercase`** constants described below. This value is not locale-dependent.

string.ascii_lowercase

The lowercase letters `'abcdefghijklmnopqrstuvwxyz'`. This value is not locale-dependent and will not change.

string.ascii_uppercase

The uppercase letters `'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`. This value is not locale-dependent and will not change.

string.digits

The string `'0123456789'`.

string.hexdigits

The string `'0123456789abcdefABCDEF'`.

string.octdigits

The string `'01234567'`.

string.punctuation

String of ASCII characters which are considered punctuation characters in the `C` locale: `!"#$%&'()*+,-./:;<=>?@[\]^_`{|}~`.

string.printable

String of ASCII characters which are considered printable. This is a combination of **`digits`**, **`ascii_letters`**, **`punctuation`**, and **`whitespace`**.

string.whitespace

A string containing all ASCII characters that are considered whitespace. This includes the characters space, tab, linefeed, return, formfeed, and vertical tab.

Custom String Formatting

The built-in string class provides the ability to do complex variable substitutions and value formatting via the **`format()`** method described in **PEP 3101** [https://peps.python.org/pep-3101/]. The **`Formatter`** class in the **`string`** module allows you to create and customize your own string formatting behaviors using the same implementation as the built-in **`format()`** method.

class string.Formatter

The **`Formatter`** class has the following public methods:

format(*format_string*, */*, **args*, ***kwargs*)

The primary API method. It takes a format string and an arbitrary set of positional and keyword arguments. It is just a wrapper that calls **`vformat()`**.

Changed in version 3.7: A format string argument is now positional-only.

vformat(*format_string*, *args*, *kwargs*)

This function does the actual work of formatting. It is exposed as a separate function for cases where you want to pass in a predefined dictionary of arguments, rather than unpacking and repacking the dictionary as individual arguments using the `*args` and `**kwargs` syntax. **`vformat()`** does the work of breaking up the format string into character data and replacement fields. It calls the various methods described below.

In addition, the **`Formatter`** defines a number of methods that are intended to be replaced by subclasses:

parse(*format_string*)

Loop over the format_string and return an iterable of tuples (*literal_text*, *field_name*, *format_spec*, *conversion*). This is used by **`vformat()`** to break the string into either literal text, or replacement fields.

The values in the tuple conceptually represent a span of literal text followed by a single replacement field. If there is no literal text (which can happen if two replacement fields occur consecutively), then *literal_text* will be a zero-length string. If there is no replacement field, then the values of *field_name*, *format_spec* and *conversion* will be `None`.

get_field(*field_name*, *args*, *kwargs*)

Given *field_name* as returned by **`parse()`** (see above), convert it to an object to be formatted. Returns a tuple (obj, used_key). The default version takes strings of the form defined in **PEP 3101** [https://peps.python.org/pep-3101/], such as “0[name]” or “label.title”. *args* and *kwargs* are as passed in to **`vformat()`**. The return value *used_key* has the same meaning as the *key* parameter to **`get_value()`**.

get_value(*key*, *args*, *kwargs*)

Retrieve a given field value. The *key* argument will be either an integer or a string. If it is an integer, it represents the index of the positional argument in *args*; if it is a string, then it represents a named argument in *kwargs*.

The *args* parameter is set to the list of positional arguments to **`vformat()`**, and the *kwargs* parameter is set to the dictionary of keyword arguments.

For compound field names, these functions are only called for the first component of the field name; subsequent components are handled through normal attribute and indexing operations.

So for example, the field expression '0.name' would cause **`get_value()`** to be called with a *key* argument of 0. The `name` attribute will be looked up after **`get_value()`** returns by calling the built-in **`getattr()`** function.

If the index or keyword refers to an item that does not exist, then an **`IndexError`** or **`KeyError`** should be raised.

check_unused_args(*used_args*, *args*, *kwargs*)

Implement checking for unused arguments if desired. The arguments to this function is the set of all argument keys that were actually referred to in the format string (integers for positional arguments, and strings for named arguments), and a reference to the *args* and *kwargs* that was passed to vformat. The set of unused args can be calculated from these parameters. **`check_unused_args()`** is assumed to raise an exception if the check fails.

format_field(*value*, *format_spec*)

`format_field()` simply calls the global **`format()`**

built-in. The method is provided so that subclasses can override it.

convert_field(*value*, *conversion*)

Converts the value (returned by **`get_field()`**) given a conversion type (as in the tuple returned by the **`parse()`** method). The default version understands ‘s’ (str), ‘r’ (repr) and ‘a’ (ascii) conversion types.

Format String Syntax

The **`str.format()`** method and the **`Formatter`** class share the same syntax for format strings (although in the case of **`Formatter`**, subclasses can define their own format string syntax). The syntax is related to that of formatted string literals, but it is less sophisticated and, in particular, does not support arbitrary expressions.

Format strings contain “replacement fields” surrounded by curly braces `{}`. Anything that is not contained in braces is considered literal text, which is copied unchanged to the output. If you need to include a brace character in the literal text, it can be escaped by doubling: `{{` and `}}`.

The grammar for a replacement field is as follows:

```
replacement_field ::=  "{" [field_name] ["!" conve
field_name        ::=  arg_name ("." attribute_nam
arg_name          ::=  [identifier | digit+]
attribute_name    ::=  identifier
element_index     ::=  digit+ | index_string
index_string      ::=  <any source character excep
conversion        ::=  "r" | "s" | "a"
format_spec       ::=  <described in the next sect
```

In less formal terms, the replacement field can start with a *field_name* that specifies the object whose value is to be formatted and inserted into the output instead of the replacement field. The *field_name* is optionally followed by a *conversion* field, which is

preceded by an exclamation point `'!'`, and a *format_spec*, which is preceded by a colon `':'`. These specify a non-default format for the replacement value.

See also the Format Specification Mini-Language section.

The *field_name* itself begins with an *arg_name* that is either a number or a keyword. If it's a number, it refers to a positional argument, and if it's a keyword, it refers to a named keyword argument. If the numerical arg_names in a format string are 0, 1, 2, … in sequence, they can all be omitted (not just some) and the numbers 0, 1, 2, … will be automatically inserted in that order. Because *arg_name* is not quote-delimited, it is not possible to specify arbitrary dictionary keys (e.g., the strings `'10'` or `':-]'`) within a format string. The *arg_name* can be followed by any number of index or attribute expressions. An expression of the form `'.name'` selects the named attribute using **`getattr()`**, while an expression of the form `'[index]'` does an index lookup using **`__getitem__()`**.

Changed in version 3.1: The positional argument specifiers can be omitted for **`str.format()`**, so `'{} {}'.format(a, b)` is equivalent to `'{0} {1}'.format(a, b)`.

Changed in version 3.4: The positional argument specifiers can be omitted for **`Formatter`**.

Some simple format string examples:

```
"First, thou shalt count to {0}"  # References first pos
"Bring me a {}"                   # Implicitly reference
"From {} to {}"                   # Same as "From {0} to
"My quest is {name}"              # References keyword a
"Weight in tons {0.weight}"       # 'weight' attribute o
"Units destroyed: {players[0]}"   # First element of key
```

The *conversion* field causes a type coercion before formatting. Normally, the job of formatting a value is done by the **`__format__()`** method of the value itself. However, in some cases it is desirable to force a type to be formatted as a string, overriding its own definition of formatting. By converting the value to a string before calling **`__format__()`**, the normal formatting logic is

bypassed.

Three conversion flags are currently supported: `'!s'` which calls **`str()`** on the value, `'!r'` which calls **`repr()`** and `'!a'` which calls **`ascii()`**.

Some examples:

```
"Harold's a clever {0!s}"        # Calls str() on the ar
"Bring out the holy {name!r}"    # Calls repr() on the a
"More {!a}"                      # Calls ascii() on the
```

The *format_spec* field contains a specification of how the value should be presented, including such details as field width, alignment, padding, decimal precision and so on. Each value type can define its own "formatting mini-language" or interpretation of the *format_spec*.

Most built-in types support a common formatting mini-language, which is described in the next section.

A *format_spec* field can also include nested replacement fields within it. These nested replacement fields may contain a field name, conversion flag and format specification, but deeper nesting is not allowed. The replacement fields within the format_spec are substituted before the *format_spec* string is interpreted. This allows the formatting of a value to be dynamically specified.

See the Format examples section for some examples.

Format Specification Mini-Language

"Format specifications" are used within replacement fields contained within a format string to define how individual values are presented (see Format String Syntax and Formatted string literals). They can also be passed directly to the built-in **`format()`** function. Each formattable type may define how the format specification is to be interpreted.

Most built-in types implement the following options for format specifications, although some of the formatting options are only

supported by the numeric types.

A general convention is that an empty format specification produces the same result as if you had called **`str()`** on the value. A non-empty format specification typically modifies the result.

The general form of a *standard format specifier* is:

```
format_spec      ::=  [[fill]align][sign][z][#][0][width]
fill             ::=  <any character>
align            ::=  "<" | ">" | "=" | "^"
sign             ::=  "+" | "-" | " "
width            ::=  digit+
grouping_option  ::=  "_" | ","
precision        ::=  digit+
type             ::=  "b" | "c" | "d" | "e" | "E" | "f" |
```

If a valid *align* value is specified, it can be preceded by a *fill* character that can be any character and defaults to a space if omitted. It is not possible to use a literal curly brace ("`{`" or "`}`") as the *fill* character in a formatted string literal or when using the **`str.format()`** method. However, it is possible to insert a curly brace with a nested replacement field. This limitation doesn't affect the **`format()`** function.

The meaning of the various alignment options is as follows:

Option	Meaning
'<'	Forces the field to be left-aligned within the available space (this is the default for most objects).
'>'	Forces the field to be right-aligned within the available space (this is the default for numbers).
'='	Forces the padding to be placed after the sign (if any) but before the digits. This is used for printing fields in the form '+000000120'. This alignment option is only valid for numeric types. It becomes the default for numbers when '0' immediately precedes the field width.
'^'	Forces the field to be centered within the available space.

Note that unless a minimum field width is defined, the field width will always be the same size as the data to fill it, so that the alignment option has no meaning in this case.

The *sign* option is only valid for number types, and can be one of the following:

Option	Meaning
`'+'`	indicates that a sign should be used for both positive as well as negative numbers.
`'-'`	indicates that a sign should be used only for negative numbers (this is the default behavior).
space	indicates that a leading space should be used on positive numbers, and a minus sign on negative numbers.

The `'z'` option coerces negative zero floating-point values to positive zero after rounding to the format precision. This option is only valid for floating-point presentation types.

Changed in version 3.11: Added the `'z'` option (see also **PEP 682** [https://peps.python.org/pep-0682/]).

The `'#'` option causes the “alternate form” to be used for the conversion. The alternate form is defined differently for different types. This option is only valid for integer, float and complex types. For integers, when binary, octal, or hexadecimal output is used, this option adds the respective prefix `'0b'`, `'0o'`, `'0x'`, or `'0X'` to the output value. For float and complex the alternate form causes the result of the conversion to always contain a decimal-point character, even if no digits follow it. Normally, a decimal-point character appears in the result of these conversions only if a digit follows it. In addition, for `'g'` and `'G'` conversions, trailing zeros are not removed from the result.

The `','` option signals the use of a comma for a thousands separator. For a locale aware separator, use the `'n'` integer presentation type instead.

Changed in version 3.1: Added the `','` option (see also **PEP 378** [https://peps.python.org/pep-0378/]).

The `'_'` option signals the use of an underscore for a thousands separator for floating point presentation types and for integer presentation type `'d'`. For integer presentation types `'b'`, `'o'`, `'x'`, and `'X'`, underscores will be inserted every 4 digits. For other presentation types, specifying this option is an error.

Changed in version 3.6: Added the `'_'` option (see also **PEP 515** [https://peps.python.org/pep-0515/]).

width is a decimal integer defining the minimum total field width, including any prefixes, separators, and other formatting characters. If not specified, then the field width will be determined by the content.

When no explicit alignment is given, preceding the *width* field by a zero (`'0'`) character enables sign-aware zero-padding for numeric types. This is equivalent to a *fill* character of `'0'` with an *alignment* type of `'='`.

Changed in version 3.10: Preceding the *width* field by `'0'` no longer affects the default alignment for strings.

The *precision* is a decimal integer indicating how many digits should be displayed after the decimal point for presentation types `'f'` and `'F'`, or before and after the decimal point for presentation types `'g'` or `'G'`. For string presentation types the field indicates the maximum field size - in other words, how many characters will be used from the field content. The *precision* is not allowed for integer presentation types.

Finally, the *type* determines how the data should be presented.

The available string presentation types are:

Type	Meaning
`'s'`	String format. This is the default type for strings and may be omitted.
None	The same as `'s'`.

The available integer presentation types are:

Type	Meaning

`'b'`	Binary format. Outputs the number in base 2.
`'c'`	Character. Converts the integer to the corresponding unicode character before printing.
`'d'`	Decimal Integer. Outputs the number in base 10.
`'o'`	Octal format. Outputs the number in base 8.
`'x'`	Hex format. Outputs the number in base 16, using lower-case letters for the digits above 9.
`'X'`	Hex format. Outputs the number in base 16, using upper-case letters for the digits above 9. In case `'#'` is specified, the prefix `'0x'` will be upper-cased to `'0X'` as well.
`'n'`	Number. This is the same as `'d'`, except that it uses the current locale setting to insert the appropriate number separator characters.
`None`	The same as `'d'`.

In addition to the above presentation types, integers can be formatted with the floating point presentation types listed below (except `'n'` and `None`). When doing so, **`float()`** is used to convert the integer to a floating point number before formatting.

The available presentation types for **`float`** and **`Decimal`** values are:

Type	Meaning
`'e'`	Scientific notation. For a given precision `p`, formats the number in scientific notation with the letter ‘e’ separating the coefficient from the exponent. The coefficient has one digit before and `p` digits after the decimal point, for a total of `p + 1` significant digits. With no precision given, uses a precision of `6` digits after the decimal point for **`float`**, and shows all coefficient digits for **`Decimal`**. If no digits follow the decimal point, the decimal point is also removed unless the `#` option is used.
`'E'`	Scientific notation. Same as `'e'` except it uses an upper case ‘E’ as the separator character.
`'f'`	Fixed-point notation. For a given precision `p`, formats the number as a decimal number with

exactly `p` digits following the decimal point. With no precision given, uses a precision of `6` digits after the decimal point for **`float`**, and uses a precision large enough to show all coefficient digits for **`Decimal`**. If no digits follow the decimal point, the decimal point is also removed unless the `#` option is used.

`'f'` Fixed-point notation. Same as `'f'`, but converts `nan` to `NAN` and `inf` to `INF`.

`'g'` General format. For a given precision `p >= 1`, this rounds the number to `p` significant digits and then formats the result in either fixed-point format or in scientific notation, depending on its magnitude. A precision of `0` is treated as equivalent to a precision of `1`.

The precise rules are as follows: suppose that the result formatted with presentation type `'e'` and precision `p-1` would have exponent `exp`. Then, if `m <= exp < p`, where `m` is -4 for floats and -6 for **`Decimals`**, the number is formatted with presentation type `'f'` and precision `p-1-exp`. Otherwise, the number is formatted with presentation type `'e'` and precision `p-1`. In both cases insignificant trailing zeros are removed from the significand, and the decimal point is also removed if there are no remaining digits following it, unless the `'#'` option is used.

With no precision given, uses a precision of `6` significant digits for **`float`**. For **`Decimal`**, the coefficient of the result is formed from the coefficient digits of the value; scientific notation is used for values smaller than `1e-6` in absolute value and values where the place value of the least significant digit is larger than 1, and fixed-point notation is used otherwise.

Positive and negative infinity, positive and negative zero, and nans, are formatted as `inf`, `-inf`, `0`, `-0` and `nan` respectively, regardless of the precision.

`'G'`	General format. Same as `'g'` except switches to `'E'` if the number gets too large. The representations of infinity and NaN are uppercased, too.
`'n'`	Number. This is the same as `'g'`, except that it uses the current locale setting to insert the appropriate number separator characters.
`'%'`	Percentage. Multiplies the number by 100 and displays in fixed (`'f'`) format, followed by a percent sign.
None	For **`float`** this is the same as `'g'`, except that when fixed-point notation is used to format the result, it always includes at least one digit past the decimal point. The precision used is as large as needed to represent the given value faithfully. For **`Decimal`**, this is the same as either `'g'` or `'G'` depending on the value of `context.capitals` for the current decimal context. The overall effect is to match the output of **`str()`** as altered by the other format modifiers.

Format examples

This section contains examples of the **`str.format()`** syntax and comparison with the old `%`-formatting.

In most of the cases the syntax is similar to the old `%`-formatting, with the addition of the `{}` and with `:` used instead of `%`. For example, `'%03.2f'` can be translated to `'{:03.2f}'`.

The new format syntax also supports new and different options, shown in the following examples.

Accessing arguments by position:

```
>>> '{0}, {1}, {2}'.format('a', 'b', 'c')
'a, b, c'
>>> '{}, {}, {}'.format('a', 'b', 'c')  # 3.1+ only
'a, b, c'
```

```
>>> '{2}, {1}, {0}'.format('a', 'b', 'c')
'c, b, a'
>>> '{2}, {1}, {0}'.format(*'abc')      # unpacking argu
'c, b, a'
>>> '{0}{1}{0}'.format('abra', 'cad')   # arguments' inc
'abracadabra'
```

Accessing arguments by name:

```
>>> 'Coordinates: {latitude}, {longitude}'.format(latitu
'Coordinates: 37.24N, -115.81W'
>>> coord = {'latitude': '37.24N', 'longitude': '-115.81
>>> 'Coordinates: {latitude}, {longitude}'.format(**coor
'Coordinates: 37.24N, -115.81W'
```

Accessing arguments' attributes:

```
>>> c = 3-5j
>>> ('The complex number {0} is formed from the real par
...  'and the imaginary part {0.imag}.').format(c)
'The complex number (3-5j) is formed from the real part
>>> class Point:
...     def __init__(self, x, y):
...         self.x, self.y = x, y
...     def __str__(self):
...         return 'Point({self.x}, {self.y})'.format(se
...
>>> str(Point(4, 2))
'Point(4, 2)'
```

Accessing arguments' items:

```
>>> coord = (3, 5)
>>> 'X: {0[0]};  Y: {0[1]}'.format(coord)
'X: 3;  Y: 5'
```

Replacing `%s` and `%r`:

```
>>> "repr() shows quotes: {!r}; str() doesn't: {!s}".for
"repr() shows quotes: 'test1'; str() doesn't: test2"
```

Aligning the text and specifying a width:

```
>>> '{:<30}'.format('left aligned')
'left aligned                  '
>>> '{:>30}'.format('right aligned')
'                 right aligned'
>>> '{:^30}'.format('centered')
'           centered           '
>>> '{:*^30}'.format('centered')  # use '*' as a fill ch
'***********centered***********'
```

Replacing `%+f`, `%-f`, and `% f` and specifying a sign:

```
>>> '{:+f}; {:+f}'.format(3.14, -3.14)  # show it always
'+3.140000; -3.140000'
>>> '{: f}; {: f}'.format(3.14, -3.14)  # show a space f
' 3.140000; -3.140000'
>>> '{:-f}; {:-f}'.format(3.14, -3.14)  # show only the
'3.140000; -3.140000'
```

Replacing `%x` and `%o` and converting the value to different bases:

```
>>> # format also supports binary numbers
>>> "int: {0:d};  hex: {0:x};  oct: {0:o};  bin: {0:b}".
'int: 42;  hex: 2a;  oct: 52;  bin: 101010'
>>> # with 0x, 0o, or 0b as prefix:
>>> "int: {0:d};  hex: {0:#x};  oct: {0:#o};  bin: {0:#b
'int: 42;  hex: 0x2a;  oct: 0o52;  bin: 0b101010'
```

Using the comma as a thousands separator:

```
>>> '{:,}'.format(1234567890)
'1,234,567,890'
```

Expressing a percentage:

```
>>> points = 19
>>> total = 22
>>> 'Correct answers: {:.2%}'.format(points/total)
'Correct answers: 86.36%'
```

Using type-specific formatting:

```
>>> import datetime
>>> d = datetime.datetime(2010, 7, 4, 12, 15, 58)
>>> '{:%Y-%m-%d %H:%M:%S}'.format(d)
'2010-07-04 12:15:58'
```

Nesting arguments and more complex examples:

```
>>> for align, text in zip('<^>', ['left', 'center', 'ri
...     '{0:{fill}{align}16}'.format(text, fill=align, a
...
'left<<<<<<<<<<<<'
'^^^^^center^^^^^'
'>>>>>>>>>>right'
>>>
>>> octets = [192, 168, 0, 1]
>>> '{:02X}{:02X}{:02X}{:02X}'.format(*octets)
'C0A80001'
>>> int(_, 16)
3232235521
>>>
>>> width = 5
>>> for num in range(5,12):
...     for base in 'dXob':
...         print('{0:{width}{base}}'.format(num, base=b
...     print()
...
    5     5     5   101
    6     6     6   110
    7     7     7   111
    8     8    10  1000
    9     9    11  1001
   10     A    12  1010
   11     B    13  1011
```

Template strings

Template strings provide simpler string substitutions as described in

PEP 292 [https://peps.python.org/pep-0292/]. A primary use case for template strings is for internationalization (i18n) since in that context, the simpler syntax and functionality makes it easier to translate than other built-in string formatting facilities in Python. As an example of a library built on template strings for i18n, see the flufl.i18n [https://flufli18n.readthedocs.io/en/latest/] package.

Template strings support `$`-based substitutions, using the following rules:

- `$$` is an escape; it is replaced with a single `$`.
- `$identifier` names a substitution placeholder matching a mapping key of `"identifier"`. By default, `"identifier"` is restricted to any case-insensitive ASCII alphanumeric string (including underscores) that starts with an underscore or ASCII letter. The first non-identifier character after the `$` character terminates this placeholder specification.
- `${identifier}` is equivalent to `$identifier`. It is required when valid identifier characters follow the placeholder but are not part of the placeholder, such as `"${noun}ification"`.

Any other appearance of `$` in the string will result in a **`ValueError`** being raised.

The **`string`** module provides a **`Template`** class that implements these rules. The methods of **`Template`** are:

class string.Template(*template*)

The constructor takes a single argument which is the template string.

substitute(*mapping*=*{}*, */*, ***kwds*)

Performs the template substitution, returning a new string. *mapping* is any dictionary-like object with keys that match the placeholders in the template. Alternatively, you can provide keyword arguments, where the keywords are the placeholders. When both *mapping* and *kwds* are given and there are duplicates,

the placeholders from *kwds* take precedence.

safe_substitute(*mapping={}*, */*, ***kwds*)

Like **substitute()**, except that if placeholders are missing from *mapping* and *kwds*, instead of raising a **KeyError** exception, the original placeholder will appear in the resulting string intact. Also, unlike with **substitute()**, any other appearances of the `$` will simply return `$` instead of raising **ValueError**.

While other exceptions may still occur, this method is called "safe" because it always tries to return a usable string instead of raising an exception. In another sense, **safe_substitute()** may be anything other than safe, since it will silently ignore malformed templates containing dangling delimiters, unmatched braces, or placeholders that are not valid Python identifiers.

is_valid()

Returns false if the template has invalid placeholders that will cause **substitute()** to raise **ValueError**.

New in version 3.11.

get_identifiers()

Returns a list of the valid identifiers in the template, in the order they first appear, ignoring any invalid identifiers.

New in version 3.11.

Template instances also provide one public data attribute:

template

This is the object passed to the constructor's *template* argument. In general, you shouldn't change it, but read-only access is not enforced.

Here is an example of how to use a Template:

```
>>> from string import Template
>>> s = Template('$who likes $what')
>>> s.substitute(who='tim', what='kung pao')
'tim likes kung pao'
>>> d = dict(who='tim')
>>> Template('Give $who $100').substitute(d)
Traceback (most recent call last):
...
ValueError: Invalid placeholder in string: line 1, col 1
>>> Template('$who likes $what').substitute(d)
Traceback (most recent call last):
...
KeyError: 'what'
>>> Template('$who likes $what').safe_substitute(d)
'tim likes $what'
```

Advanced usage: you can derive subclasses of **`Template`** to customize the placeholder syntax, delimiter character, or the entire regular expression used to parse template strings. To do this, you can override these class attributes:

- *delimiter* – This is the literal string describing a placeholder introducing delimiter. The default value is `$`. Note that this should *not* be a regular expression, as the implementation will call **`re.escape()`** on this string as needed. Note further that you cannot change the delimiter after class creation (i.e. a different delimiter must be set in the subclass's class namespace).

- *idpattern* – This is the regular expression describing the pattern for non-braced placeholders. The default value is the regular expression `(?a:[_a-z][_a-z0-9]*)`. If this is given and *braceidpattern* is `None` this pattern will also apply to braced placeholders.

  Note

  Since default *flags* is `re.IGNORECASE`, pattern `[a-z]`

can match with some non-ASCII characters. That's why we use the local `a` flag here.

Changed in version 3.7: braceidpattern can be used to define separate patterns used inside and outside the braces.

- *braceidpattern* – This is like *idpattern* but describes the pattern for braced placeholders. Defaults to `None` which means to fall back to *idpattern* (i.e. the same pattern is used both inside and outside braces). If given, this allows you to define different patterns for braced and unbraced placeholders.

  New in version 3.7.

- *flags* – The regular expression flags that will be applied when compiling the regular expression used for recognizing substitutions. The default value is `re.IGNORECASE`. Note that `re.VERBOSE` will always be added to the flags, so custom *idpattern*s must follow conventions for verbose regular expressions.

  New in version 3.2.

Alternatively, you can provide the entire regular expression pattern by overriding the class attribute *pattern*. If you do this, the value must be a regular expression object with four named capturing groups. The capturing groups correspond to the rules given above, along with the invalid placeholder rule:

- *escaped* – This group matches the escape sequence, e.g. `$$`, in the default pattern.
- *named* – This group matches the unbraced placeholder name; it should not include the delimiter in capturing group.
- *braced* – This group matches the brace enclosed placeholder name; it should not include either the delimiter or braces in the capturing group.
- *invalid* – This group matches any other delimiter pattern (usually a single delimiter), and it should appear last in the regular expression.

The methods on this class will raise **`ValueError`** if the pattern

matches the template without one of these named groups matching.

Helper functions

string.capwords(*s*, *sep*=*None*)

Split the argument into words using **`str.split()`**, capitalize each word using **`str.capitalize()`**, and join the capitalized words using **`str.join()`**. If the optional second argument *sep* is absent or `None`, runs of whitespace characters are replaced by a single space and leading and trailing whitespace are removed, otherwise *sep* is used to split and join the words.

`re` — Regular expression operations

Source code: Lib/re/ [https://github.com/python/cpython/tree/3.11/Lib/re/]

This module provides regular expression matching operations similar to those found in Perl.

Both patterns and strings to be searched can be Unicode strings (`str`) as well as 8-bit strings (`bytes`). However, Unicode strings and 8-bit strings cannot be mixed: that is, you cannot match a Unicode string with a byte pattern or vice-versa; similarly, when asking for a substitution, the replacement string must be of the same type as both the pattern and the search string.

Regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This collides with Python's usage of the same character for the same purpose in string literals; for example, to match a literal backslash, one might have to write `'\\\\'` as the pattern string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. Also, please note that any invalid escape sequences in Python's usage of the backslash in string literals now generate a `DeprecationWarning` and in the future this will become a `SyntaxError`. This behaviour will happen even if it is a valid escape sequence for a regular expression.

The solution is to use Python's raw string notation for regular expression patterns; backslashes are not handled in any special way in a string literal prefixed with `'r'`. So `r"\n"` is a two-character string containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Usually patterns will be expressed in Python code using this raw string notation.

It is important to note that most regular expression operations are available as module-level functions and methods on compiled regular expressions. The functions are shortcuts that don't require you to compile a regex object first, but miss some fine-tuning parameters.

See also

The third-party regex [https://pypi.org/project/regex/] module, which has an API compatible with the standard library `re` module, but offers additional functionality and a more thorough Unicode support.

Regular Expression Syntax

A regular expression (or RE) specifies a set of strings that matches it; the functions in this module let you check if a particular string matches a given regular expression (or if a given regular expression matches a particular string, which comes down to the same thing).

Regular expressions can be concatenated to form new regular expressions; if *A* and *B* are both regular expressions, then *AB* is also a regular expression. In general, if a string *p* matches *A* and another string *q* matches *B*, the string *pq* will match AB. This holds unless *A* or *B* contain low precedence operations; boundary conditions between *A* and *B*; or have numbered group references. Thus, complex expressions can easily be constructed from simpler primitive expressions like the ones described here. For details of the theory and implementation of regular expressions, consult the Friedl book [Frie09], or almost any textbook about compiler construction.

A brief explanation of the format of regular expressions follows. For further information and a gentler presentation, consult the Regular Expression HOWTO.

Regular expressions can contain both special and ordinary characters. Most ordinary characters, like `'A'`, `'a'`, or `'0'`, are the simplest regular expressions; they simply match themselves.

You can concatenate ordinary characters, so `last` matches the string `'last'`. (In the rest of this section, we'll write RE's in `this special style`, usually without quotes, and strings to be matched `'in single quotes'`.)

Some characters, like `'|'` or `'('`, are special. Special characters either stand for classes of ordinary characters, or affect how the regular expressions around them are interpreted.

Repetition operators or quantifiers (`*`, `+`, `?`, `{m,n}`, etc) cannot be directly nested. This avoids ambiguity with the non-greedy modifier suffix `?`, and with other modifiers in other implementations. To apply a second repetition to an inner repetition, parentheses may be used. For example, the expression `(?:a{6})*` matches any multiple of six `'a'` characters.

The special characters are:

`.`

(Dot.) In the default mode, this matches any character except a newline. If the **`DOTALL`** flag has been specified, this matches any character including a newline.

`^`

(Caret.) Matches the start of the string, and in **`MULTILINE`** mode also matches immediately after each newline.

`$`

Matches the end of the string or just before the newline at the end of the string, and in **`MULTILINE`** mode also matches before a newline. `foo` matches both 'foo' and 'foobar', while the regular expression `foo$` matches only 'foo'. More interestingly, searching for `foo.$` in `'foo1\nfoo2\n'` matches 'foo2' normally, but 'foo1' in **`MULTILINE`** mode; searching for a single `$` in `'foo\n'` will find two (empty) matches: one just before the newline, and one at the end of the string.

`*`

Causes the resulting RE to match 0 or more repetitions of the

preceding RE, as many repetitions as are possible. `ab*` will match ‘a’, ‘ab’, or ‘a’ followed by any number of ‘b’s.

`+`

Causes the resulting RE to match 1 or more repetitions of the preceding RE. `ab+` will match ‘a’ followed by any non-zero number of ‘b’s; it will not match just ‘a’.

`?`

Causes the resulting RE to match 0 or 1 repetitions of the preceding RE. `ab?` will match either ‘a’ or ‘ab’.

`*?, +?, ??`

The `'*'`, `'+'`, and `'?'` quantifiers are all *greedy*; they match as much text as possible. Sometimes this behaviour isn’t desired; if the RE `<.*>` is matched against `'<a> b <c>'`, it will match the entire string, and not just `'<a>'`. Adding `?` after the quantifier makes it perform the match in *non-greedy* or *minimal* fashion; as *few* characters as possible will be matched. Using the RE `<.*?>` will match only `'<a>'`.

`*+, ++, ?+`

Like the `'*'`, `'+'`, and `'?'` quantifiers, those where `'+'` is appended also match as many times as possible. However, unlike the true greedy quantifiers, these do not allow back-tracking when the expression following it fails to match. These are known as *possessive* quantifiers. For example, `a*a` will match `'aaaa'` because the `a*` will match all 4 `'a'`s, but, when the final `'a'` is encountered, the expression is backtracked so that in the end the `a*` ends up matching 3 `'a'`s total, and the fourth `'a'` is matched by the final `'a'`. However, when `a*+a` is used to match `'aaaa'`, the `a*+` will match all 4 `'a'`, but when the final `'a'` fails to find any more characters to match, the expression cannot be backtracked and will thus fail to match. `x*+`, `x++` and `x?+` are equivalent to `(?>x*)`, `(?>x+)` and `(?>x?)` correspondingly.

New in version 3.11.

`{m}`

Specifies that exactly *m* copies of the previous RE should be matched; fewer matches cause the entire RE not to match. For example, `a{6}` will match exactly six `'a'` characters, but not five.

`{m,n}`

Causes the resulting RE to match from *m* to *n* repetitions of the preceding RE, attempting to match as many repetitions as possible. For example, `a{3,5}` will match from 3 to 5 `'a'` characters. Omitting *m* specifies a lower bound of zero, and omitting *n* specifies an infinite upper bound. As an example, `a{4,}b` will match `'aaaab'` or a thousand `'a'` characters followed by a `'b'`, but not `'aaab'`. The comma may not be omitted or the modifier would be confused with the previously described form.

`{m,n}?`

Causes the resulting RE to match from *m* to *n* repetitions of the preceding RE, attempting to match as *few* repetitions as possible. This is the non-greedy version of the previous quantifier. For example, on the 6-character string `'aaaaaa'`, `a{3,5}` will match 5 `'a'` characters, while `a{3,5}?` will only match 3 characters.

`{m,n}+`

Causes the resulting RE to match from *m* to *n* repetitions of the preceding RE, attempting to match as many repetitions as possible *without* establishing any backtracking points. This is the possessive version of the quantifier above. For example, on the 6-character string `'aaaaaa'`, `a{3,5}+aa` attempt to match 5 `'a'` characters, then, requiring 2 more `'a'`s, will need more characters than available and thus fail, while `a{3,5}aa` will match with `a{3,5}` capturing 5, then 4 `'a'`s by backtracking and then the final 2 `'a'`s are matched by the final `aa` in the pattern. `x{m,n}+` is equivalent to `(?>x{m,n})`.

New in version 3.11.

`\`

Either escapes special characters (permitting you to match characters like `'*'`, `'?'`, and so forth), or signals a special sequence; special sequences are discussed below.

If you're not using a raw string to express the pattern, remember that Python also uses the backslash as an escape sequence in string literals; if the escape sequence isn't recognized by Python's parser, the backslash and subsequent character are included in the resulting string. However, if Python would recognize the resulting sequence, the backslash should be repeated twice. This is complicated and hard to understand, so it's highly recommended that you use raw strings for all but the simplest expressions.

`[]`

Used to indicate a set of characters. In a set:

- Characters can be listed individually, e.g. `[amk]` will match `'a'`, `'m'`, or `'k'`.
- Ranges of characters can be indicated by giving two characters and separating them by a `'-'`, for example `[a-z]` will match any lowercase ASCII letter, `[0-5][0-9]` will match all the two-digits numbers from `00` to `59`, and `[0-9A-Fa-f]` will match any hexadecimal digit. If `-` is escaped (e.g. `[a\-z]`) or if it's placed as the first or last character (e.g. `[-a]` or `[a-]`), it will match a literal `'-'`.
- Special characters lose their special meaning inside sets. For example, `[(+*)]` will match any of the literal characters `'('`, `'+'`, `'*'`, or `')'`.
- Character classes such as `\w` or `\S` (defined below) are also accepted inside a set, although the characters they match depends on whether **`ASCII`** or **`LOCALE`** mode is in force.

- Characters that are not within a range can be matched by *complementing* the set. If the first character of the set is `'^'`, all the characters that are *not* in the set will be matched. For example, `[^5]` will match any character except `'5'`, and `[^^]` will match any character except `'^'`. `^` has no special meaning if it's not the first character in the set.
- To match a literal `']'` inside a set, precede it with a backslash, or place it at the beginning of the set. For example, both `[()[\]{}]` and `[]()[{}]` will both match a parenthesis.

- Support of nested sets and set operations as in Unicode Technical Standard #18 [https://unicode.org/reports/tr18/] might be added in the future. This would change the syntax, so to facilitate this change a **`FutureWarning`** will be raised in ambiguous cases for the time being. That includes sets starting with a literal `'['` or containing literal character sequences `'--'`, `'&&'`, `'~~'`, and `'||'`. To avoid a warning escape them with a backslash.

Changed in version 3.7: **`FutureWarning`** is raised if a character set contains constructs that will change semantically in the future.

|

`A|B`, where *A* and *B* can be arbitrary REs, creates a regular expression that will match either *A* or *B*. An arbitrary number of REs can be separated by the `'|'` in this way. This can be used inside groups (see below) as well. As the target string is scanned, REs separated by `'|'` are tried from left to right. When one pattern completely matches, that branch is accepted. This means that once *A* matches, *B* will not be tested further, even if it would produce a longer overall match. In other words, the `'|'` operator is never greedy. To match a literal `'|'`, use `\|`, or enclose it inside a character class, as in `[|]`.

`(...)`

Matches whatever regular expression is inside the parentheses, and indicates the start and end of a group; the contents of a group can be retrieved after a match has been performed, and can be matched later in the string with the `\number` special sequence, described below. To match the literals `'('` or `')'`, use `\(` or `\)`, or enclose them inside a character class: `[(]`, `[)]`.

`(?...)`

This is an extension notation (a `'?'` following a `'('` is not meaningful otherwise). The first character after the `'?'` determines what the meaning and further syntax of the construct is. Extensions usually do not create a new group; `(?P<name>...)` is the only exception to this rule. Following are the currently supported extensions.

`(?aiLmsux)`

(One or more letters from the set `'a'`, `'i'`, `'L'`, `'m'`, `'s'`, `'u'`, `'x'`.) The group matches the empty string; the letters set the corresponding flags: **`re.A`** (ASCII-only matching), **`re.I`** (ignore case), **`re.L`** (locale dependent), **`re.M`** (multi-line), **`re.S`** (dot matches all), **`re.U`** (Unicode matching), and **`re.X`** (verbose), for the entire regular expression. (The flags are described in Module Contents.) This is useful if you wish to include the flags as part of the regular expression, instead of passing a *flag* argument to the **`re.compile()`** function. Flags should be used first in the expression string.

Changed in version 3.11: This construction can only be used at the start of the expression.

`(?:...)`

A non-capturing version of regular parentheses. Matches whatever regular expression is inside the parentheses, but the substring matched by the group *cannot* be retrieved after performing a match or referenced later in the pattern.

`(?aiLmsux-imsx:...)`

(Zero or more letters from the set `'a'`, `'i'`, `'L'`, `'m'`, `'s'`, `'u'`, `'x'`, optionally followed by `'-'` followed by one or more letters from the `'i'`, `'m'`, `'s'`, `'x'`.) The letters set or remove the corresponding flags: **`re.A`** (ASCII-only matching), **`re.I`** (ignore case), **`re.L`** (locale dependent), **`re.M`** (multi-line), **`re.S`** (dot matches all), **`re.U`** (Unicode matching), and **`re.X`** (verbose), for the part of the expression. (The flags are described in Module Contents.)

The letters `'a'`, `'L'` and `'u'` are mutually exclusive when used as inline flags, so they can't be combined or follow `'-'`. Instead, when one of them appears in an inline group, it overrides the matching mode in the enclosing group. In Unicode patterns `(?a:...)` switches to ASCII-only matching, and `(?u:...)` switches to Unicode matching (default). In byte pattern `(?L:...)` switches to locale depending matching, and `(?a:...)` switches to ASCII-only matching (default). This override is only in effect for the narrow inline group, and the original matching mode is restored outside of the group.

New in version 3.6.

Changed in version 3.7: The letters `'a'`, `'L'` and `'u'` also can be used in a group.

`(?>...)`

Attempts to match `...` as if it was a separate regular expression, and if successful, continues to match the rest of the pattern following it. If the subsequent pattern fails to match, the stack can only be unwound to a point *before* the `(?>...)` because once exited, the expression, known as an *atomic group*, has thrown away all stack points within itself. Thus, `(?>.*).` would never match anything because first the `.*` would match all characters possible, then, having nothing left to match, the final `.` would fail to match. Since there are no stack points saved in the Atomic Group, and there is no stack point before it, the entire expression would thus fail to match.

New in version 3.11.

`(?P<name>...)`

Similar to regular parentheses, but the substring matched by the group is accessible via the symbolic group name *name*. Group names must be valid Python identifiers, and each group name must be defined only once within a regular expression. A symbolic group is also a numbered group, just as if the group were not named.

Named groups can be referenced in three contexts. If the pattern is `(?P<quote>['"]).*?(?P=quote)` (i.e. matching a string quoted with either single or double quotes):

Context of reference to group “quote”	Ways to refer to it
in the same pattern itself	• `(?P=quote)` (as shown) • `\1`
when processing match object *m*	• `m.group('quote')` • `m.end('quote')` (etc.)
in a string passed to the *repl* argument of `re.sub()`	• `\g<quote>` • `\g<1>` • `\1`

Deprecated since version 3.11: Group names containing non-ASCII characters in bytes patterns.

`(?P=name)`

A backreference to a named group; it matches whatever text was matched by the earlier group named *name*.

`(?#...)`

A comment; the contents of the parentheses are simply ignored.

`(?=...)`

Matches if `...` matches next, but doesn’t consume any of the string. This is called a *lookahead assertion*. For example, `Isaac (?=Asimov)` will match `'Isaac '` only if it’s followed by `'Asimov'`.

`(?!...)`

Matches if `...` doesn’t match next. This is a *negative*

lookahead assertion. For example, `Isaac (?!Asimov)` will match `'Isaac '` only if it's *not* followed by `'Asimov'`.

`(?<=...)`

Matches if the current position in the string is preceded by a match for `...` that ends at the current position. This is called a *positive lookbehind assertion*. `(?<=abc)def` will find a match in `'abcdef'`, since the lookbehind will back up 3 characters and check if the contained pattern matches. The contained pattern must only match strings of some fixed length, meaning that `abc` or `a|b` are allowed, but `a*` and `a{3,4}` are not. Note that patterns which start with positive lookbehind assertions will not match at the beginning of the string being searched; you will most likely want to use the **`search()`** function rather than the **`match()`** function:

```
>>> import re
>>> m = re.search('(?<=abc)def', 'abcdef')
>>> m.group(0)
'def'
```

This example looks for a word following a hyphen:

```
>>> m = re.search(r'(?<=-)\w+', 'spam-egg')
>>> m.group(0)
'egg'
```

Changed in version 3.5: Added support for group references of fixed length.

`(?<!...)`

Matches if the current position in the string is not preceded by a match for `...`. This is called a *negative lookbehind assertion*. Similar to positive lookbehind assertions, the contained pattern must only match strings of some fixed length. Patterns which start with negative lookbehind assertions may match at the beginning of the string being searched.

`(?(id/name)yes-pattern|no-pattern)`

Will try to match with `yes-pattern` if the group with given *id* or *name* exists, and with `no-pattern` if it doesn't. `no-pattern` is optional and can be omitted. For example, `(<)?(\w+@\w+(?:\.\w+)+)(?(1)>|$)` is a poor email matching pattern, which will match with `'<user@host.com>'` as well as `'user@host.com'`, but not with `'<user@host.com'` nor `'user@host.com>'`.

Deprecated since version 3.11: Group *id* containing anything except ASCII digits.

The special sequences consist of `'\'` and a character from the list below. If the ordinary character is not an ASCII digit or an ASCII letter, then the resulting RE will match the second character. For example, `\$` matches the character `'$'`.

`\number`
: Matches the contents of the group of the same number. Groups are numbered starting from 1. For example, `(.+)\1` matches `'the the'` or `'55 55'`, but not `'thethe'` (note the space after the group). This special sequence can only be used to match one of the first 99 groups. If the first digit of *number* is 0, or *number* is 3 octal digits long, it will not be interpreted as a group match, but as the character with octal value *number*. Inside the `'['` and `']'` of a character class, all numeric escapes are treated as characters.

`\A`
: Matches only at the start of the string.

`\b`
: Matches the empty string, but only at the beginning or end of a word. A word is defined as a sequence of word characters. Note that formally, `\b` is defined as the boundary between a `\w` and a `\W` character (or vice versa), or between `\w` and the beginning/end of the string. This means that `r'\bfoo\b'` matches `'foo'`, `'foo.'`, `'(foo)'`, `'bar foo baz'` but not `'foobar'` or `'foo3'`.

  By default Unicode alphanumerics are the ones used in

Unicode patterns, but this can be changed by using the **ASCII** flag. Word boundaries are determined by the current locale if the **LOCALE** flag is used. Inside a character range, `\b` represents the backspace character, for compatibility with Python's string literals.

`\B`

Matches the empty string, but only when it is *not* at the beginning or end of a word. This means that `r'py\B'` matches `'python'`, `'py3'`, `'py2'`, but not `'py'`, `'py.'`, or `'py!'`. `\B` is just the opposite of `\b`, so word characters in Unicode patterns are Unicode alphanumerics or the underscore, although this can be changed by using the **ASCII** flag. Word boundaries are determined by the current locale if the **LOCALE** flag is used.

`\d`

For Unicode (str) patterns:

Matches any Unicode decimal digit (that is, any character in Unicode character category [Nd]). This includes `[0-9]`, and also many other digit characters. If the **ASCII** flag is used only `[0-9]` is matched.

For 8-bit (bytes) patterns:

Matches any decimal digit; this is equivalent to `[0-9]`.

`\D`

Matches any character which is not a decimal digit. This is the opposite of `\d`. If the **ASCII** flag is used this becomes the equivalent of `[^0-9]`.

`\s`

For Unicode (str) patterns:

Matches Unicode whitespace characters (which includes `[ \t\n\r\f\v]`, and also many other characters, for example the non-breaking spaces mandated by typography rules in many languages). If the **ASCII** flag is used, only `[ \t\n\r\f\v]` is

matched.

For 8-bit (bytes) patterns:
Matches characters considered whitespace in the ASCII character set; this is equivalent to `[ \t\n\r\f\v]`.

`\S`
Matches any character which is not a whitespace character. This is the opposite of `\s`. If the **ASCII** flag is used this becomes the equivalent of `[^ \t\n\r\f\v]`.

`\w`

For Unicode (str) patterns:
Matches Unicode word characters; this includes most characters that can be part of a word in any language, as well as numbers and the underscore. If the **ASCII** flag is used, only `[a-zA-Z0-9_]` is matched.

For 8-bit (bytes) patterns:
Matches characters considered alphanumeric in the ASCII character set; this is equivalent to `[a-zA-Z0-9_]`. If the **LOCALE** flag is used, matches characters considered alphanumeric in the current locale and the underscore.

`\W`
Matches any character which is not a word character. This is the opposite of `\w`. If the **ASCII** flag is used this becomes the equivalent of `[^a-zA-Z0-9_]`. If the **LOCALE** flag is used, matches characters which are neither alphanumeric in the current locale nor the underscore.

`\Z`
Matches only at the end of the string.

Most of the standard escapes supported by Python string literals are also accepted by the regular expression parser:

`\a` `\b` `\f` `\n`

```
\N      \r      \t      \u
\U      \v      \x      \\
```

(Note that `\b` is used to represent word boundaries, and means "backspace" only inside character classes.)

`'\u'`, `'\U'`, and `'\N'` escape sequences are only recognized in Unicode patterns. In bytes patterns they are errors. Unknown escapes of ASCII letters are reserved for future use and treated as errors.

Octal escapes are included in a limited form. If the first digit is a 0, or if there are three octal digits, it is considered an octal escape. Otherwise, it is a group reference. As for string literals, octal escapes are always at most three digits in length.

Changed in version 3.3: The `'\u'` and `'\U'` escape sequences have been added.

Changed in version 3.6: Unknown escapes consisting of `'\'` and an ASCII letter now are errors.

Changed in version 3.8: The `'\N{name}'` escape sequence has been added. As in string literals, it expands to the named Unicode character (e.g. `'\N{EM DASH}'`).

Module Contents

The module defines several functions, constants, and an exception. Some of the functions are simplified versions of the full featured methods for compiled regular expressions. Most non-trivial applications always use the compiled form.

Flags

Changed in version 3.6: Flag constants are now instances of **`RegexFlag`**, which is a subclass of **`enum.IntFlag`**.

class re.RegexFlag

An **`enum.IntFlag`** class containing the regex options listed

below.

New in version 3.11: - added to `__all__`

re.A
re.ASCII

Make `\w`, `\W`, `\b`, `\B`, `\d`, `\D`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns. Corresponds to the inline flag `(?a)`.

Note that for backward compatibility, the **`re.U`** flag still exists (as well as its synonym **`re.UNICODE`** and its embedded counterpart `(?u)`), but these are redundant in Python 3 since matches are Unicode by default for strings (and Unicode matching isn't allowed for bytes).

re.DEBUG

Display debug information about compiled expression. No corresponding inline flag.

re.I
re.IGNORECASE

Perform case-insensitive matching; expressions like `[A-Z]` will also match lowercase letters. Full Unicode matching (such as `Ü` matching `ü`) also works unless the **`re.ASCII`** flag is used to disable non-ASCII matches. The current locale does not change the effect of this flag unless the **`re.LOCALE`** flag is also used. Corresponds to the inline flag `(?i)`.

Note that when the Unicode patterns `[a-z]` or `[A-Z]` are used in combination with the **`IGNORECASE`** flag, they will match the 52 ASCII letters and 4 additional non-ASCII letters: 'İ' (U+0130, Latin capital letter I with dot above), 'ı' (U+0131, Latin small letter dotless i), 'ſ' (U+017F, Latin small letter long s) and 'K' (U+212A, Kelvin sign). If the **`ASCII`** flag is used, only letters 'a' to 'z' and 'A' to 'Z' are matched.

re.L

re.LOCALE

Make `\w`, `\W`, `\b`, `\B` and case-insensitive matching dependent on the current locale. This flag can be used only with bytes patterns. The use of this flag is discouraged as the locale mechanism is very unreliable, it only handles one "culture" at a time, and it only works with 8-bit locales. Unicode matching is already enabled by default in Python 3 for Unicode (str) patterns, and it is able to handle different locales/languages. Corresponds to the inline flag `(?L)`.

Changed in version 3.6: **`re.LOCALE`** can be used only with bytes patterns and is not compatible with **`re.ASCII`**.

Changed in version 3.7: Compiled regular expression objects with the **`re.LOCALE`** flag no longer depend on the locale at compile time. Only the locale at matching time affects the result of matching.

re.M
re.MULTILINE

When specified, the pattern character `'^'` matches at the beginning of the string and at the beginning of each line (immediately following each newline); and the pattern character `'$'` matches at the end of the string and at the end of each line (immediately preceding each newline). By default, `'^'` matches only at the beginning of the string, and `'$'` only at the end of the string and immediately before the newline (if any) at the end of the string. Corresponds to the inline flag `(?m)`.

re.NOFLAG

Indicates no flag being applied, the value is `0`. This flag may be used as a default value for a function keyword argument or as a base value that will be conditionally ORed with other flags. Example of use as a default value:

```
def myfunc(text, flag=re.NOFLAG):
    return re.match(text, flag)
```

New in version 3.11.

re.S
re.DOTALL

Make the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline. Corresponds to the inline flag `(?s)`.

re.X
re.VERBOSE

This flag allows you to write regular expressions that look nicer and are more readable by allowing you to visually separate logical sections of the pattern and add comments. Whitespace within the pattern is ignored, except when in a character class, or when preceded by an unescaped backslash, or within tokens like `*?`, `(?:` or `(?P<...>`. For example, `(? :` and `* ?` are not allowed. When a line contains a `#` that is not in a character class and is not preceded by an unescaped backslash, all characters from the leftmost such `#` through the end of the line are ignored.

This means that the two following regular expression objects that match a decimal number are functionally equal:

```
a = re.compile(r"""\d +  # the integral part
                   \.    # the decimal point
                   \d *  # some fractional digits""")
b = re.compile(r"\d+\.\d*")
```

Corresponds to the inline flag `(?x)`.

Functions

re.compile(*pattern*, *flags*=*0*)

Compile a regular expression pattern into a regular expression object, which can be used for matching using its **`match()`**, **`search()`** and other methods, described below.

The expression's behaviour can be modified by specifying a *flags* value. Values can be any of the following variables,

combined using bitwise OR (the | operator).

The sequence

```
prog = re.compile(pattern)
result = prog.match(string)
```

is equivalent to

```
result = re.match(pattern, string)
```

but using **re.compile()** and saving the resulting regular expression object for reuse is more efficient when the expression will be used several times in a single program.

Note

The compiled versions of the most recent patterns passed to **re.compile()** and the module-level matching functions are cached, so programs that use only a few regular expressions at a time needn't worry about compiling regular expressions.

re.search(*pattern*, *string*, *flags*=*0*)

Scan through *string* looking for the first location where the regular expression *pattern* produces a match, and return a corresponding match object. Return `None` if no position in the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

re.match(*pattern*, *string*, *flags*=*0*)

If zero or more characters at the beginning of *string* match the regular expression *pattern*, return a corresponding match object. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

Note that even in **MULTILINE** mode, **re.match()** will only match at the beginning of the string and not at the beginning of each line.

If you want to locate a match anywhere in *string*, use **`search()`** instead (see also search() vs. match()).

re.fullmatch(*pattern*, *string*, *flags*=*0*)

If the whole *string* matches the regular expression *pattern*, return a corresponding match object. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

New in version 3.4.

re.split(*pattern*, *string*, *maxsplit*=*0*, *flags*=*0*)

Split *string* by the occurrences of *pattern*. If capturing parentheses are used in *pattern*, then the text of all groups in the pattern are also returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits occur, and the remainder of the string is returned as the final element of the list.

```
>>> re.split(r'\W+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split(r'(\W+)', 'Words, words, words.')
['Words', ', ', 'words', ', ', 'words', '.', '']
>>> re.split(r'\W+', 'Words, words, words.', 1)
['Words', 'words, words.']
>>> re.split('[a-f]+', '0a3B9', flags=re.IGNORECASE
['0', '3', '9']
```

If there are capturing groups in the separator and it matches at the start of the string, the result will start with an empty string. The same holds for the end of the string:

```
>>> re.split(r'(\W+)', '...words, words...')
['', '...', 'words', ', ', 'words', '...', '']
```

That way, separator components are always found at the same relative indices within the result list.

Empty matches for the pattern split the string only when not

adjacent to a previous empty match.

```
>>> re.split(r'\b', 'Words, words, words.')
['', 'Words', ', ', 'words', ', ', 'words', '.']
>>> re.split(r'\W*', '...words...')
['', '', 'w', 'o', 'r', 'd', 's', '', '']
>>> re.split(r'(\W*)', '...words...')
['', '...', '', '', 'w', '', 'o', '', 'r', '', 'd',
```

Changed in version 3.1: Added the optional flags argument.

Changed in version 3.7: Added support of splitting on a pattern that could match an empty string.

re.findall(*pattern*, *string*, *flags*=*0*)

Return all non-overlapping matches of *pattern* in *string*, as a list of strings or tuples. The *string* is scanned left-to-right, and matches are returned in the order found. Empty matches are included in the result.

The result depends on the number of capturing groups in the pattern. If there are no groups, return a list of strings matching the whole pattern. If there is exactly one group, return a list of strings matching that group. If multiple groups are present, return a list of tuples of strings matching the groups. Non-capturing groups do not affect the form of the result.

```
>>> re.findall(r'\bf[a-z]*', 'which foot or hand fe
['foot', 'fell', 'fastest']
>>> re.findall(r'(\w+)=(\d+)', 'set width=20 and he
[('width', '20'), ('height', '10')]
```

Changed in version 3.7: Non-empty matches can now start just after a previous empty match.

re.finditer(*pattern*, *string*, *flags*=*0*)

Return an iterator yielding match objects over all non-overlapping matches for the RE *pattern* in *string*. The *string* is

scanned left-to-right, and matches are returned in the order found. Empty matches are included in the result.

Changed in version 3.7: Non-empty matches can now start just after a previous empty match.

re.sub(*pattern*, *repl*, *string*, *count*=*0*, *flags*=*0*)

Return the string obtained by replacing the leftmost non-overlapping occurrences of *pattern* in *string* by the replacement *repl*. If the pattern isn't found, *string* is returned unchanged. *repl* can be a string or a function; if it is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes of ASCII letters are reserved for future use and treated as errors. Other unknown escapes such as `\&` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by group 6 in the pattern. For example:

```
>>> re.sub(r'def\s+([a-zA-Z_][a-zA-Z_0-9]*)\s*\(\s*
...         r'static PyObject*\npy_\1(void)\n{',
...         'def myfunc():')
'static PyObject*\npy_myfunc(void)\n{'
```

If *repl* is a function, it is called for every non-overlapping occurrence of *pattern*. The function takes a single match object argument, and returns the replacement string. For example:

```
>>> def dashrepl(matchobj):
...     if matchobj.group(0) == '-': return ' '
...     else: return '-'
>>> re.sub('-{1,2}', dashrepl, 'pro----gram-files')
'pro--gram files'
>>> re.sub(r'\sAND\s', ' & ', 'Baked Beans And Spam
'Baked Beans & Spam'
```

The pattern may be a string or a pattern object.

The optional argument *count* is the maximum number of

pattern occurrences to be replaced; *count* must be a non-negative integer. If omitted or zero, all occurrences will be replaced. Empty matches for the pattern are replaced only when not adjacent to a previous empty match, so `sub('x*', '-', 'abxd')` returns `'-a-b--d-'`.

In string-type *repl* arguments, in addition to the character escapes and backreferences described above, `\g<name>` will use the substring matched by the group named `name`, as defined by the `(?P<name>...)` syntax. `\g<number>` uses the corresponding group number; `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement such as `\g<2>0`. `\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`. The backreference `\g<0>` substitutes in the entire substring matched by the RE.

Changed in version 3.1: Added the optional flags argument.

Changed in version 3.5: Unmatched groups are replaced with an empty string.

Changed in version 3.6: Unknown escapes in *pattern* consisting of `'\'` and an ASCII letter now are errors.

Changed in version 3.7: Unknown escapes in *repl* consisting of `'\'` and an ASCII letter now are errors.

Changed in version 3.7: Empty matches for the pattern are replaced when adjacent to a previous non-empty match.

Deprecated since version 3.11: Group *id* containing anything except ASCII digits. Group names containing non-ASCII characters in bytes replacement strings.

re.subn(*pattern*, *repl*, *string*, *count*=*0*, *flags*=*0*)

Perform the same operation as **`sub()`**, but return a tuple `(new_string, number_of_subs_made)`.

Changed in version 3.1: Added the optional flags argument.

Changed in version 3.5: Unmatched groups are replaced with an empty string.

re.escape(*pattern*)

Escape special characters in *pattern*. This is useful if you want to match an arbitrary literal string that may have regular expression metacharacters in it. For example:

```
>>> print(re.escape('https://www.python.org'))
https://www\.python\.org

>>> legal_chars = string.ascii_lowercase + string.d
>>> print('[%s]+' % re.escape(legal_chars))
[abcdefghijklmnopqrstuvwxyz0123456789!\#\$%\&'\*\+\

>>> operators = ['+', '-', '*', '/', '**']
>>> print('|'.join(map(re.escape, sorted(operators,
/|\-|\+|\*\*|\*
```

This function must not be used for the replacement string in **`sub()`** and **`subn()`**, only backslashes should be escaped. For example:

```
>>> digits_re = r'\d+'
>>> sample = '/usr/sbin/sendmail - 0 errors, 12 war
>>> print(re.sub(digits_re, digits_re.replace('\\',
/usr/sbin/sendmail - \d+ errors, \d+ warnings
```

Changed in version 3.3: The `'_'` character is no longer escaped.

Changed in version 3.7: Only characters that can have special meaning in a regular expression are escaped. As a result, `'!'`, `'"'`, `'%'`, `"'"`, `','`, `'/'`, `':'`, `';'`, `'<'`, `'='`, `'>'`, `'@'`, and `"`"` are no longer escaped.

re.purge()

Clear the regular expression cache.

Exceptions

exception re.error(*msg*, *pattern*=*None*, *pos*=*None*)

Exception raised when a string passed to one of the functions here is not a valid regular expression (for example, it might contain unmatched parentheses) or when some other error occurs during compilation or matching. It is never an error if a string contains no match for a pattern. The error instance has the following additional attributes:

msg

The unformatted error message.

pattern

The regular expression pattern.

pos

The index in *pattern* where compilation failed (may be `None`).

lineno

The line corresponding to *pos* (may be `None`).

colno

The column corresponding to *pos* (may be `None`).

Changed in version 3.5: Added additional attributes.

Regular Expression Objects

Compiled regular expression objects support the following methods and attributes:

Pattern.search(*string*[, *pos*[, *endpos*]])

Scan through *string* looking for the first location where this regular expression produces a match, and return a corresponding match object. Return `None` if no position in

the string matches the pattern; note that this is different from finding a zero-length match at some point in the string.

The optional second parameter *pos* gives an index in the string where the search is to start; it defaults to `0`. This is not completely equivalent to slicing the string; the `'^'` pattern character matches at the real beginning of the string and at positions just after a newline, but not necessarily at the index where the search is to start.

The optional parameter *endpos* limits how far the string will be searched; it will be as if the string is *endpos* characters long, so only the characters from *pos* to `endpos - 1` will be searched for a match. If *endpos* is less than *pos*, no match will be found; otherwise, if *rx* is a compiled regular expression object, `rx.search(string, 0, 50)` is equivalent to `rx.search(string[:50], 0)`.

```
>>> pattern = re.compile("d")
>>> pattern.search("dog")      # Match at index 0
<re.Match object; span=(0, 1), match='d'>
>>> pattern.search("dog", 1)   # No match; search do
```

Pattern.match(*string*[, *pos*[, *endpos*]])

If zero or more characters at the *beginning* of *string* match this regular expression, return a corresponding match object. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

The optional *pos* and *endpos* parameters have the same meaning as for the **`search()`** method.

```
>>> pattern = re.compile("o")
>>> pattern.match("dog")      # No match as "o" is
>>> pattern.match("dog", 1)   # Match as "o" is the
<re.Match object; span=(1, 2), match='o'>
```

If you want to locate a match anywhere in *string*, use **`search()`** instead (see also search() vs. match()).

Pattern.fullmatch(*string*[, *pos*[, *endpos*]])

If the whole *string* matches this regular expression, return a corresponding match object. Return `None` if the string does not match the pattern; note that this is different from a zero-length match.

The optional *pos* and *endpos* parameters have the same meaning as for the **`search()`** method.

```
>>> pattern = re.compile("o[gh]")
>>> pattern.fullmatch("dog")      # No match as "o"
>>> pattern.fullmatch("ogre")     # No match as not
>>> pattern.fullmatch("doggie", 1, 3)   # Matches w
<re.Match object; span=(1, 3), match='og'>
```

New in version 3.4.

Pattern.split(*string*, *maxsplit*=*0*)

Identical to the **`split()`** function, using the compiled pattern.

Pattern.findall(*string*[, *pos*[, *endpos*]])

Similar to the **`findall()`** function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for **`search()`**.

Pattern.finditer(*string*[, *pos*[, *endpos*]])

Similar to the **`finditer()`** function, using the compiled pattern, but also accepts optional *pos* and *endpos* parameters that limit the search region like for **`search()`**.

Pattern.sub(*repl*, *string*, *count*=*0*)

Identical to the **`sub()`** function, using the compiled pattern.

Pattern.subn(*repl*, *string*, *count*=*0*)

Identical to the **`subn()`** function, using the compiled pattern.

Pattern.flags

The regex matching flags. This is a combination of the flags given to `compile()`, any `(?...)` inline flags in the pattern, and implicit flags such as `UNICODE` if the pattern is a Unicode string.

Pattern.groups

The number of capturing groups in the pattern.

Pattern.groupindex

A dictionary mapping any symbolic group names defined by `(?P<id>)` to group numbers. The dictionary is empty if no symbolic groups were used in the pattern.

Pattern.pattern

The pattern string from which the pattern object was compiled.

Changed in version 3.7: Added support of `copy.copy()` and `copy.deepcopy()`. Compiled regular expression objects are considered atomic.

Match Objects

Match objects always have a boolean value of `True`. Since `match()` and `search()` return `None` when there is no match, you can test whether there was a match with a simple `if` statement:

```
match = re.search(pattern, string)
if match:
    process(match)
```

Match objects support the following methods and attributes:

Match.expand(*template*)

Return the string obtained by doing backslash substitution on the template string *template*, as done by the `sub()` method.

Escapes such as `\n` are converted to the appropriate characters, and numeric backreferences (`\1`, `\2`) and named backreferences (`\g<1>`, `\g<name>`) are replaced by the contents of the corresponding group.

Changed in version 3.5: Unmatched groups are replaced with an empty string.

Match.group([*group1*, ...])

Returns one or more subgroups of the match. If there is a single argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. Without arguments, *group1* defaults to zero (the whole match is returned). If a *groupN* argument is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the corresponding parenthesized group. If a group number is negative or larger than the number of groups defined in the pattern, an **IndexError** exception is raised. If a group is contained in a part of the pattern that did not match, the corresponding result is `None`. If a group is contained in a part of the pattern that matched multiple times, the last match is returned.

```
>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, phy
>>> m.group(0)       # The entire match
'Isaac Newton'
>>> m.group(1)       # The first parenthesized subg
'Isaac'
>>> m.group(2)       # The second parenthesized sub
'Newton'
>>> m.group(1, 2)    # Multiple arguments give us a
('Isaac', 'Newton')
```

If the regular expression uses the `(?P<name>...)` syntax, the *groupN* arguments may also be strings identifying groups by their group name. If a string argument is not used as a group name in the pattern, an **IndexError** exception is raised.

A moderately complicated example:

```
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_nam
>>> m.group('first_name')
'Malcolm'
>>> m.group('last_name')
'Reynolds'
```

Named groups can also be referred to by their index:

```
>>> m.group(1)
'Malcolm'
>>> m.group(2)
'Reynolds'
```

If a group matches multiple times, only the last match is accessible:

```
>>> m = re.match(r"(..)+", "a1b2c3")  # Matches 3 t
>>> m.group(1)                        # Returns onl
'c3'
```

Match._getitem_(*g*)

This is identical to `m.group(g)`. This allows easier access to an individual group from a match:

```
>>> m = re.match(r"(\w+) (\w+)", "Isaac Newton, phy
>>> m[0]       # The entire match
'Isaac Newton'
>>> m[1]       # The first parenthesized subgroup.
'Isaac'
>>> m[2]       # The second parenthesized subgroup.
'Newton'
```

Named groups are supported as well:

```
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_nam
>>> m['first_name']
'Isaac'
>>> m['last_name']
```

```
'Newton'
```

New in version 3.6.

Match.groups(*default=None*)

Return a tuple containing all the subgroups of the match, from 1 up to however many groups are in the pattern. The *default* argument is used for groups that did not participate in the match; it defaults to `None`.

For example:

```
>>> m = re.match(r"(\d+)\.(\d+)", "24.1632")
>>> m.groups()
('24', '1632')
```

If we make the decimal place and everything after it optional, not all groups might participate in the match. These groups will default to `None` unless the *default* argument is given:

```
>>> m = re.match(r"(\d+)\.?(\d+)?", "24")
>>> m.groups()      # Second group defaults to None
('24', None)
>>> m.groups('0')   # Now, the second group default
('24', '0')
```

Match.groupdict(*default=None*)

Return a dictionary containing all the *named* subgroups of the match, keyed by the subgroup name. The *default* argument is used for groups that did not participate in the match; it defaults to `None`. For example:

```
>>> m = re.match(r"(?P<first_name>\w+) (?P<last_nam
>>> m.groupdict()
{'first_name': 'Malcolm', 'last_name': 'Reynolds'}
```

Match.start([*group*])

Match.end([*group*])

Return the indices of the start and end of the substring matched by *group*; *group* defaults to zero (meaning the whole matched substring). Return `-1` if *group* exists but did not contribute to the match. For a match object *m*, and a group *g* that did contribute to the match, the substring matched by group *g* (equivalent to `m.group(g)`) is

```
m.string[m.start(g):m.end(g)]
```

Note that `m.start(group)` will equal `m.end(group)` if *group* matched a null string. For example, after `m = re.search('b(c?)', 'cba')`, `m.start(0)` is 1, `m.end(0)` is 2, `m.start(1)` and `m.end(1)` are both 2, and `m.start(2)` raises an **`IndexError`** exception.

An example that will remove *remove_this* from email addresses:

```
>>> email = "tony@tiremove_thisger.net"
>>> m = re.search("remove_this", email)
>>> email[:m.start()] + email[m.end():]
'tony@tiger.net'
```

Match.span([*group*])

For a match *m*, return the 2-tuple `(m.start(group), m.end(group))`. Note that if *group* did not contribute to the match, this is `(-1, -1)`. *group* defaults to zero, the entire match.

Match.pos

The value of *pos* which was passed to the **`search()`** or **`match()`** method of a regex object. This is the index into the string at which the RE engine started looking for a match.

Match.endpos

The value of *endpos* which was passed to the **`search()`** or **`match()`** method of a regex object. This is the index into the string beyond which the RE engine will not go.

Match.lastindex

The integer index of the last matched capturing group, or `None` if no group was matched at all. For example, the expressions `(a)b`, `((a)(b))`, and `((ab))` will have `lastindex == 1` if applied to the string `'ab'`, while the expression `(a)(b)` will have `lastindex == 2`, if applied to the same string.

Match.lastgroup

The name of the last matched capturing group, or `None` if the group didn't have a name, or if no group was matched at all.

Match.re

The regular expression object whose **`match()`** or **`search()`** method produced this match instance.

Match.string

The string passed to **`match()`** or **`search()`**.

Changed in version 3.7: Added support of **`copy.copy()`** and **`copy.deepcopy()`**. Match objects are considered atomic.

Regular Expression Examples

Checking for a Pair

In this example, we'll use the following helper function to display match objects a little more gracefully:

```
def displaymatch(match):
    if match is None:
        return None
    return '<Match: %r, groups=%r>' % (match.group(), ma
```

Suppose you are writing a poker program where a player's hand is represented as a 5-character string with each character representing a card, "a" for ace, "k" for king, "q" for queen, "j" for jack, "t" for

10, and “2” through “9” representing the card with that value.

To see if a given string is a valid hand, one could do the following:

```
>>> valid = re.compile(r"^[a2-9tjqk]{5}$")
>>> displaymatch(valid.match("akt5q"))  # Valid.
"<Match: 'akt5q', groups=()>"
>>> displaymatch(valid.match("akt5e"))  # Invalid.
>>> displaymatch(valid.match("akt"))    # Invalid.
>>> displaymatch(valid.match("727ak"))  # Valid.
"<Match: '727ak', groups=()>"
```

That last hand, `"727ak"`, contained a pair, or two of the same valued cards. To match this with a regular expression, one could use backreferences as such:

```
>>> pair = re.compile(r".*(.).*\1")
>>> displaymatch(pair.match("717ak"))     # Pair of 7s.
"<Match: '717', groups=('7',)>"
>>> displaymatch(pair.match("718ak"))     # No pairs.
>>> displaymatch(pair.match("354aa"))     # Pair of aces
"<Match: '354aa', groups=('a',)>"
```

To find out what card the pair consists of, one could use the **`group()`** method of the match object in the following manner:

```
>>> pair = re.compile(r".*(.).*\1")
>>> pair.match("717ak").group(1)
'7'

# Error because re.match() returns None, which doesn't h
>>> pair.match("718ak").group(1)
Traceback (most recent call last):
  File "<pyshell#23>", line 1, in <module>
    re.match(r".*(.).*\1", "718ak").group(1)
AttributeError: 'NoneType' object has no attribute 'grou

>>> pair.match("354aa").group(1)
'a'
```

Simulating scanf()

Python does not currently have an equivalent to **`scanf()`**. Regular expressions are generally more powerful, though also more verbose, than **`scanf()`** format strings. The table below offers some more-or-less equivalent mappings between **`scanf()`** format tokens and regular expressions.

Regular Expression	
%c	
%5[a-z]	
%d	[+-]?\d+
%e, %E, %f, %g	[+-]?(\d+(\.\d*)?|\.\d+)([eE][+-]?\d+)?
%i	[+-]?(0[xX][\dA-Fa-f]+|0[0-7]*|\d+)
%o	[+-]?[0-7]+
%s	\S+
%u	\d+
%x, %X	[+-]?(0[xX])?[\dA-Fa-f]+

To extract the filename and numbers from a string like

```
/usr/sbin/sendmail - 0 errors, 4 warnings
```

you would use a **`scanf()`** format like

```
%s - %d errors, %d warnings
```

The equivalent regular expression would be

```
(\S+) - (\d+) errors, (\d+) warnings
```

search() vs. match()

Python offers different primitive operations based on regular expressions:

- **`re.match()`** checks for a match only at the beginning of the string
- **`re.search()`** checks for a match anywhere in the string (this is what Perl does by default)
- **`re.fullmatch()`** checks for entire string to be a match

For example:

```
>>> re.match("c", "abcdef")    # No match
>>> re.search("c", "abcdef")   # Match
<re.Match object; span=(2, 3), match='c'>
>>> re.fullmatch("p.*n", "python") # Match
<re.Match object; span=(0, 6), match='python'>
>>> re.fullmatch("r.*n", "python") # No match
```

Regular expressions beginning with `'^'` can be used with **`search()`** to restrict the match at the beginning of the string:

```
>>> re.match("c", "abcdef")    # No match
>>> re.search("^c", "abcdef")  # No match
>>> re.search("^a", "abcdef")  # Match
<re.Match object; span=(0, 1), match='a'>
```

Note however that in **`MULTILINE`** mode **`match()`** only matches at the beginning of the string, whereas using **`search()`** with a regular expression beginning with `'^'` will match at the beginning of each line.

```
>>> re.match("X", "A\nB\nX", re.MULTILINE)  # No match
>>> re.search("^X", "A\nB\nX", re.MULTILINE)  # Match
<re.Match object; span=(4, 5), match='X'>
```

Making a Phonebook

`split()` splits a string into a list delimited by the passed pattern. The method is invaluable for converting textual data into data structures that can be easily read and modified by Python as demonstrated in the following example that creates a phonebook.

First, here is the input. Normally it may come from a file, here we are using triple-quoted string syntax

```
>>> text = """Ross McFluff: 834.345.1254 155 Elm Street
...
... Ronald Heathmore: 892.345.3428 436 Finley Avenue
... Frank Burger: 925.541.7625 662 South Dogwood Way
```

```
...
...
... Heather Albrecht: 548.326.4584 919 Park Place"""
```

The entries are separated by one or more newlines. Now we convert the string into a list with each nonempty line having its own entry:

```
>>> entries = re.split("\n+", text)
>>> entries
['Ross McFluff: 834.345.1254 155 Elm Street',
'Ronald Heathmore: 892.345.3428 436 Finley Avenue',
'Frank Burger: 925.541.7625 662 South Dogwood Way',
'Heather Albrecht: 548.326.4584 919 Park Place']
```

Finally, split each entry into a list with first name, last name, telephone number, and address. We use the `maxsplit` parameter of **`split()`** because the address has spaces, our splitting pattern, in it:

```
>>> [re.split(":? ", entry, 3) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155 Elm Street'],
['Ronald', 'Heathmore', '892.345.3428', '436 Finley Aven
['Frank', 'Burger', '925.541.7625', '662 South Dogwood W
['Heather', 'Albrecht', '548.326.4584', '919 Park Place'
```

The `:?` pattern matches the colon after the last name, so that it does not occur in the result list. With a `maxsplit` of `4`, we could separate the house number from the street name:

```
>>> [re.split(":? ", entry, 4) for entry in entries]
[['Ross', 'McFluff', '834.345.1254', '155', 'Elm Street'
['Ronald', 'Heathmore', '892.345.3428', '436', 'Finley A
['Frank', 'Burger', '925.541.7625', '662', 'South Dogwoo
['Heather', 'Albrecht', '548.326.4584', '919', 'Park Pla
```

Text Munging

`sub()` replaces every occurrence of a pattern with a string or the result of a function. This example demonstrates using **`sub()`** with a function to “munge” text, or randomize the order of all the

characters in each word of a sentence except for the first and last characters:

```
>>> def repl(m):
...     inner_word = list(m.group(2))
...     random.shuffle(inner_word)
...     return m.group(1) + "".join(inner_word) + m.grou
>>> text = "Professor Abdolmalek, please report your abs
>>> re.sub(r"(\w)(\w+)(\w)", repl, text)
'Poefsrosr Aealmlobdk, pslaee reorpt your abnseces plmrp
>>> re.sub(r"(\w)(\w+)(\w)", repl, text)
'Pofsroser Aodlambelk, plasee reoprt yuor asnebces potlm
```

Finding all Adverbs

`findall()` matches *all* occurrences of a pattern, not just the first one as `search()` does. For example, if a writer wanted to find all of the adverbs in some text, they might use `findall()` in the following manner:

```
>>> text = "He was carefully disguised but captured quic
>>> re.findall(r"\w+ly\b", text)
['carefully', 'quickly']
```

Finding all Adverbs and their Positions

If one wants more information about all matches of a pattern than the matched text, `finditer()` is useful as it provides match objects instead of strings. Continuing with the previous example, if a writer wanted to find all of the adverbs *and their positions* in some text, they would use `finditer()` in the following manner:

```
>>> text = "He was carefully disguised but captured quic
>>> for m in re.finditer(r"\w+ly\b", text):
...     print('%02d-%02d: %s' % (m.start(), m.end(), m.g
07-16: carefully
40-47: quickly
```

Raw String Notation

Raw string notation (`r"text"`) keeps regular expressions sane. Without it, every backslash (`'\'`) in a regular expression would have to be prefixed with another one to escape it. For example, the two following lines of code are functionally identical:

```
>>> re.match(r"\W(.)\1\W", " ff ")
<re.Match object; span=(0, 4), match=' ff '>
>>> re.match("\\W(.)\\1\\W", " ff ")
<re.Match object; span=(0, 4), match=' ff '>
```

When one wants to match a literal backslash, it must be escaped in the regular expression. With raw string notation, this means `r"\\"`. Without raw string notation, one must use `"\\\\"`, making the following lines of code functionally identical:

```
>>> re.match(r"\\", r"\\")
<re.Match object; span=(0, 1), match='\\'>
>>> re.match("\\\\", r"\\")
<re.Match object; span=(0, 1), match='\\'>
```

Writing a Tokenizer

A tokenizer or scanner [https://en.wikipedia.org/wiki/Lexical_analysis] analyzes a string to categorize groups of characters. This is a useful first step in writing a compiler or interpreter.

The text categories are specified with regular expressions. The technique is to combine those into a single master regular expression and to loop over successive matches:

```
from typing import NamedTuple
import re

class Token(NamedTuple):
    type: str
    value: str
    line: int
    column: int

def tokenize(code):
```

```
    keywords = {'IF', 'THEN', 'ENDIF', 'FOR', 'NEXT', 'G
    token_specification = [
        ('NUMBER',   r'\d+(\.\d*)?'),  # Integer or deci
        ('ASSIGN',   r':='),           # Assignment oper
        ('END',      r';'),            # Statement termi
        ('ID',       r'[A-Za-z]+'),    # Identifiers
        ('OP',       r'[+\-*/]'),      # Arithmetic oper
        ('NEWLINE',  r'\n'),           # Line endings
        ('SKIP',     r'[ \t]+'),       # Skip over space
        ('MISMATCH', r'.'),            # Any other chara
    ]
    tok_regex = '|'.join('(?P<%s>%s)' % pair for pair in
    line_num = 1
    line_start = 0
    for mo in re.finditer(tok_regex, code):
        kind = mo.lastgroup
        value = mo.group()
        column = mo.start() - line_start
        if kind == 'NUMBER':
            value = float(value) if '.' in value else in
        elif kind == 'ID' and value in keywords:
            kind = value
        elif kind == 'NEWLINE':
            line_start = mo.end()
            line_num += 1
            continue
        elif kind == 'SKIP':
            continue
        elif kind == 'MISMATCH':
            raise RuntimeError(f'{value!r} unexpected on
        yield Token(kind, value, line_num, column)

statements = '''
    IF quantity THEN
        total := total + price * quantity;
        tax := price * 0.05;
    ENDIF;
'''
```

```
for token in tokenize(statements):
    print(token)
```

The tokenizer produces the following output:

```
Token(type='IF', value='IF', line=2, column=4)
Token(type='ID', value='quantity', line=2, column=7)
Token(type='THEN', value='THEN', line=2, column=16)
Token(type='ID', value='total', line=3, column=8)
Token(type='ASSIGN', value=':=', line=3, column=14)
Token(type='ID', value='total', line=3, column=17)
Token(type='OP', value='+', line=3, column=23)
Token(type='ID', value='price', line=3, column=25)
Token(type='OP', value='*', line=3, column=31)

Friedl, Jeffrey. Mastering Regular Expressions. 3rd ed., O'Reilly Media, 2009. The third edition of the book no longer covers Python at all, but the first edition covered writing good regular expression patterns in great detail.

`difflib` — Helpers for computing deltas

Source code: Lib/difflib.py [https://github.com/python/cpython/tree/3.11/Lib/difflib.py]

This module provides classes and functions for comparing sequences. It can be used for example, for comparing files, and can produce information about file differences in various formats, including HTML and context and unified diffs. For comparing directories and files, see also, the `filecmp` module.

class difflib.SequenceMatcher

This is a flexible class for comparing pairs of sequences of any type, so long as the sequence elements are hashable. The basic algorithm predates, and is a little fancier than, an algorithm published in the late 1980's by Ratcliff and Obershelp under the hyperbolic name "gestalt pattern matching." The idea is to find the longest contiguous matching subsequence that contains no "junk" elements; these "junk" elements are ones that are uninteresting in some sense, such as blank lines or whitespace. (Handling junk is an extension to the Ratcliff and Obershelp algorithm.) The same idea is then applied recursively to the pieces of the sequences to the left and to the right of the matching subsequence. This does not yield minimal edit sequences, but does tend to yield matches that "look right" to people.

Timing: The basic Ratcliff-Obershelp algorithm is cubic time in the worst case and quadratic time in the expected case. `SequenceMatcher` is quadratic time for the worst case and has expected-case behavior dependent in a complicated way on how many elements the sequences have in common; best case time is linear.

Automatic junk heuristic: `SequenceMatcher` supports a heuristic that automatically treats certain sequence items as junk. The heuristic counts how many times each individual item appears in the sequence. If an item's duplicates (after the first one) account for more than 1% of the sequence and the sequence is at least 200 items long, this item is marked as "popular" and is treated as junk for the purpose of sequence matching. This heuristic can be turned off by setting the `autojunk` argument to `False` when creating the `SequenceMatcher`.

New in version 3.2: The *autojunk* parameter.

class difflib.Differ

This is a class for comparing sequences of lines of text, and producing human-readable differences or deltas. Differ uses `SequenceMatcher` both to compare sequences of lines, and to compare sequences of characters within similar (near-matching) lines.

Each line of a `Differ` delta begins with a two-letter code:

Code	Meaning
'- '	line unique to sequence 1
'+ '	line unique to sequence 2
' '	line common to both sequences
'? '	line not present in either input sequence

Lines beginning with '`?`' attempt to guide the eye to intraline differences, and were not present in either input sequence. These lines can be confusing if the sequences contain tab characters.

class difflib.HtmlDiff

This class can be used to create an HTML table (or a complete HTML file containing the table) showing a side by side, line by line comparison of text with inter-line and intra-line change highlights. The table can be generated in either full or contextual difference mode.

The constructor for this class is:

init(*tabsize*=*8*, *wrapcolumn*=*None*, *linejunk*=*None*, *charjunk*=*IS_CHARACTER_JUNK*)

Initializes instance of **`HtmlDiff`**.

tabsize is an optional keyword argument to specify tab stop spacing and defaults to `8`.

wrapcolumn is an optional keyword to specify column number where lines are broken and wrapped, defaults to `None` where lines are not wrapped.

linejunk and *charjunk* are optional keyword arguments passed into **`ndiff()`** (used by **`HtmlDiff`** to generate the side by side HTML differences). See **`ndiff()`** documentation for argument default values and descriptions.

The following methods are public:

make_file(*fromlines*, *tolines*, *fromdesc*=*''*, *todesc*=*''*, *context*=*False*, *numlines*=*5*, ***, *charset*=*'utf-8'*)

Compares *fromlines* and *tolines* (lists of strings) and returns a string which is a complete HTML file containing a table showing line by line differences with inter-line and intra-line changes highlighted.

fromdesc and *todesc* are optional keyword arguments to specify from/to file column header strings (both default to an empty string).

context and *numlines* are both optional keyword arguments. Set *context* to `True` when contextual differences are to be shown, else the default is `False` to show the full files. *numlines* defaults to `5`. When *context* is `True` *numlines* controls the number of context lines which surround the difference highlights. When *context* is `False` *numlines* controls the number of lines which are shown before a difference highlight

when using the “next” hyperlinks (setting to zero would cause the “next” hyperlinks to place the next difference highlight at the top of the browser without any leading context).

Note

fromdesc and *todesc* are interpreted as unescaped HTML and should be properly escaped while receiving input from untrusted sources.

Changed in version 3.5: charset keyword-only argument was added. The default charset of HTML document changed from `'ISO-8859-1'` to `'utf-8'`.

make_table(*fromlines*, *tolines*, *fromdesc*=*''*, *todesc*=*''*, *context*=*False*, *numlines*=*5*)

Compares *fromlines* and *tolines* (lists of strings) and returns a string which is a complete HTML table showing line by line differences with inter-line and intra-line changes highlighted.

The arguments for this method are the same as those for the **`make_file()`** method.

`Tools/scripts/diff.py` is a command-line front-end to this class and contains a good example of its use.

difflib.context_diff(*a*, *b*, *fromfile*=*''*, *tofile*=*''*, *fromfiledate*=*''*, *tofiledate*=*''*, *n*=*3*, *lineterm*=*'\n'*)

Compare *a* and *b* (lists of strings); return a delta (a generator generating the delta lines) in context diff format.

Context diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in a before/after style. The number of context lines is set by *n* which defaults to three.

By default, the diff control lines (those with `***` or `---`) are

created with a trailing newline. This is helpful so that inputs created from **`io.IOBase.readlines()`** result in diffs that are suitable for use with **`io.IOBase.writelines()`** since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the *lineterm* argument to `""` so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for *fromfile*, *tofile*, *fromfiledate*, and *tofiledate*. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n']
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido
>>> sys.stdout.writelines(context_diff(s1, s2, from
*** before.py
--- after.py
***************
*** 1,4 ****
! bacon
! eggs
! ham
  guido
--- 1,4 ----
! python
! eggy
! hamster
  guido
```

See A command-line interface to difflib for a more detailed example.

difflib.get_close_matches(*word*, *possibilities*, *n*=*3*, *cutoff*=*0.6*)

Return a list of the best “good enough” matches. *word* is a sequence for which close matches are desired (typically a string), and *possibilities* is a list of sequences against which to

match *word* (typically a list of strings).

Optional argument *n* (default `3`) is the maximum number of close matches to return; *n* must be greater than `0`.

Optional argument *cutoff* (default `0.6`) is a float in the range [0, 1]. Possibilities that don't score at least that similar to *word* are ignored.

The best (no more than *n*) matches among the possibilities are returned in a list, sorted by similarity score, most similar first.

```
>>> get_close_matches('appel', ['ape', 'apple', 'pe
['apple', 'ape']
>>> import keyword
>>> get_close_matches('wheel', keyword.kwlist)
['while']
>>> get_close_matches('pineapple', keyword.kwlist)
[]
>>> get_close_matches('accept', keyword.kwlist)
['except']
```

difflib.ndiff(*a*, *b*, *linejunk*=*None*, *charjunk*=*IS_CHARACTER_JUNK*)

Compare *a* and *b* (lists of strings); return a **`Differ`**-style delta (a generator generating the delta lines).

Optional keyword parameters *linejunk* and *charjunk* are filtering functions (or `None`):

linejunk: A function that accepts a single string argument, and returns true if the string is junk, or false if not. The default is `None`. There is also a module-level function **`IS_LINE_JUNK()`**, which filters out lines without visible characters, except for at most one pound character (`'#'`) – however the underlying **`SequenceMatcher`** class does a dynamic analysis of which lines are so frequent as to constitute noise, and this usually works better than using this function.

charjunk: A function that accepts a character (a string of length 1), and returns if the character is junk, or false if not. The default is module-level function **IS_CHARACTER_JUNK()**, which filters out whitespace characters (a blank or tab; it's a bad idea to include newline in this!).

`Tools/scripts/ndiff.py` is a command-line front-end to this function.

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(kee
...              'ore\ntree\nemu\n'.splitlines(keep
>>> print(''.join(diff), end="")
- one
?  ^
+ ore
?  ^
- two
- three
?  -
+ tree
+ emu
```

difflib.restore(*sequence*, *which*)

Return one of the two sequences that generated a delta.

Given a *sequence* produced by **Differ.compare()** or **ndiff()**, extract lines originating from file 1 or 2 (parameter *which*), stripping off line prefixes.

Example:

```
>>> diff = ndiff('one\ntwo\nthree\n'.splitlines(kee
...              'ore\ntree\nemu\n'.splitlines(keep
>>> diff = list(diff) # materialize the generated d
>>> print(''.join(restore(diff, 1)), end="")
one
two
three
```

```
>>> print(''.join(restore(diff, 2)), end="")
ore
tree
emu
```

difflib.unified_diff(*a*, *b*, *fromfile*='', *tofile*='', *fromfiledate*='', *tofiledate*='', *n*=3, *lineterm*='\n')

Compare *a* and *b* (lists of strings); return a delta (a generator generating the delta lines) in unified diff format.

Unified diffs are a compact way of showing just the lines that have changed plus a few lines of context. The changes are shown in an inline style (instead of separate before/after blocks). The number of context lines is set by *n* which defaults to three.

By default, the diff control lines (those with `---`, `+++`, or `@@`) are created with a trailing newline. This is helpful so that inputs created from **`io.IOBase.readlines()`** result in diffs that are suitable for use with **`io.IOBase.writelines()`** since both the inputs and outputs have trailing newlines.

For inputs that do not have trailing newlines, set the *lineterm* argument to `""` so that the output will be uniformly newline free.

The context diff format normally has a header for filenames and modification times. Any or all of these may be specified using strings for *fromfile*, *tofile*, *fromfiledate*, and *tofiledate*. The modification times are normally expressed in the ISO 8601 format. If not specified, the strings default to blanks.

```
>>> s1 = ['bacon\n', 'eggs\n', 'ham\n', 'guido\n']
>>> s2 = ['python\n', 'eggy\n', 'hamster\n', 'guido
>>> sys.stdout.writelines(unified_diff(s1, s2, from
--- before.py
+++ after.py
@@ -1,4 +1,4 @@
-bacon
```

```
-eggs
-ham
+python
+eggy
+hamster
 guido
```

See A command-line interface to difflib for a more detailed example.

difflib.diff_bytes(*dfunc*, *a*, *b*, *fromfile*=*b''*, *tofile*=*b''*, *fromfiledate*=*b''*, *tofiledate*=*b''*, *n*=*3*, *lineterm*=*b'\n'*)

Compare *a* and *b* (lists of bytes objects) using *dfunc*; yield a sequence of delta lines (also bytes) in the format returned by *dfunc*. *dfunc* must be a callable, typically either **`unified_diff()`** or **`context_diff()`**.

Allows you to compare data with unknown or inconsistent encoding. All inputs except *n* must be bytes objects, not str. Works by losslessly converting all inputs (except *n*) to str, and calling `dfunc(a, b, fromfile, tofile, fromfiledate, tofiledate, n, lineterm)`. The output of *dfunc* is then converted back to bytes, so the delta lines that you receive have the same unknown/inconsistent encodings as *a* and *b*.

New in version 3.5.

difflib.IS_LINE_JUNK(*line*)

Return `True` for ignorable lines. The line *line* is ignorable if *line* is blank or contains a single `'#'`, otherwise it is not ignorable. Used as a default for parameter *linejunk* in **`ndiff()`** in older versions.

difflib.IS_CHARACTER_JUNK(*ch*)

Return `True` for ignorable characters. The character *ch* is ignorable if *ch* is a space or tab, otherwise it is not ignorable. Used as a default for parameter *charjunk* in **`ndiff()`**.

Discussion of a similar algorithm by John W. Ratcliff and D. E. Metzener. This was published in Dr. Dobb's Journal [https://www.drdobbs.com/] in July, 1988.

SequenceMatcher Objects

The `SequenceMatcher` class has this constructor:

class difflib.SequenceMatcher(*isjunk=None*, *a=''*, *b=''*, *autojunk=True*)

Optional argument *isjunk* must be `None` (the default) or a one-argument function that takes a sequence element and returns true if and only if the element is "junk" and should be ignored. Passing `None` for *isjunk* is equivalent to passing `lambda x: False`; in other words, no elements are ignored. For example, pass:

```
lambda x: x in " \t"
```

if you're comparing lines as sequences of characters, and don't want to synch up on blanks or hard tabs.

The optional arguments *a* and *b* are sequences to be compared; both default to empty strings. The elements of both sequences must be hashable.

The optional argument *autojunk* can be used to disable the automatic junk heuristic.

New in version 3.2: The *autojunk* parameter.

SequenceMatcher objects get three data attributes: *bjunk* is the set of elements of *b* for which *isjunk* is `True`; *bpopular* is the set of non-junk elements considered popular by the

heuristic (if it is not disabled); *b2j* is a dict mapping the remaining elements of *b* to a list of positions where they occur. All three are reset whenever *b* is reset with **set_seqs()** or **set_seq2()**.

New in version 3.2: The *bjunk* and *bpopular* attributes.

SequenceMatcher objects have the following methods:

set_seqs(*a*, *b*)

Set the two sequences to be compared.

SequenceMatcher computes and caches detailed information about the second sequence, so if you want to compare one sequence against many sequences, use **set_seq2()** to set the commonly used sequence once and call **set_seq1()** repeatedly, once for each of the other sequences.

set_seq1(*a*)

Set the first sequence to be compared. The second sequence to be compared is not changed.

set_seq2(*b*)

Set the second sequence to be compared. The first sequence to be compared is not changed.

find_longest_match(*alo=0*, *ahi=None*, *blo=0*, *bhi=None*)

Find longest matching block in `a[alo:ahi]` and `b[blo:bhi]`.

If *isjunk* was omitted or `None`, **find_longest_match()** returns `(i, j, k)` such that `a[i:i+k]` is equal to `b[j:j+k]`, where `alo <= i <= i+k <= ahi` and `blo <= j <= j+k <= bhi`. For all `(i', j', k')` meeting those conditions, the additional conditions `k >= k'`, `i <= i'`, and if `i == i'`, `j <= j'` are also met. In other words, of all maximal matching blocks, return one that starts earliest

in *a*, and of all those maximal matching blocks that start earliest in *a*, return the one that starts earliest in *b*.

```
>>> s = SequenceMatcher(None, " abcd", "abcd ab
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=0, b=4, size=5)
```

If *isjunk* was provided, first the longest matching block is determined as above, but with the additional restriction that no junk element appears in the block. Then that block is extended as far as possible by matching (only) junk elements on both sides. So the resulting block never matches on junk except as identical junk happens to be adjacent to an interesting match.

Here's the same example as before, but considering blanks to be junk. That prevents `' abcd'` from matching the `' abcd'` at the tail end of the second sequence directly. Instead only the `'abcd'` can match, and matches the leftmost `'abcd'` in the second sequence:

```
>>> s = SequenceMatcher(lambda x: x==" ", " abc
>>> s.find_longest_match(0, 5, 0, 9)
Match(a=1, b=0, size=4)
```

If no blocks match, this returns `(alo, blo, 0)`.

This method returns a named tuple `Match(a, b, size)`.

Changed in version 3.9: Added default arguments.

get_matching_blocks()

Return list of triples describing non-overlapping matching subsequences. Each triple is of the form `(i, j, n)`, and means that `a[i:i+n] == b[j:j+n]`. The triples are monotonically increasing in *i* and *j*.

The last triple is a dummy, and has the value `(len(a), len(b), 0)`. It is the only triple with `n == 0`. If `(i, j, n)` and `(i', j', n')` are adjacent triples in the list, and the second is not the last triple in the list, then `i+n < i'` or `j+n < j'`; in other words, adjacent triples always describe non-adjacent equal blocks.

```
>>> s = SequenceMatcher(None, "abxcd", "abcd")
>>> s.get_matching_blocks()
[Match(a=0, b=0, size=2), Match(a=3, b=2, size=
```

get_opcodes()

Return list of 5-tuples describing how to turn *a* into *b*. Each tuple is of the form `(tag, i1, i2, j1, j2)`. The first tuple has `i1 == j1 == 0`, and remaining tuples have *i1* equal to the *i2* from the preceding tuple, and, likewise, *j1* equal to the previous *j2*.

The *tag* values are strings, with these meanings:

Value	Meaning
`'replace'`	`a[i1:i2]` should be replaced by `b[j1:j2]`.
`'delete'`	`a[i1:i2]` should be deleted. Note that `j1 == j2` in this case.
`'insert'`	`b[j1:j2]` should be inserted at `a[i1:i1]`. Note that `i1 == i2` in this case.
`'equal'`	`a[i1:i2] == b[j1:j2]` (the sub-sequences are equal).

For example:

```
>>> a = "qabxcd"
>>> b = "abycdf"
>>> s = SequenceMatcher(None, a, b)
>>> for tag, i1, i2, j1, j2 in s.get_opcodes():
...     print('{:7}   a[{}:{}] --> b[{}:{}] {!r
...         tag, i1, i2, j1, j2, a[i1:i2], b[j1
delete    a[0:1] --> b[0:0]      'q' --> ''
equal     a[1:3] --> b[0:2]     'ab' --> 'ab'
```

```
replace   a[3:4] --> b[2:3]      'x' --> 'y'
equal     a[4:6] --> b[3:5]     'cd' --> 'cd'
insert    a[6:6] --> b[5:6]       '' --> 'f'
```

get_grouped_opcodes(*n*=*3*)

Return a generator of groups with up to *n* lines of context.

Starting with the groups returned by **`get_opcodes()`**, this method splits out smaller change clusters and eliminates intervening ranges which have no changes.

The groups are returned in the same format as **`get_opcodes()`**.

ratio()

Return a measure of the sequences' similarity as a float in the range [0, 1].

Where T is the total number of elements in both sequences, and M is the number of matches, this is 2.0*M / T. Note that this is `1.0` if the sequences are identical, and `0.0` if they have nothing in common.

This is expensive to compute if **`get_matching_blocks()`** or **`get_opcodes()`** hasn't already been called, in which case you may want to try **`quick_ratio()`** or **`real_quick_ratio()`** first to get an upper bound.

Note

Caution: The result of a **`ratio()`** call may depend on the order of the arguments. For instance:

```
>>> SequenceMatcher(None, 'tide', 'diet').rati
0.25
>>> SequenceMatcher(None, 'diet', 'tide').rati
0.5
```

quick_ratio()

Return an upper bound on **`ratio()`** relatively quickly.

real_quick_ratio()

Return an upper bound on **`ratio()`** very quickly.

The three methods that return the ratio of matching to total characters can give different results due to differing levels of approximation, although **`quick_ratio()`** and **`real_quick_ratio()`** are always at least as large as **`ratio()`**:

```
>>> s = SequenceMatcher(None, "abcd", "bcde")
>>> s.ratio()
0.75
>>> s.quick_ratio()
0.75
>>> s.real_quick_ratio()
1.0
```

SequenceMatcher Examples

This example compares two strings, considering blanks to be “junk”:

```
>>> s = SequenceMatcher(lambda x: x == " ",
...                     "private Thread currentThread;",
...                     "private volatile Thread current
```

`ratio()` returns a float in [0, 1], measuring the similarity of the sequences. As a rule of thumb, a **`ratio()`** value over 0.6 means the sequences are close matches:

```
>>> print(round(s.ratio(), 3))
0.866
```

If you’re only interested in where the sequences match, **`get_matching_blocks()`** is handy:

```
>>> for block in s.get_matching_blocks():
```

```
...     print("a[%d] and b[%d] match for %d elements" %
a[0] and b[0] match for 8 elements
a[8] and b[17] match for 21 elements
a[29] and b[38] match for 0 elements
```

Note that the last tuple returned by **`get_matching_blocks()`** is always a dummy, `(len(a), len(b), 0)`, and this is the only case in which the last tuple element (number of elements matched) is `0`.

If you want to know how to change the first sequence into the second, use **`get_opcodes()`**:

```
>>> for opcode in s.get_opcodes():
...     print("%6s a[%d:%d] b[%d:%d]" % opcode)
 equal a[0:8] b[0:8]
insert a[8:8] b[8:17]
 equal a[8:29] b[17:38]
```

- Simple version control recipe [https://code.activestate.com/recipes/576729/] for a small application built with **`SequenceMatcher`**.

Differ Objects

Note that **`Differ`**-generated deltas make no claim to be **minimal** diffs. To the contrary, minimal diffs are often counter-intuitive, because they synch up anywhere possible, sometimes accidental matches 100 pages apart. Restricting synch points to contiguous matches preserves some notion of locality, at the occasional cost of producing a longer diff.

The **`Differ`** class has this constructor:

class difflib.Differ(*linejunk=None*, *charjunk=None*)

Optional keyword parameters *linejunk* and *charjunk* are for filter functions (or `None`):

linejunk: A function that accepts a single string argument, and returns true if the string is junk. The default is `None`, meaning that no line is considered junk.

charjunk: A function that accepts a single character argument (a string of length 1), and returns true if the character is junk. The default is `None`, meaning that no character is considered junk.

These junk-filtering functions speed up matching to find differences and do not cause any differing lines or characters to be ignored. Read the description of the **`find_longest_match()`** method's *isjunk* parameter for an explanation.

`Differ` objects are used (deltas generated) via a single method:

compare(*a*, *b*)

Compare two sequences of lines, and generate the delta (a sequence of lines).

Each sequence must contain individual single-line strings ending with newlines. Such sequences can be obtained from the **`readlines()`** method of file-like objects. The delta generated also consists of newline-terminated strings, ready to be printed as-is via the **`writelines()`** method of a file-like object.

Differ Example

This example compares two texts. First we set up the texts, sequences of individual single-line strings ending with newlines (such sequences can also be obtained from the **`readlines()`** method of file-like objects):

```
>>> text1 = '''  1. Beautiful is better than ugly.
...   2. Explicit is better than implicit.
...   3. Simple is better than complex.
...   4. Complex is better than complicated.
... '''.splitlines(keepends=True)
>>> len(text1)
4
>>> text1[0][-1]
'\n'
>>> text2 = '''  1. Beautiful is better than ugly.
...   3.   Simple is better than complex.
...   4. Complicated is better than complex.
...   5. Flat is better than nested.
... '''.splitlines(keepends=True)
```

Next we instantiate a Differ object:

```
>>> d = Differ()
```

Note that when instantiating a **`Differ`** object we may pass functions to filter out line and character "junk." See the **`Differ()`** constructor for details.

Finally, we compare the two:

```
>>> result = list(d.compare(text1, text2))
```

`result` is a list of strings, so let's pretty-print it:

```
>>> from pprint import pprint
>>> pprint(result)
['    1. Beautiful is better than ugly.\n',
 '-   2. Explicit is better than implicit.\n',
 '-   3. Simple is better than complex.\n',
 '+   3.   Simple is better than complex.\n',
 '?     ++\n',
 '-   4. Complex is better than complicated.\n',
 '?            ^                     ---- ^\n',
 '+   4. Complicated is better than complex.\n',
 '?           ++++ ^                     ^\n',
```

```
 '+   5. Flat is better than nested.\n']
```

As a single multi-line string it looks like this:

```
>>> import sys
>>> sys.stdout.writelines(result)
    1. Beautiful is better than ugly.
-   2. Explicit is better than implicit.
-   3. Simple is better than complex.
+   3.   Simple is better than complex.
?     ++
-   4. Complex is better than complicated.
?           ^                     ---- ^
+   4. Complicated is better than complex.
?          ++++ ^                      ^
+   5. Flat is better than nested.
```

A command-line interface to difflib

This example shows how to use difflib to create a `diff`-like utility. It is also contained in the Python source distribution, as `Tools/scripts/diff.py`.

```
#!/usr/bin/env python3
""" Command line interface to difflib.py providing diffs

* ndiff:    lists every line and highlights interline ch
* context:  highlights clusters of changes in a before/a
* unified:  highlights clusters of changes in an inline
* html:     generates side by side comparison with chang

`textwrap` — Text wrapping and filling

Source code: Lib/textwrap.py [https://github.com/python/cpython/tree/3.11/Lib/textwrap.py]

The `textwrap` module provides some convenience functions, as well as `TextWrapper`, the class that does all the work. If you're just wrapping or filling one or two text strings, the convenience functions should be good enough; otherwise, you should use an instance of `TextWrapper` for efficiency.

textwrap.wrap(*text*, *width*=*70*, ***, *initial_indent*='', *subsequent_indent*='', *expand_tabs*=*True*, *replace_whitespace*=*True*, *fix_sentence_endings*=*False*, *break_long_words*=*True*, *drop_whitespace*=*True*, *break_on_hyphens*=*True*, *tabsize*=*8*, *max_lines*=*None*, *placeholder*=' [...]')

> Wraps the single paragraph in *text* (a string) so every line is at most *width* characters long. Returns a list of output lines, without final newlines.
>
> Optional keyword arguments correspond to the instance attributes of `TextWrapper`, documented below.
>
> See the `TextWrapper.wrap()` method for additional details on how `wrap()` behaves.

textwrap.fill(*text*, *width*=*70*, ***, *initial_indent*='', *subsequent_indent*='', *expand_tabs*=*True*, *replace_whitespace*=*True*, *fix_sentence_endings*=*False*, *break_long_words*=*True*, *drop_whitespace*=*True*, *break_on_hyphens*=*True*, *tabsize*=*8*, *max_lines*=*None*, *placeholder*=' [...]')

> Wraps the single paragraph in *text*, and returns a single string

containing the wrapped paragraph. **fill()** is shorthand for

```
"\n".join(wrap(text, ...))
```

In particular, **fill()** accepts exactly the same keyword arguments as **wrap()**.

textwrap.shorten(*text*, *width*, *, *fix_sentence_endings*=*False*, *break_long_words*=*True*, *break_on_hyphens*=*True*, *placeholder*=*' [...]'*)

Collapse and truncate the given *text* to fit in the given *width*.

First the whitespace in *text* is collapsed (all whitespace is replaced by single spaces). If the result fits in the *width*, it is returned. Otherwise, enough words are dropped from the end so that the remaining words plus the **placeholder** fit within **width**:

```
>>> textwrap.shorten("Hello  world!", width=12)
'Hello world!'
>>> textwrap.shorten("Hello  world!", width=11)
'Hello [...]'
>>> textwrap.shorten("Hello world", width=10, place
'Hello...'
```

Optional keyword arguments correspond to the instance attributes of **TextWrapper**, documented below. Note that the whitespace is collapsed before the text is passed to the **TextWrapper fill()** function, so changing the value of **tabsize**, **expand_tabs**, **drop_whitespace**, and **replace_whitespace** will have no effect.

New in version 3.4.

textwrap.dedent(*text*)

Remove any common leading whitespace from every line in *text*.

This can be used to make triple-quoted strings line up with the left edge of the display, while still presenting them in the source code in indented form.

Note that tabs and spaces are both treated as whitespace, but they are not equal: the lines `"  hello"` and `"\thello"` are considered to have no common leading whitespace.

Lines containing only whitespace are ignored in the input and normalized to a single newline character in the output.

For example:

```
def test():
    # end first line with \ to avoid the empty line
    s = '''\
    hello
      world
    '''
    print(repr(s))           # prints '    hello\n
    print(repr(dedent(s)))   # prints 'hello\n  worl
```

textwrap.indent(*text*, *prefix*, *predicate=None*)

Add *prefix* to the beginning of selected lines in *text*.

Lines are separated by calling `text.splitlines(True)`.

By default, *prefix* is added to all lines that do not consist solely of whitespace (including any line endings).

For example:

```
>>> s = 'hello\n\n \nworld'
>>> indent(s, '  ')
'  hello\n\n \n  world'
```

The optional *predicate* argument can be used to control which lines are indented. For example, it is easy to add *prefix* to even empty and whitespace-only lines:

```
>>> print(indent(s, '+ ', lambda line: True))
+ hello
+
+
```

```
+ world
```

New in version 3.3.

wrap(), **fill()** and **shorten()** work by creating a **TextWrapper** instance and calling a single method on it. That instance is not reused, so for applications that process many text strings using **wrap()** and/or **fill()**, it may be more efficient to create your own **TextWrapper** object.

Text is preferably wrapped on whitespaces and right after the hyphens in hyphenated words; only then will long words be broken if necessary, unless **TextWrapper.break_long_words** is set to false.

class textwrap.TextWrapper(***kwargs*)

The **TextWrapper** constructor accepts a number of optional keyword arguments. Each keyword argument corresponds to an instance attribute, so for example

```
wrapper = TextWrapper(initial_indent="* ")
```

is the same as

```
wrapper = TextWrapper()
wrapper.initial_indent = "* "
```

You can re-use the same **TextWrapper** object many times, and you can change any of its options through direct assignment to instance attributes between uses.

The **TextWrapper** instance attributes (and keyword arguments to the constructor) are as follows:

width

(default: `70`) The maximum length of wrapped lines. As long as there are no individual words in the input text longer than **width**, **TextWrapper** guarantees that no output line will be longer than **width** characters.

expand_tabs

(default: `True`) If true, then all tab characters in *text* will be expanded to spaces using the **`expandtabs()`** method of *text*.

tabsize

(default: `8`) If **`expand_tabs`** is true, then all tab characters in *text* will be expanded to zero or more spaces, depending on the current column and the given tab size.

New in version 3.3.

replace_whitespace

(default: `True`) If true, after tab expansion but before wrapping, the **`wrap()`** method will replace each whitespace character with a single space. The whitespace characters replaced are as follows: tab, newline, vertical tab, formfeed, and carriage return (`'\t\n\v\f\r'`).

Note

If **`expand_tabs`** is false and **`replace_whitespace`** is true, each tab character will be replaced by a single space, which is *not* the same as tab expansion.

Note

If **`replace_whitespace`** is false, newlines may appear in the middle of a line and cause strange output. For this reason, text should be split into paragraphs (using **`str.splitlines()`** or similar) which are wrapped separately.

drop_whitespace

(default: `True`) If true, whitespace at the beginning and ending of every line (after wrapping but before indenting) is dropped. Whitespace at the beginning of the paragraph, however, is not dropped if non-whitespace follows it. If whitespace being dropped takes up an entire line, the whole line is dropped.

initial_indent

(default: `''`) String that will be prepended to the first line of wrapped output. Counts towards the length of the first line. The empty string is not indented.

subsequent_indent

(default: `''`) String that will be prepended to all lines of wrapped output except the first. Counts towards the length of each line except the first.

fix_sentence_endings

(default: `False`) If true, **`TextWrapper`** attempts to detect sentence endings and ensure that sentences are always separated by exactly two spaces. This is generally desired for text in a monospaced font. However, the sentence detection algorithm is imperfect: it assumes that a sentence ending consists of a lowercase letter followed by one of `'.'`, `'!'`, or `'?'`, possibly followed by one of `'"'` or `"'"`, followed by a space. One problem with this is algorithm is that it is unable to detect the difference between “Dr.” in

```
[...] Dr. Frankenstein's monster [...]
```

and “Spot.” in

```
[...] See Spot. See Spot run [...]
```

`fix_sentence_endings` is false by default.

Since the sentence detection algorithm relies on `string.lowercase` for the definition of “lowercase letter”, and a convention of using two spaces after a

period to separate sentences on the same line, it is specific to English-language texts.

break_long_words

(default: `True`) If true, then words longer than **`width`** will be broken in order to ensure that no lines are longer than **`width`**. If it is false, long words will not be broken, and some lines may be longer than **`width`**. (Long words will be put on a line by themselves, in order to minimize the amount by which **`width`** is exceeded.)

break_on_hyphens

(default: `True`) If true, wrapping will occur preferably on whitespaces and right after hyphens in compound words, as it is customary in English. If false, only whitespaces will be considered as potentially good places for line breaks, but you need to set **`break_long_words`** to false if you want truly insecable words. Default behaviour in previous versions was to always allow breaking hyphenated words.

max_lines

(default: `None`) If not `None`, then the output will contain at most *max_lines* lines, with *placeholder* appearing at the end of the output.

New in version 3.4.

placeholder

(default: `' [...]'`) String that will appear at the end of the output text if it has been truncated.

New in version 3.4.

`TextWrapper` also provides some public methods, analogous to the module-level convenience functions:

wrap(*text*)

Wraps the single paragraph in *text* (a string) so every line is at most **`width`** characters long. All wrapping options are taken from instance attributes of the **`TextWrapper`** instance. Returns a list of output lines, without final newlines. If the wrapped output has no content, the returned list is empty.

fill(*text*)

Wraps the single paragraph in *text*, and returns a single string containing the wrapped paragraph.

`unicodedata` — Unicode Database

This module provides access to the Unicode Character Database (UCD) which defines character properties for all Unicode characters. The data contained in this database is compiled from the UCD version 14.0.0 [https://www.unicode.org/Public/14.0.0/ucd].

The module uses the same names and symbols as defined by Unicode Standard Annex #44, "Unicode Character Database" [https://www.unicode.org/reports/tr44/]. It defines the following functions:

unicodedata.lookup(*name*)

> Look up character by name. If a character with the given name is found, return the corresponding character. If not found, **`KeyError`** is raised.
>
> *Changed in version 3.3:* Support for name aliases 1 and named sequences 2 has been added.

unicodedata.name(*chr*[, *default*])

> Returns the name assigned to the character *chr* as a string. If no name is defined, *default* is returned, or, if not given, **`ValueError`** is raised.

unicodedata.decimal(*chr*[, *default*])

> Returns the decimal value assigned to the character *chr* as integer. If no such value is defined, *default* is returned, or, if not given, **`ValueError`** is raised.

unicodedata.digit(*chr*[, *default*])

Returns the digit value assigned to the character *chr* as integer. If no such value is defined, *default* is returned, or, if not given, **ValueError** is raised.

unicodedata.numeric(*chr*[, *default*])

Returns the numeric value assigned to the character *chr* as float. If no such value is defined, *default* is returned, or, if not given, **ValueError** is raised.

unicodedata.category(*chr*)

Returns the general category assigned to the character *chr* as string.

unicodedata.bidirectional(*chr*)

Returns the bidirectional class assigned to the character *chr* as string. If no such value is defined, an empty string is returned.

unicodedata.combining(*chr*)

Returns the canonical combining class assigned to the character *chr* as integer. Returns `0` if no combining class is defined.

unicodedata.east_asian_width(*chr*)

Returns the east asian width assigned to the character *chr* as string.

unicodedata.mirrored(*chr*)

Returns the mirrored property assigned to the character *chr* as integer. Returns `1` if the character has been identified as a "mirrored" character in bidirectional text, `0` otherwise.

unicodedata.decomposition(*chr*)

Returns the character decomposition mapping assigned to the character *chr* as string. An empty string is returned in case no such mapping is defined.

unicodedata.normalize(*form*, *unistr*)

Return the normal form *form* for the Unicode string *unistr*. Valid values for *form* are ‘NFC’, ‘NFKC’, ‘NFD’, and ‘NFKD’.

The Unicode standard defines various normalization forms of a Unicode string, based on the definition of canonical equivalence and compatibility equivalence. In Unicode, several characters can be expressed in various way. For example, the character U+00C7 (LATIN CAPITAL LETTER C WITH CEDILLA) can also be expressed as the sequence U+0043 (LATIN CAPITAL LETTER C) U+0327 (COMBINING CEDILLA).

For each character, there are two normal forms: normal form C and normal form D. Normal form D (NFD) is also known as canonical decomposition, and translates each character into its decomposed form. Normal form C (NFC) first applies a canonical decomposition, then composes pre-combined characters again.

In addition to these two forms, there are two additional normal forms based on compatibility equivalence. In Unicode, certain characters are supported which normally would be unified with other characters. For example, U+2160 (ROMAN NUMERAL ONE) is really the same thing as U+0049 (LATIN CAPITAL LETTER I). However, it is supported in Unicode for compatibility with existing character sets (e.g. gb2312).

The normal form KD (NFKD) will apply the compatibility decomposition, i.e. replace all compatibility characters with their equivalents. The normal form KC (NFKC) first applies the compatibility decomposition, followed by the canonical composition.

Even if two unicode strings are normalized and look the same to a human reader, if one has combining characters and the other doesn’t, they may not compare equal.

unicodedata.is_normalized(*form*, *unistr*)

Return whether the Unicode string *unistr* is in the normal form *form*. Valid values for *form* are 'NFC', 'NFKC', 'NFD', and 'NFKD'.

New in version 3.8.

In addition, the module exposes the following constant:

unicodedata.unidata_version
: The version of the Unicode database used in this module.

unicodedata.ucd_3_2_0
: This is an object that has the same methods as the entire module, but uses the Unicode database version 3.2 instead, for applications that require this specific version of the Unicode database (such as IDNA).

Examples:

```
>>> import unicodedata
>>> unicodedata.lookup('LEFT CURLY BRACKET')
'{'
>>> unicodedata.name('/')
'SOLIDUS'
>>> unicodedata.decimal('9')
9
>>> unicodedata.decimal('a')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: not a decimal
>>> unicodedata.category('A')  # 'L'etter, 'u'ppercase
'Lu'
>>> unicodedata.bidirectional('\u0660') # 'A'rabic, 'N'u
'AN'
```

`stringprep` — Internet String Preparation

Source code: Lib/stringprep.py [https://github.com/python/cpython/tree/3.11/Lib/stringprep.py]

When identifying things (such as host names) in the internet, it is often necessary to compare such identifications for "equality". Exactly how this comparison is executed may depend on the application domain, e.g. whether it should be case-insensitive or not. It may be also necessary to restrict the possible identifications, to allow only identifications consisting of "printable" characters.

RFC 3454 [https://datatracker.ietf.org/doc/html/rfc3454.html] defines a procedure for "preparing" Unicode strings in internet protocols. Before passing strings onto the wire, they are processed with the preparation procedure, after which they have a certain normalized form. The RFC defines a set of tables, which can be combined into profiles. Each profile must define which tables it uses, and what other optional parts of the `stringprep` procedure are part of the profile. One example of a `stringprep` profile is `nameprep`, which is used for internationalized domain names.

The module **`stringprep`** only exposes the tables from **RFC 3454** [https://datatracker.ietf.org/doc/html/rfc3454.html]. As these tables would be very large to represent them as dictionaries or lists, the module uses the Unicode character database internally. The module source code itself was generated using the `mkstringprep.py` utility.

As a result, these tables are exposed as functions, not as data structures. There are two kinds of tables in the RFC: sets and mappings. For a set, **`stringprep`** provides the "characteristic function", i.e. a function that returns `True` if the parameter is part of the set. For mappings, it provides the mapping function: given the key, it returns the associated value. Below is a list of all

functions available in the module.

stringprep.in_table_a1(*code*)

Determine whether *code* is in tableA.1 (Unassigned code points in Unicode 3.2).

stringprep.in_table_b1(*code*)

Determine whether *code* is in tableB.1 (Commonly mapped to nothing).

stringprep.map_table_b2(*code*)

Return the mapped value for *code* according to tableB.2 (Mapping for case-folding used with NFKC).

stringprep.map_table_b3(*code*)

Return the mapped value for *code* according to tableB.3 (Mapping for case-folding used with no normalization).

stringprep.in_table_c11(*code*)

Determine whether *code* is in tableC.1.1 (ASCII space characters).

stringprep.in_table_c12(*code*)

Determine whether *code* is in tableC.1.2 (Non-ASCII space characters).

stringprep.in_table_c11_c12(*code*)

Determine whether *code* is in tableC.1 (Space characters, union of C.1.1 and C.1.2).

stringprep.in_table_c21(*code*)

Determine whether *code* is in tableC.2.1 (ASCII control characters).

stringprep.in_table_c22(*code*)

Determine whether *code* is in tableC.2.2 (Non-ASCII control characters).

stringprep.in_table_c21_c22(*code*)

Determine whether *code* is in tableC.2 (Control characters, union of C.2.1 and C.2.2).

stringprep.in_table_c3(*code*)

Determine whether *code* is in tableC.3 (Private use).

stringprep.in_table_c4(*code*)

Determine whether *code* is in tableC.4 (Non-character code points).

stringprep.in_table_c5(*code*)

Determine whether *code* is in tableC.5 (Surrogate codes).

stringprep.in_table_c6(*code*)

Determine whether *code* is in tableC.6 (Inappropriate for plain text).

stringprep.in_table_c7(*code*)

Determine whether *code* is in tableC.7 (Inappropriate for canonical representation).

stringprep.in_table_c8(*code*)

Determine whether *code* is in tableC.8 (Change display properties or are deprecated).

stringprep.in_table_c9(*code*)

Determine whether *code* is in tableC.9 (Tagging characters).

stringprep.in_table_d1(*code*)

Determine whether *code* is in tableD.1 (Characters with bidirectional property “R” or “AL”).

stringprep.in_table_d2(*code*)

Determine whether *code* is in tableD.2 (Characters with bidirectional property “L”).

`readline` — GNU readline interface

The `readline` module defines a number of functions to facilitate completion and reading/writing of history files from the Python interpreter. This module can be used directly, or via the `rlcompleter` module, which supports completion of Python identifiers at the interactive prompt. Settings made using this module affect the behaviour of both the interpreter's interactive prompt and the prompts offered by the built-in `input()` function.

Readline keybindings may be configured via an initialization file, typically `.inputrc` in your home directory. See Readline Init File [https://tiswww.cwru.edu/php/chet/readline/rluserman.html#SEC9] in the GNU Readline manual for information about the format and allowable constructs of that file, and the capabilities of the Readline library in general.

Note

The underlying Readline library API may be implemented by the `libedit` library instead of GNU readline. On macOS the `readline` module detects which library is being used at run time.

The configuration file for `libedit` is different from that of GNU readline. If you programmatically load configuration strings you can check for the text "libedit" in `readline.__doc__` to differentiate between GNU readline and libedit.

If you use *editline*/`libedit` readline emulation on macOS, the initialization file located in your home directory is named `.editrc`. For example, the following content in `~/.editrc` will turn ON *vi* keybindings and TAB completion:

```
python:bind -v
python:bind ^I rl_complete
```

Init file

The following functions relate to the init file and user configuration:

readline.parse_and_bind(*string*)

Execute the init line provided in the *string* argument. This calls **`rl_parse_and_bind()`** in the underlying library.

readline.read_init_file([*filename*])

Execute a readline initialization file. The default filename is the last filename used. This calls **`rl_read_init_file()`** in the underlying library.

Line buffer

The following functions operate on the line buffer:

readline.get_line_buffer()

Return the current contents of the line buffer (**`rl_line_buffer`** in the underlying library).

readline.insert_text(*string*)

Insert text into the line buffer at the cursor position. This calls **`rl_insert_text()`** in the underlying library, but ignores the return value.

readline.redisplay()

Change what's displayed on the screen to reflect the current contents of the line buffer. This calls **`rl_redisplay()`** in the underlying library.

History file

The following functions operate on a history file:

readline.read_history_file([*filename*])

Load a readline history file, and append it to the history list. The default filename is `~/.history`. This calls **`read_history()`** in the underlying library.

readline.write_history_file([*filename*])

Save the history list to a readline history file, overwriting any existing file. The default filename is `~/.history`. This calls **`write_history()`** in the underlying library.

readline.append_history_file(*nelements*[, *filename*])

Append the last *nelements* items of history to a file. The default filename is `~/.history`. The file must already exist. This calls **`append_history()`** in the underlying library. This function only exists if Python was compiled for a version of the library that supports it.

New in version 3.5.

readline.get_history_length()
readline.set_history_length(*length*)

Set or return the desired number of lines to save in the history file. The **`write_history_file()`** function uses this value to truncate the history file, by calling **`history_truncate_file()`** in the underlying library. Negative values imply unlimited history file size.

History list

The following functions operate on a global history list:

readline.clear_history()

Clear the current history. This calls **`clear_history()`** in the underlying library. The Python function only exists if Python was compiled for a version of the library that supports

it.

readline.get_current_history_length()

Return the number of items currently in the history. (This is different from **get_history_length()**, which returns the maximum number of lines that will be written to a history file.)

readline.get_history_item(*index*)

Return the current contents of history item at *index*. The item index is one-based. This calls **history_get()** in the underlying library.

readline.remove_history_item(*pos*)

Remove history item specified by its position from the history. The position is zero-based. This calls **remove_history()** in the underlying library.

readline.replace_history_item(*pos*, *line*)

Replace history item specified by its position with *line*. The position is zero-based. This calls **replace_history_entry()** in the underlying library.

readline.add_history(*line*)

Append *line* to the history buffer, as if it was the last line typed. This calls **add_history()** in the underlying library.

readline.set_auto_history(*enabled*)

Enable or disable automatic calls to **add_history()** when reading input via readline. The *enabled* argument should be a Boolean value that when true, enables auto history, and that when false, disables auto history.

New in version 3.6.

CPython implementation detail: Auto history is enabled by default, and changes to this do not persist across multiple

sessions.

Startup hooks

readline.set_startup_hook([*function*])

Set or remove the function invoked by the **`rl_startup_hook`** callback of the underlying library. If *function* is specified, it will be used as the new hook function; if omitted or `None`, any function already installed is removed. The hook is called with no arguments just before readline prints the first prompt.

readline.set_pre_input_hook([*function*])

Set or remove the function invoked by the **`rl_pre_input_hook`** callback of the underlying library. If *function* is specified, it will be used as the new hook function; if omitted or `None`, any function already installed is removed. The hook is called with no arguments after the first prompt has been printed and just before readline starts reading input characters. This function only exists if Python was compiled for a version of the library that supports it.

Completion

The following functions relate to implementing a custom word completion function. This is typically operated by the Tab key, and can suggest and automatically complete a word being typed. By default, Readline is set up to be used by **`rlcompleter`** to complete Python identifiers for the interactive interpreter. If the **`readline`** module is to be used with a custom completer, a different set of word delimiters should be set.

readline.set_completer([*function*])

Set or remove the completer function. If *function* is specified, it will be used as the new completer function; if omitted or `None`, any completer function already installed is removed. The completer function is called as `function(text,`

`state)`, for *state* in `0, 1, 2`, ..., until it returns a non-string value. It should return the next possible completion starting with *text*.

The installed completer function is invoked by the *entry_func* callback passed to **`rl_completion_matches()`** in the underlying library. The *text* string comes from the first parameter to the **`rl_attempted_completion_function`** callback of the underlying library.

readline.get_completer()

Get the completer function, or `None` if no completer function has been set.

readline.get_completion_type()

Get the type of completion being attempted. This returns the **`rl_completion_type`** variable in the underlying library as an integer.

readline.get_begidx()
readline.get_endidx()

Get the beginning or ending index of the completion scope. These indexes are the *start* and *end* arguments passed to the **`rl_attempted_completion_function`** callback of the underlying library. The values may be different in the same input editing scenario based on the underlying C readline implementation. Ex: libedit is known to behave differently than libreadline.

readline.set_completer_delims(*string*)
readline.get_completer_delims()

Set or get the word delimiters for completion. These determine the start of the word to be considered for completion (the completion scope). These functions access the **`rl_completer_word_break_characters`** variable in the underlying library.

readline.set_completion_display_matches_hook([*function*])

Set or remove the completion display function. If *function* is specified, it will be used as the new completion display function; if omitted or `None`, any completion display function already installed is removed. This sets or clears the **`rl_completion_display_matches_hook`** callback in the underlying library. The completion display function is called as `function(substitution, [matches], longest_match_length)` once each time matches need to be displayed.

Example

The following example demonstrates how to use the **`readline`** module's history reading and writing functions to automatically load and save a history file named `.python_history` from the user's home directory. The code below would normally be executed automatically during interactive sessions from the user's **`PYTHONSTARTUP`** file.

```
import atexit
import os
import readline

histfile = os.path.join(os.path.expanduser("~"), ".pytho
try:
    readline.read_history_file(histfile)
    # default history len is -1 (infinite), which may gr
    readline.set_history_length(1000)
except FileNotFoundError:
    pass

atexit.register(readline.write_history_file, histfile)
```

This code is actually automatically run when Python is run in interactive mode (see Readline configuration).

The following example achieves the same goal but supports concurrent interactive sessions, by only appending the new history.

```
import atexit
import os
import readline
histfile = os.path.join(os.path.expanduser("~"), ".pytho

try:
    readline.read_history_file(histfile)
    h_len = readline.get_current_history_length()
except FileNotFoundError:
    open(histfile, 'wb').close()
    h_len = 0

def save(prev_h_len, histfile):
    new_h_len = readline.get_current_history_length()
    readline.set_history_length(1000)
    readline.append_history_file(new_h_len - prev_h_len,
atexit.register(save, h_len, histfile)
```

The following example extends the **`code.InteractiveConsole`** class to support history save/restore.

```
import atexit
import code
import os
import readline

class HistoryConsole(code.InteractiveConsole):
    def __init__(self, locals=None, filename="<console>"
                 histfile=os.path.expanduser("~/.console
        code.InteractiveConsole.__init__(self, locals, f
        self.init_history(histfile)

    def init_history(self, histfile):
        readline.parse_and_bind("tab: complete")
        if hasattr(readline, "read_history_file"):
            try:
                readline.read_history_file(histfile)
            except FileNotFoundError:
                pass
```

```
            atexit.register(self.save_history, histfile)

    def save_history(self, histfile):
        readline.set_history_length(1000)
        readline.write_history_file(histfile)
```

`rlcompleter` — Completion function for GNU readline

Source code: Lib/rlcompleter.py [https://github.com/python/cpython/tree/3.11/Lib/rlcompleter.py]

The `rlcompleter` module defines a completion function suitable for the `readline` module by completing valid Python identifiers and keywords.

When this module is imported on a Unix platform with the `readline` module available, an instance of the `Completer` class is automatically created and its `complete()` method is set as the `readline` completer.

Example:

```
>>> import rlcompleter
>>> import readline
>>> readline.parse_and_bind("tab: complete")
>>> readline. <TAB PRESSED>
readline.__doc__          readline.get_line_buffer(  rea
readline.__file__         readline.insert_text(      rea
readline.__name__         readline.parse_and_bind(
>>> readline.
```

The `rlcompleter` module is designed for use with Python's interactive mode. Unless Python is run with the `-S` option, the module is automatically imported and configured (see Readline configuration).

On platforms without `readline`, the `Completer` class defined by this module can still be used for custom purposes.

Completer Objects

Completer objects have the following method:

Completer.complete(*text*, *state*)

Return the *state*th completion for *text*.

If called for *text* that doesn't include a period character (`'.'`), it will complete from names currently defined in **`__main__`**, **`builtins`** and keywords (as defined by the **`keyword`** module).

If called for a dotted name, it will try to evaluate anything without obvious side-effects (functions will not be evaluated, but it can generate calls to **`__getattr__()`**) up to the last part, and find matches for the rest via the **`dir()`** function. Any exception raised during the evaluation of the expression is caught, silenced and **`None`** is returned.

Binary Data Services

The modules described in this chapter provide some basic services operations for manipulation of binary data. Other operations on binary data, specifically in relation to file formats and network protocols, are described in the relevant sections.

Some libraries described under Text Processing Services also work with either ASCII-compatible binary formats (for example, **`re`**) or all binary data (for example, **`difflib`**).

In addition, see the documentation for Python's built-in binary data types in Binary Sequence Types — bytes, bytearray, memoryview.

`struct` — Interpret bytes as packed binary data

Source code: Lib/struct.py [https://github.com/python/cpython/tree/3.11/Lib/struct.py]

This module converts between Python values and C structs represented as Python `bytes` objects. Compact format strings describe the intended conversions to/from Python values. The module's functions and objects can be used for two largely distinct applications, data exchange with external sources (files or network connections), or data transfer between the Python application and the C layer.

Note

When no prefix character is given, native mode is the default. It packs or unpacks data based on the platform and compiler on which the Python interpreter was built. The result of packing a given C struct includes pad bytes which maintain proper alignment for the C types involved; similarly, alignment is taken into account when unpacking. In contrast, when communicating data between external sources, the programmer is responsible for defining byte ordering and padding between elements. See Byte Order, Size, and Alignment for details.

Several `struct` functions (and methods of `Struct`) take a *buffer* argument. This refers to objects that implement the Buffer Protocol and provide either a readable or read-writable buffer. The most common types used for that purpose are `bytes` and `bytearray`, but many other types that can be viewed as an array of bytes implement the buffer protocol, so that they can be read/filled without additional copying from a `bytes` object.

Functions and Exceptions

The module defines the following exception and functions:

exception struct.error

Exception raised on various occasions; argument is a string describing what is wrong.

struct.pack(*format*, *v1*, *v2*, ...)

Return a bytes object containing the values *v1*, *v2*, … packed according to the format string *format*. The arguments must match the values required by the format exactly.

struct.pack_into(*format*, *buffer*, *offset*, *v1*, *v2*, ...)

Pack the values *v1*, *v2*, … according to the format string *format* and write the packed bytes into the writable buffer *buffer* starting at position *offset*. Note that *offset* is a required argument.

struct.unpack(*format*, *buffer*)

Unpack from the buffer *buffer* (presumably packed by `pack(format, ...)`) according to the format string *format*. The result is a tuple even if it contains exactly one item. The buffer's size in bytes must match the size required by the format, as reflected by **`calcsize()`**.

struct.unpack_from(*format*, */*, *buffer*, *offset=0*)

Unpack from *buffer* starting at position *offset*, according to the format string *format*. The result is a tuple even if it contains exactly one item. The buffer's size in bytes, starting at position *offset*, must be at least the size required by the format, as reflected by **`calcsize()`**.

struct.iter_unpack(*format*, *buffer*)

Iteratively unpack from the buffer *buffer* according to the format string *format*. This function returns an iterator which will read equally sized chunks from the buffer until all its

contents have been consumed. The buffer's size in bytes must be a multiple of the size required by the format, as reflected by `calcsize()`.

Each iteration yields a tuple as specified by the format string.

New in version 3.4.

struct.calcsize(*format*)

Return the size of the struct (and hence of the bytes object produced by `pack(format, ...)`) corresponding to the format string *format*.

Format Strings

Format strings describe the data layout when packing and unpacking data. They are built up from format characters, which specify the type of data being packed/unpacked. In addition, special characters control the byte order, size and alignment. Each format string consists of an optional prefix character which describes the overall properties of the data and one or more format characters which describe the actual data values and padding.

Byte Order, Size, and Alignment

By default, C types are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler). This behavior is chosen so that the bytes of a packed struct correspond exactly to the memory layout of the corresponding C struct. Whether to use native byte ordering and padding or standard formats depends on the application.

Alternatively, the first character of the format string can be used to indicate the byte order, size and alignment of the packed data, according to the following table:

Character	Byte order	Size	Alignment
@	native	native	native

	standard
	little-endian
	big-endian
	standard (= big-endian)

If the first character is not one of these, `'@'` is assumed.

Native byte order is big-endian or little-endian, depending on the host system. For example, Intel x86, AMD64 (x86-64), and Apple M1 are little-endian; IBM z and many legacy architectures are big-endian. Use **`sys.byteorder`** to check the endianness of your system.

Native size and alignment are determined using the C compiler's `sizeof` expression. This is always combined with native byte order.

Standard size depends only on the format character; see the table in the Format Characters section.

Note the difference between `'@'` and `'='`: both use native byte order, but the size and alignment of the latter is standardized.

The form `'!'` represents the network byte order which is always big-endian as defined in IETF RFC 1700 [https://tools.ietf.org/html/rfc1700].

There is no way to indicate non-native byte order (force byte-swapping); use the appropriate choice of `'<'` or `'>'`.

Notes:

1. Padding is only automatically added between successive structure members. No padding is added at the beginning or the end of the encoded struct.
2. No padding is added when using non-native size and alignment, e.g. with '<', '>', '=', and '!'.
3. To align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero. See Examples.

Format Characters

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types. The ‘Standard size’ column refers to the size of the packed value in bytes when using standard size; that is, when the format string starts with one of `'<'`, `'>'`, `'!'` or `'='`. When using native size, the size of the packed value is platform-dependent.

Format	C type	Python type	Standard size	Notes
(2)	value			
	bytes of length 1			
	char			
	signed char			
	_Bool			
	short			
	signed short			
	int			
	signed int			
	long			
	signed long			
	long long			
	signed long long			
	double			

Changed in version 3.3: Added support for the `'n'` and `'N'` formats.

Changed in version 3.6: Added support for the `'e'` format.

Notes:

1. The `'?'` conversion code corresponds to the _Bool type defined by C99. If this type is not available, it is simulated

using a char. In standard mode, it is always represented by one byte.

2. When attempting to pack a non-integer using any of the integer conversion codes, if the non-integer has a **`__index__()`** method then that method is called to convert the argument to an integer before packing.

   Changed in version 3.2: Added use of the **`__index__()`** method for non-integers.

3. The `'n'` and `'N'` conversion codes are only available for the native size (selected as the default or with the `'@'` byte order character). For the standard size, you can use whichever of the other integer formats fits your application.

4. For the `'f'`, `'d'` and `'e'` conversion codes, the packed representation uses the IEEE 754 binary32, binary64 or binary16 format (for `'f'`, `'d'` or `'e'` respectively), regardless of the floating-point format used by the platform.

5. The `'P'` format character is only available for the native byte ordering (selected as the default or with the `'@'` byte order character). The byte order character `'='` chooses to use little- or big-endian ordering based on the host system. The struct module does not interpret this as native ordering, so the `'P'` format is not available.

6. The IEEE 754 binary16 “half precision” type was introduced in the 2008 revision of the IEEE 754 standard [https://en.wikipedia.org/wiki/IEEE_754-2008_revision]. It has a sign bit, a 5-bit exponent and 11-bit precision (with 10 bits explicitly stored), and can represent numbers between approximately `6.1e-05` and `6.5e+04` at full precision. This type is not widely supported by C compilers: on a typical machine, an unsigned short can be used for storage, but not for math operations. See the Wikipedia page on the half-precision floating-point format [https://en.wikipedia.org/wiki/Half-precision_floating-point_format] for more information.

7. When packing, `'x'` inserts one NUL byte.

8. The `'p'` format character encodes a “Pascal string”, meaning a short variable-length string stored in a *fixed number of bytes*, given by the count. The first byte stored is the length of the string, or 255, whichever is smaller. The bytes of the string follow. If the string passed in to **`pack()`** is too long (longer than the count minus 1), only the leading `count-1` bytes of the string are stored. If the string is shorter than `count-1`, it is padded with null bytes so that exactly count bytes in all are used. Note that for **`unpack()`**, the `'p'` format character consumes `count` bytes, but that the string returned can never contain more than 255 bytes.

9. For the `'s'` format character, the count is interpreted as the length of the bytes, not a repeat count like for the other format characters; for example, `'10s'` means a single 10-byte string mapping to or from a single Python byte string, while `'10c'` means 10 separate one byte character elements (e.g., `cccccccccc`) mapping to or from ten different Python byte objects. (See Examples for a concrete demonstration of the difference.) If a count is not given, it defaults to 1. For packing, the string is truncated or padded with null bytes as appropriate to make it fit. For unpacking, the resulting bytes object always has exactly the specified number of bytes. As a special case, `'0s'` means a single, empty string (while `'0c'` means 0 characters).

A format character may be preceded by an integral repeat count. For example, the format string `'4h'` means exactly the same as `'hhhh'`.

Whitespace characters between formats are ignored; a count and its format must not contain whitespace though.

When packing a value `x` using one of the integer formats (`'b'`, `'B'`, `'h'`, `'H'`, `'i'`, `'I'`, `'l'`, `'L'`, `'q'`, `'Q'`), if `x` is outside the valid range for that format then **`struct.error`** is raised.

Changed in version 3.1: Previously, some of the integer formats wrapped out-of-range values and raised **`DeprecationWarning`** instead of **`struct.error`**.

For the `'?'` format character, the return value is either **`True`** or **`False`**. When packing, the truth value of the argument object is used. Either 0 or 1 in the native or standard bool representation will be packed, and any non-zero value will be `True` when unpacking.

Examples

> **Note**
>
> Native byte order examples (designated by the `'@'` format prefix or lack of any prefix character) may not match what the reader's machine produces as that depends on the platform and compiler.

Pack and unpack integers of three different sizes, using big endian ordering:

```
>>> from struct import *
>>> pack(">bhl", 1, 2, 3)
b'\x01\x00\x02\x00\x00\x00\x03'
>>> unpack('>bhl', b'\x01\x00\x02\x00\x00\x00\x03'
(1, 2, 3)
>>> calcsize('>bhl')
7
```

Attempt to pack an integer which is too large for the defined field:

```
>>> pack(">h", 99999)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
struct.error: 'h' format requires -32768 <= number <= 32
```

Demonstrate the difference between `'s'` and `'c'` format characters:

```
>>> pack("@ccc", b'1', b'2', b'3')
b'123'
>>> pack("@3s", b'123')
b'123'
```

Unpacked fields can be named by assigning them to variables or by wrapping the result in a named tuple:

```
>>> record = b'raymond   \x32\x12\x08\x01\x08'
>>> name, serialnum, school, gradelevel = unpack('<10sHH

>>> from collections import namedtuple
>>> Student = namedtuple('Student', 'name serialnum scho
>>> Student._make(unpack('<10sHHb', record))
Student(name=b'raymond   ', serialnum=4658, school=264,
```

The ordering of format characters may have an impact on size in native mode since padding is implicit. In standard mode, the user is responsible for inserting any desired padding. Note in the first `pack` call below that three NUL bytes were added after the packed `'#'` to align the following integer on a four-byte boundary. In this example, the output was produced on a little endian machine:

```
>>> pack('@ci', b'#', 0x12131415)
b'#\x00\x00\x00\x15\x14\x13\x12'
>>> pack('@ic', 0x12131415, b'#')
b'\x15\x14\x13\x12#'
>>> calcsize('@ci')
8
>>> calcsize('@ic')
5
```

The following format `'llh0l'` results in two pad bytes being added at the end, assuming the platform's longs are aligned on 4-byte boundaries:

```
>>> pack('@llh0l', 1, 2, 3)
b'\x00\x00\x00\x01\x00\x00\x00\x02\x00\x03\x00\x00'
```

Module `pickle`
Python object serialization.

Applications

Two main applications for the `struct` module exist, data interchange between Python and C code within an application or another application compiled using the same compiler (native formats), and data interchange between applications using agreed upon data layout (standard formats). Generally speaking, the format strings constructed for these two domains are distinct.

Native Formats

When constructing format strings which mimic native layouts, the compiler and machine architecture determine byte ordering and padding. In such cases, the `@` format character should be used to specify native byte ordering and data sizes. Internal pad bytes are normally inserted automatically. It is possible that a zero-repeat format code will be needed at the end of a format string to round up to the correct byte boundary for proper alignment of consective chunks of data.

Consider these two simple examples (on a 64-bit, little-endian machine):

```
>>> calcsize('@lhl')
24
>>> calcsize('@llh')
18
```

Data is not padded to an 8-byte boundary at the end of the second format string without the use of extra padding. A zero-repeat format code solves that problem:

```
>>> calcsize('@llh0l')
24
```

The `'x'` format code can be used to specify the repeat, but for native formats it is better to use a zero-repeat format like `'0l'`.

By default, native byte ordering and alignment is used, but it is better to be explicit and use the `'@'` prefix character.

Standard Formats

When exchanging data beyond your process such as networking or storage, be precise. Specify the exact byte order, size, and alignment. Do not assume they match the native order of a particular machine. For example, network byte order is big-endian, while many popular CPUs are little-endian. By defining this explicitly, the user need not care about the specifics of the platform their code is running on. The first character should typically be `<` or `>` (or `!`). Padding is the responsibility of the programmer. The zero-repeat format character won't work. Instead, the user must explicitly add `'x'` pad bytes where needed. Revisiting the examples from the previous section, we have:

```
>>> calcsize('<qh6xq')
24
>>> pack('<qh6xq', 1, 2, 3) == pack('@lhl', 1, 2, 3)
True
>>> calcsize('@llh')
18
>>> pack('@llh', 1, 2, 3) == pack('<qqh', 1, 2, 3)
True
>>> calcsize('<qqh6x')
24
>>> calcsize('@llh0l')
24
>>> pack('@llh0l', 1, 2, 3) == pack('<qqh6x', 1, 2, 3)
True
```

The above results (executed on a 64-bit machine) aren't guaranteed to match when executed on different machines. For example, the examples below were executed on a 32-bit machine:

```
>>> calcsize('<qqh6x')
```

```
24
>>> calcsize('@llh0l')
12
>>> pack('@llh0l', 1, 2, 3) == pack('<qqh6x', 1, 2, 3)
False
```

Classes

The **`struct`** module also defines the following type:

class struct.Struct(*format*)

Return a new Struct object which writes and reads binary data according to the format string *format*. Creating a `Struct` object once and calling its methods is more efficient than calling module-level functions with the same format since the format string is only compiled once.

Note

The compiled versions of the most recent format strings passed to **`Struct`** and the module-level functions are cached, so programs that use only a few format strings needn't worry about reusing a single **`Struct`** instance.

Compiled Struct objects support the following methods and attributes:

pack(*v1*, *v2*, ...)

Identical to the **`pack()`** function, using the compiled format. (`len(result)` will equal **`size`**.)

pack_into(*buffer*, *offset*, *v1*, *v2*, ...)

Identical to the **`pack_into()`** function, using the compiled format.

unpack(*buffer*)

Identical to the **`unpack()`** function, using the

compiled format. The buffer's size in bytes must equal **size**.

unpack_from(*buffer*, *offset*=*0*)

Identical to the **unpack_from()** function, using the compiled format. The buffer's size in bytes, starting at position *offset*, must be at least **size**.

iter_unpack(*buffer*)

Identical to the **iter_unpack()** function, using the compiled format. The buffer's size in bytes must be a multiple of **size**.

New in version 3.4.

format

The format string used to construct this Struct object.

Changed in version 3.7: The format string type is now **str** instead of **bytes**.

size

The calculated size of the struct (and hence of the bytes object produced by the **pack()** method) corresponding to **format**.

`codecs` — Codec registry and base classes

Source code: Lib/codecs.py [https://github.com/python/cpython/tree/3.11/Lib/codecs.py]

This module defines base classes for standard Python codecs (encoders and decoders) and provides access to the internal Python codec registry, which manages the codec and error handling lookup process. Most standard codecs are text encodings, which encode text to bytes (and decode bytes to text), but there are also codecs provided that encode text to text, and bytes to bytes. Custom codecs may encode and decode between arbitrary types, but some module features are restricted to be used specifically with text encodings or with codecs that encode to `bytes`.

The module defines the following functions for encoding and decoding with any codec:

codecs.encode(*obj*, *encoding='utf-8'*, *errors='strict'*)

Encodes *obj* using the codec registered for *encoding*.

Errors may be given to set the desired error handling scheme. The default error handler is `'strict'` meaning that encoding errors raise `ValueError` (or a more codec specific subclass, such as `UnicodeEncodeError`). Refer to Codec Base Classes for more information on codec error handling.

codecs.decode(*obj*, *encoding='utf-8'*, *errors='strict'*)

Decodes *obj* using the codec registered for *encoding*.

Errors may be given to set the desired error handling scheme. The default error handler is `'strict'` meaning that decoding errors raise `ValueError` (or a more codec specific

subclass, such as **`UnicodeDecodeError`**). Refer to Codec Base Classes for more information on codec error handling.

The full details for each codec can also be looked up directly:

codecs.lookup(*encoding*)

Looks up the codec info in the Python codec registry and returns a **`CodecInfo`** object as defined below.

Encodings are first looked up in the registry's cache. If not found, the list of registered search functions is scanned. If no **`CodecInfo`** object is found, a **`LookupError`** is raised. Otherwise, the **`CodecInfo`** object is stored in the cache and returned to the caller.

class codecs.CodecInfo(*encode*, *decode*, *streamreader*=*None*, *streamwriter*=*None*, *incrementalencoder*=*None*, *incrementaldecoder*=*None*, *name*=*None*)

Codec details when looking up the codec registry. The constructor arguments are stored in attributes of the same name:

name

The name of the encoding.

encode
decode

The stateless encoding and decoding functions. These must be functions or methods which have the same interface as the **`encode()`** and **`decode()`** methods of Codec instances (see Codec Interface). The functions or methods are expected to work in a stateless mode.

incrementalencoder
incrementaldecoder

Incremental encoder and decoder classes or factory functions. These have to provide the interface defined by the base classes **`IncrementalEncoder`** and

`IncrementalDecoder`, respectively. Incremental codecs can maintain state.

streamwriter
streamreader

Stream writer and reader classes or factory functions. These have to provide the interface defined by the base classes `StreamWriter` and `StreamReader`, respectively. Stream codecs can maintain state.

To simplify access to the various codec components, the module provides these additional functions which use `lookup()` for the codec lookup:

codecs.getencoder(*encoding*)

Look up the codec for the given encoding and return its encoder function.

Raises a `LookupError` in case the encoding cannot be found.

codecs.getdecoder(*encoding*)

Look up the codec for the given encoding and return its decoder function.

Raises a `LookupError` in case the encoding cannot be found.

codecs.getincrementalencoder(*encoding*)

Look up the codec for the given encoding and return its incremental encoder class or factory function.

Raises a `LookupError` in case the encoding cannot be found or the codec doesn't support an incremental encoder.

codecs.getincrementaldecoder(*encoding*)

Look up the codec for the given encoding and return its incremental decoder class or factory function.

Raises a **LookupError** in case the encoding cannot be found or the codec doesn't support an incremental decoder.

codecs.getreader(*encoding*)

Look up the codec for the given encoding and return its **StreamReader** class or factory function.

Raises a **LookupError** in case the encoding cannot be found.

codecs.getwriter(*encoding*)

Look up the codec for the given encoding and return its **StreamWriter** class or factory function.

Raises a **LookupError** in case the encoding cannot be found.

Custom codecs are made available by registering a suitable codec search function:

codecs.register(*search_function*)

Register a codec search function. Search functions are expected to take one argument, being the encoding name in all lower case letters with hyphens and spaces converted to underscores, and return a **CodecInfo** object. In case a search function cannot find a given encoding, it should return `None`.

Changed in version 3.9: Hyphens and spaces are converted to underscore.

codecs.unregister(*search_function*)

Unregister a codec search function and clear the registry's cache. If the search function is not registered, do nothing.

New in version 3.10.

While the builtin **open()** and the associated **io** module are the

recommended approach for working with encoded text files, this module provides additional utility functions and classes that allow the use of a wider range of codecs when working with binary files:

codecs.open(*filename*, *mode='r'*, *encoding=None*, *errors='strict'*, *buffering=-1*)

Open an encoded file using the given *mode* and return an instance of **StreamReaderWriter**, providing transparent encoding/decoding. The default file mode is `'r'`, meaning to open the file in read mode.

Note

If *encoding* is not `None`, then the underlying encoded files are always opened in binary mode. No automatic conversion of `'\n'` is done on reading and writing. The *mode* argument may be any binary mode acceptable to the built-in **open()** function; the `'b'` is automatically added.

encoding specifies the encoding which is to be used for the file. Any encoding that encodes to and decodes from bytes is allowed, and the data types supported by the file methods depend on the codec used.

errors may be given to define the error handling. It defaults to `'strict'` which causes a **ValueError** to be raised in case an encoding error occurs.

buffering has the same meaning as for the built-in **open()** function. It defaults to -1 which means that the default buffer size will be used.

Changed in version 3.11: The `'U'` mode has been removed.

codecs.EncodedFile(*file*, *data_encoding*, *file_encoding=None*, *errors='strict'*)

Return a **StreamRecoder** instance, a wrapped version of *file* which provides transparent transcoding. The original file is

closed when the wrapped version is closed.

Data written to the wrapped file is decoded according to the given *data_encoding* and then written to the original file as bytes using *file_encoding*. Bytes read from the original file are decoded according to *file_encoding*, and the result is encoded using *data_encoding*.

If *file_encoding* is not given, it defaults to *data_encoding*.

errors may be given to define the error handling. It defaults to `'strict'`, which causes **`ValueError`** to be raised in case an encoding error occurs.

codecs.iterencode(*iterator*, *encoding*, *errors='strict'*, ***kwargs*)

Uses an incremental encoder to iteratively encode the input provided by *iterator*. This function is a generator. The *errors* argument (as well as any other keyword argument) is passed through to the incremental encoder.

This function requires that the codec accept text **`str`** objects to encode. Therefore it does not support bytes-to-bytes encoders such as `base64_codec`.

codecs.iterdecode(*iterator*, *encoding*, *errors='strict'*, ***kwargs*)

Uses an incremental decoder to iteratively decode the input provided by *iterator*. This function is a generator. The *errors* argument (as well as any other keyword argument) is passed through to the incremental decoder.

This function requires that the codec accept **`bytes`** objects to decode. Therefore it does not support text-to-text encoders such as `rot_13`, although `rot_13` may be used equivalently with **`iterencode()`**.

The module also provides the following constants which are useful for reading and writing to platform dependent files:

codecs.BOM
codecs.BOM_BE

codecs.BOM_LE
codecs.BOM_UTF8
codecs.BOM_UTF16
codecs.BOM_UTF16_BE
codecs.BOM_UTF16_LE
codecs.BOM_UTF32
codecs.BOM_UTF32_BE
codecs.BOM_UTF32_LE

These constants define various byte sequences, being Unicode byte order marks (BOMs) for several encodings. They are used in UTF-16 and UTF-32 data streams to indicate the byte order used, and in UTF-8 as a Unicode signature. **BOM_UTF16** is either **BOM_UTF16_BE** or **BOM_UTF16_LE** depending on the platform's native byte order, **BOM** is an alias for **BOM_UTF16**, **BOM_LE** for **BOM_UTF16_LE** and **BOM_BE** for **BOM_UTF16_BE**. The others represent the BOM in UTF-8 and UTF-32 encodings.

Codec Base Classes

The **codecs** module defines a set of base classes which define the interfaces for working with codec objects, and can also be used as the basis for custom codec implementations.

Each codec has to define four interfaces to make it usable as codec in Python: stateless encoder, stateless decoder, stream reader and stream writer. The stream reader and writers typically reuse the stateless encoder/decoder to implement the file protocols. Codec authors also need to define how the codec will handle encoding and decoding errors.

Error Handlers

To simplify and standardize error handling, codecs may implement different error handling schemes by accepting the *errors* string argument:

```
>>> 'German ß, ♬'.encode(encoding='ascii', errors='backs
b'German \\xdf, \\u266c'
```

```
>>> 'German ß, ♬'.encode(encoding='ascii', errors='xmlch
b'German ß, ♬'
```

The following error handlers can be used with all Python Standard Encodings codecs:

Value	Meaning
`'strict'`	Raise `UnicodeError` (or a subclass), this is the default. Implemented in `strict_errors()`.
`'ignore'`	Ignore the malformed data and continue without further notice. Implemented in `ignore_errors()`.
`'replace'`	Replace with a replacement marker. On encoding, use `?` (ASCII character). On decoding, use `�` (U+FFFD, the official REPLACEMENT CHARACTER). Implemented in `replace_errors()`.
`'backslashreplace'`	Replace with backslashed escape sequences. On encoding, use hexadecimal form of Unicode code point with formats `\xhh` `\uxxxx` `\Uxxxxxxxx`. On decoding, use hexadecimal form of byte value with format `\xhh`. Implemented in `backslashreplace_errors()`.
`'surrogateescape'`	On decoding, replace byte with individual surrogate code ranging from `U+DC80` to `U+DCFF`. This code will then be turned back into the same byte when the `'surrogateescape'` error handler is used when encoding the data. (See **PEP 383** for more.)

The following error handlers are only applicable to encoding (within text encodings):

Value	Meaning
`'xmlcharrefreplace'`	Replace with XML/HTML numeric character reference, which is a decimal form of Unicode code point with format `&#num;` Implemented in `xmlcharrefreplace_errors()`.
`'namereplace'`	Replace with `\N{...}` escape sequences, what appears in the braces is the Name property from Unicode Character Database. Implemented in `namereplace_errors()`.

In addition, the following error handler is specific to the given codecs:

Value	Meaning
`'surrogatepass'`	Allow encoding and decoding of surrogate code points (`U+D800` - `U`

+DFFF) as normal code point. Otherwise these codecs treat the presence of surrogate code point in **str** as an error.

New in version 3.1: The `'surrogateescape'` and `'surrogatepass'` error handlers.

Changed in version 3.4: The `'surrogatepass'` error handler now works with utf-16* and utf-32* codecs.

New in version 3.5: The `'namereplace'` error handler.

Changed in version 3.5: The `'backslashreplace'` error handler now works with decoding and translating.

The set of allowed values can be extended by registering a new named error handler:

codecs.register_error(*name*, *error_handler*)

Register the error handling function *error_handler* under the name *name*. The *error_handler* argument will be called during encoding and decoding in case of an error, when *name* is specified as the errors parameter.

For encoding, *error_handler* will be called with a **UnicodeEncodeError** instance, which contains information about the location of the error. The error handler must either raise this or a different exception, or return a tuple with a replacement for the unencodable part of the input and a position where encoding should continue. The replacement may be either **str** or **bytes**. If the replacement is bytes, the encoder will simply copy them into the output buffer. If the replacement is a string, the encoder will encode the replacement. Encoding continues on original input at the specified position. Negative position values will be treated as being relative to the end of the input string. If the resulting position is out of bound an **IndexError** will be raised.

Decoding and translating works similarly, except **UnicodeDecodeError** or **UnicodeTranslateError** will be passed to the handler and that the replacement from the error handler will be put into the output directly.

Previously registered error handlers (including the standard error handlers) can be looked up by name:

codecs.lookup_error(*name*)

Return the error handler previously registered under the name *name*.

Raises a **LookupError** in case the handler cannot be found.

The following standard error handlers are also made available as module level functions:

codecs.strict_errors(*exception*)

Implements the `'strict'` error handling.

Each encoding or decoding error raises a **UnicodeError**.

codecs.ignore_errors(*exception*)

Implements the `'ignore'` error handling.

Malformed data is ignored; encoding or decoding is continued without further notice.

codecs.replace_errors(*exception*)

Implements the `'replace'` error handling.

Substitutes `?` (ASCII character) for encoding errors or `\ufffd` (U+FFFD, the official REPLACEMENT CHARACTER) for decoding errors.

codecs.backslashreplace_errors(*exception*)

Implements the `'backslashreplace'` error handling.

Malformed data is replaced by a backslashed escape sequence. On encoding, use the hexadecimal form of Unicode code point with formats `\xhh` `\uxxxx` `\Uxxxxxxxx`. On decoding, use the hexadecimal form of byte value with format `\xhh`.

Changed in version 3.5: Works with decoding and translating.

codecs.xmlcharrefreplace_errors(*exception*)

Implements the `'xmlcharrefreplace'` error handling (for encoding within text encoding only).

The unencodable character is replaced by an appropriate XML/HTML numeric character reference, which is a decimal form of Unicode code point with format `&#num;` .

codecs.namereplace_errors(*exception*)

Implements the `'namereplace'` error handling (for encoding within text encoding only).

The unencodable character is replaced by a `\N{...}` escape sequence. The set of characters that appear in the braces is the Name property from Unicode Character Database. For example, the German lowercase letter `'ß'` will be converted to byte sequence `\N{LATIN SMALL LETTER SHARP S}` .

New in version 3.5.

Stateless Encoding and Decoding

The base **`Codec`** class defines these methods which also define the function interfaces of the stateless encoder and decoder:

Codec.encode(*input*, *errors='strict'*)

Encodes the object *input* and returns a tuple (output object, length consumed). For instance, text encoding converts a string object to a bytes object using a particular character set encoding (e.g., `cp1252` or `iso-8859-1`).

The *errors* argument defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the **`Codec`** instance. Use **`StreamWriter`** for codecs which have to keep state in order to make encoding efficient.

The encoder must be able to handle zero length input and return an empty object of the output object type in this situation.

Codec.decode(*input*, *errors*='strict')

Decodes the object *input* and returns a tuple (output object, length consumed). For instance, for a text encoding, decoding converts a bytes object encoded using a particular character set encoding to a string object.

For text encodings and bytes-to-bytes codecs, *input* must be a bytes object or one which provides the read-only buffer interface – for example, buffer objects and memory mapped files.

The *errors* argument defines the error handling to apply. It defaults to `'strict'` handling.

The method may not store state in the **`Codec`** instance. Use **`StreamReader`** for codecs which have to keep state in order to make decoding efficient.

The decoder must be able to handle zero length input and return an empty object of the output object type in this situation.

Incremental Encoding and Decoding

The **`IncrementalEncoder`** and **`IncrementalDecoder`** classes provide the basic interface for incremental encoding and decoding. Encoding/decoding the input isn't done with one call to the stateless encoder/decoder function, but with multiple calls to the **`encode()`**/**`decode()`** method of the incremental encoder/decoder. The incremental encoder/decoder keeps track of the encoding/decoding process during method calls.

The joined output of calls to the **`encode()`**/**`decode()`** method is the same as if all the single inputs were joined into one, and this input was encoded/decoded with the stateless encoder/decoder.

IncrementalEncoder Objects

The **`IncrementalEncoder`** class is used for encoding an input in multiple steps. It defines the following methods which every incremental encoder must define in order to be compatible with the Python codec registry.

class codecs.IncrementalEncoder(*errors='strict'*)

Constructor for an **`IncrementalEncoder`** instance.

All incremental encoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The **`IncrementalEncoder`** may implement different error handling schemes by providing the *errors* keyword argument. See Error Handlers for possible values.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **`IncrementalEncoder`** object.

encode(*object*, *final=False*)

Encodes *object* (taking the current state of the encoder into account) and returns the resulting encoded object. If this is the last call to **`encode()`** *final* must be true (the default is false).

reset()

Reset the encoder to the initial state. The output is discarded: call `.encode(object, final=True)`, passing an empty byte or text string if necessary, to reset the encoder and to get the output.

getstate()

Return the current state of the encoder which must be an integer. The implementation should make sure that

`0` is the most common state. (States that are more complicated than integers can be converted into an integer by marshaling/pickling the state and encoding the bytes of the resulting string into an integer.)

setstate(*state*)

Set the state of the encoder to *state*. *state* must be an encoder state returned by `getstate()`.

IncrementalDecoder Objects

The `IncrementalDecoder` class is used for decoding an input in multiple steps. It defines the following methods which every incremental decoder must define in order to be compatible with the Python codec registry.

class codecs.IncrementalDecoder(*errors*=*'strict'*)

Constructor for an `IncrementalDecoder` instance.

All incremental decoders must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The `IncrementalDecoder` may implement different error handling schemes by providing the *errors* keyword argument. See Error Handlers for possible values.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the `IncrementalDecoder` object.

decode(*object*, *final*=*False*)

Decodes *object* (taking the current state of the decoder into account) and returns the resulting decoded object. If this is the last call to `decode()` *final* must be true (the default is false). If *final* is true the decoder must decode the input completely and must flush all buffers.

If this isn't possible (e.g. because of incomplete byte sequences at the end of the input) it must initiate error handling just like in the stateless case (which might raise an exception).

reset()

Reset the decoder to the initial state.

getstate()

Return the current state of the decoder. This must be a tuple with two items, the first must be the buffer containing the still undecoded input. The second must be an integer and can be additional state info. (The implementation should make sure that `0` is the most common additional state info.) If this additional state info is `0` it must be possible to set the decoder to the state which has no input buffered and `0` as the additional state info, so that feeding the previously buffered input to the decoder returns it to the previous state without producing any output. (Additional state info that is more complicated than integers can be converted into an integer by marshaling/pickling the info and encoding the bytes of the resulting string into an integer.)

setstate(*state*)

Set the state of the decoder to *state*. *state* must be a decoder state returned by **`getstate()`**.

Stream Encoding and Decoding

The **`StreamWriter`** and **`StreamReader`** classes provide generic working interfaces which can be used to implement new encoding submodules very easily. See **`encodings.utf_8`** for an example of how this is done.

StreamWriter Objects

The **StreamWriter** class is a subclass of **Codec** and defines the following methods which every stream writer must define in order to be compatible with the Python codec registry.

class codecs.StreamWriter(*stream*, *errors*='*strict*')

Constructor for a **StreamWriter** instance.

All stream writers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The *stream* argument must be a file-like object open for writing text or binary data, as appropriate for the specific codec.

The **StreamWriter** may implement different error handling schemes by providing the *errors* keyword argument. See Error Handlers for the standard error handlers the underlying stream codec may support.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **StreamWriter** object.

write(*object*)

Writes the object's contents encoded to the stream.

writelines(*list*)

Writes the concatenated iterable of strings to the stream (possibly by reusing the **write()** method). Infinite or very large iterables are not supported. The standard bytes-to-bytes codecs do not support this method.

reset()

Resets the codec buffers used for keeping internal state.

Calling this method should ensure that the data on the output is put into a clean state that allows appending of

new fresh data without having to rescan the whole stream to recover state.

In addition to the above methods, the **StreamWriter** must also inherit all other methods and attributes from the underlying stream.

StreamReader Objects

The **StreamReader** class is a subclass of **Codec** and defines the following methods which every stream reader must define in order to be compatible with the Python codec registry.

class codecs.StreamReader(*stream*, *errors* = *'strict'*)

Constructor for a **StreamReader** instance.

All stream readers must provide this constructor interface. They are free to add additional keyword arguments, but only the ones defined here are used by the Python codec registry.

The *stream* argument must be a file-like object open for reading text or binary data, as appropriate for the specific codec.

The **StreamReader** may implement different error handling schemes by providing the *errors* keyword argument. See Error Handlers for the standard error handlers the underlying stream codec may support.

The *errors* argument will be assigned to an attribute of the same name. Assigning to this attribute makes it possible to switch between different error handling strategies during the lifetime of the **StreamReader** object.

The set of allowed values for the *errors* argument can be extended with **register_error()**.

read(*size* = *- 1*, *chars* = *- 1*, *firstline* = *False*)

Decodes data from the stream and returns the resulting object.

The *chars* argument indicates the number of decoded code points or bytes to return. The `read()` method will never return more data than requested, but it might return less, if there is not enough available.

The *size* argument indicates the approximate maximum number of encoded bytes or code points to read for decoding. The decoder can modify this setting as appropriate. The default value -1 indicates to read and decode as much as possible. This parameter is intended to prevent having to decode huge files in one step.

The *firstline* flag indicates that it would be sufficient to only return the first line, if there are decoding errors on later lines.

The method should use a greedy read strategy meaning that it should read as much data as is allowed within the definition of the encoding and the given size, e.g. if optional encoding endings or state markers are available on the stream, these should be read too.

readline(*size* = *None*, *keepends* = *True*)

Read one line from the input stream and return the decoded data.

size, if given, is passed as size argument to the stream's `read()` method.

If *keepends* is false line-endings will be stripped from the lines returned.

readlines(*sizehint* = *None*, *keepends* = *True*)

Read all lines available on the input stream and return them as a list of lines.

Line-endings are implemented using the codec's `decode()` method and are included in the list entries if *keepends* is true.

sizehint, if given, is passed as the *size* argument to the stream's `read()` method.

reset()

Resets the codec buffers used for keeping internal state.

Note that no stream repositioning should take place. This method is primarily intended to be able to recover from decoding errors.

In addition to the above methods, the `StreamReader` must also inherit all other methods and attributes from the underlying stream.

StreamReaderWriter Objects

The `StreamReaderWriter` is a convenience class that allows wrapping streams which work in both read and write modes.

The design is such that one can use the factory functions returned by the `lookup()` function to construct the instance.

class codecs.StreamReaderWriter(*stream*, *Reader*, *Writer*, *errors*='*strict*')

Creates a `StreamReaderWriter` instance. *stream* must be a file-like object. *Reader* and *Writer* must be factory functions or classes providing the `StreamReader` and `StreamWriter` interface resp. Error handling is done in the same way as defined for the stream readers and writers.

`StreamReaderWriter` instances define the combined interfaces of `StreamReader` and `StreamWriter` classes. They inherit all other methods and attributes from the underlying stream.

StreamRecoder Objects

The `StreamRecoder` translates data from one encoding to another, which is sometimes useful when dealing with different encoding environments.

The design is such that one can use the factory functions returned by the **`lookup()`** function to construct the instance.

class codecs.StreamRecoder(*stream*, *encode*, *decode*, *Reader*, *Writer*, *errors* = *'strict'*)

> Creates a **`StreamRecoder`** instance which implements a two-way conversion: *encode* and *decode* work on the frontend — the data visible to code calling **`read()`** and **`write()`**, while *Reader* and *Writer* work on the backend — the data in *stream*.
>
> You can use these objects to do transparent transcodings, e.g., from Latin-1 to UTF-8 and back.
>
> The *stream* argument must be a file-like object.
>
> The *encode* and *decode* arguments must adhere to the **`Codec`** interface. *Reader* and *Writer* must be factory functions or classes providing objects of the **`StreamReader`** and **`StreamWriter`** interface respectively.
>
> Error handling is done in the same way as defined for the stream readers and writers.

`StreamRecoder` instances define the combined interfaces of **`StreamReader`** and **`StreamWriter`** classes. They inherit all other methods and attributes from the underlying stream.

Encodings and Unicode

Strings are stored internally as sequences of code points in range `U+0000`–`U+10FFFF`. (See **PEP 393** [https://peps.python.org/pep-0393/] for more details about the implementation.) Once a string object is used outside of CPU and memory, endianness and how these arrays are stored as bytes become an issue. As with other codecs, serialising a string into a sequence of bytes is known as *encoding*, and recreating the string from the sequence of bytes is known as *decoding*. There are a variety of different text serialisation codecs, which are collectivity referred to as text encodings.

The simplest text encoding (called `'latin-1'` or `'iso-8859-1'`) maps the code points 0–255 to the bytes `0x0`–`0xff`, which means that a string object that contains code points above `U+00FF` can't be encoded with this codec. Doing so will raise a **`UnicodeEncodeError`** that looks like the following (although the details of the error message may differ):

```
UnicodeEncodeError: 'latin-1' codec can't encode
character '\u1234' in position 3: ordinal not in
range(256).
```

There's another group of encodings (the so called charmap encodings) that choose a different subset of all Unicode code points and how these code points are mapped to the bytes `0x0`–`0xff`. To see how this is done simply open e.g. `encodings/cp1252.py` (which is an encoding that is used primarily on Windows). There's a string constant with 256 characters that shows you which character is mapped to which byte value.

All of these encodings can only encode 256 of the 1114112 code points defined in Unicode. A simple and straightforward way that can store each Unicode code point, is to store each code point as four consecutive bytes. There are two possibilities: store the bytes in big endian or in little endian order. These two encodings are called `UTF-32-BE` and `UTF-32-LE` respectively. Their disadvantage is that if e.g. you use `UTF-32-BE` on a little endian machine you will always have to swap bytes on encoding and decoding. `UTF-32` avoids this problem: bytes will always be in natural endianness. When these bytes are read by a CPU with a different endianness, then bytes have to be swapped though. To be able to detect the endianness of a `UTF-16` or `UTF-32` byte sequence, there's the so called BOM ("Byte Order Mark"). This is the Unicode character `U+FEFF`. This character can be prepended to every `UTF-16` or `UTF-32` byte sequence. The byte swapped version of this character (`0xFFFE`) is an illegal character that may not appear in a Unicode text. So when the first character in a `UTF-16` or `UTF-32` byte sequence appears to be a `U+FFFE` the bytes have to be swapped on decoding. Unfortunately the character `U+FEFF` had a second purpose as a `ZERO WIDTH NO-BREAK SPACE`: a character that has no width and doesn't allow a word to be split. It can e.g. be used to give hints to a ligature algorithm. With Unicode 4.0 using `U`

+FEFF as a ZERO WIDTH NO-BREAK SPACE has been deprecated (with U+2060 (WORD JOINER) assuming this role). Nevertheless Unicode software still must be able to handle U+FEFF in both roles: as a BOM it's a device to determine the storage layout of the encoded bytes, and vanishes once the byte sequence has been decoded into a string; as a ZERO WIDTH NO-BREAK SPACE it's a normal character that will be decoded like any other.

There's another encoding that is able to encode the full range of Unicode characters: UTF-8. UTF-8 is an 8-bit encoding, which means there are no issues with byte order in UTF-8. Each byte in a UTF-8 byte sequence consists of two parts: marker bits (the most significant bits) and payload bits. The marker bits are a sequence of zero to four 1 bits followed by a 0 bit. Unicode characters are encoded like this (with x being payload bits, which when concatenated give the Unicode character):

Range	Encoding
U-00000000 ... U-0000007F	0xxxxxxx
U-00000080 ... U-000007FF	110xxxxx 10xxxxxx
U-00000800 ... U-0000FFFF	1110xxxx 10xxxxxx 10xxxxxx
U-00010000 ... U-0010FFFF	11110xxx 10xxxxxx 10xxxxxx 10xxxxxx

The least significant bit of the Unicode character is the rightmost x bit.

As UTF-8 is an 8-bit encoding no BOM is required and any U+FEFF character in the decoded string (even if it's the first character) is treated as a ZERO WIDTH NO-BREAK SPACE.

Without external information it's impossible to reliably determine which encoding was used for encoding a string. Each charmap encoding can decode any random byte sequence. However that's not possible with UTF-8, as UTF-8 byte sequences have a structure that doesn't allow arbitrary byte sequences. To increase the reliability with which a UTF-8 encoding can be detected, Microsoft invented a variant of UTF-8 (that Python calls "utf-8-sig") for its Notepad program: Before any of the Unicode characters is written to the file, a UTF-8 encoded BOM (which looks like this as a byte sequence: 0xef, 0xbb, 0xbf) is written. As it's rather improbable that any charmap encoded file starts with these byte

values (which would e.g. map to

> LATIN SMALL LETTER I WITH DIAERESIS
> RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK
> INVERTED QUESTION MARK

in iso-8859-1), this increases the probability that a `utf-8-sig` encoding can be correctly guessed from the byte sequence. So here the BOM is not used to be able to determine the byte order used for generating the byte sequence, but as a signature that helps in guessing the encoding. On encoding the utf-8-sig codec will write `0xef`, `0xbb`, `0xbf` as the first three bytes to the file. On decoding `utf-8-sig` will skip those three bytes if they appear as the first three bytes in the file. In UTF-8, the use of the BOM is discouraged and should generally be avoided.

Standard Encodings

Python comes with a number of codecs built-in, either implemented as C functions or with dictionaries as mapping tables. The following table lists the codecs by name, together with a few common aliases, and the languages for which the encoding is likely used. Neither the list of aliases nor the list of languages is meant to be exhaustive. Notice that spelling alternatives that only differ in case or use a hyphen instead of an underscore are also valid aliases; therefore, e.g. `'utf-8'` is a valid alias for the `'utf_8'` codec.

CPython implementation detail: Some common encodings can bypass the codecs lookup machinery to improve performance. These optimization opportunities are only recognized by CPython for a limited set of (case insensitive) aliases: utf-8, utf8, latin-1, latin1, iso-8859-1, iso8859-1, mbcs (Windows only), ascii, us-ascii, utf-16, utf16, utf-32, utf32, and the same using underscores instead of dashes. Using alternative aliases for these encodings may result in slower execution.

Changed in version 3.6: Optimization opportunity recognized for us-ascii.

Many of the character sets support the same languages. They vary in individual characters (e.g. whether the EURO SIGN is supported or not), and in the assignment of characters to code positions. For the European languages in particular, the following variants typically exist:

- an ISO 8859 codeset
- a Microsoft Windows code page, which is typically derived from an 8859 codeset, but replaces control characters with additional graphic characters
- an IBM EBCDIC code page
- an IBM PC code page, which is ASCII compatible

Codeset	Languages
646	English-ascii
big5	traditional Chinese
big5-hkscs	traditional Chinese
cp037	English, IBM037, IBM039
cp273	German, IBM273, csIBM273
New in version 3.4.

Changed in version 3.4: The utf-16* and utf-32* encoders no longer allow surrogate code points (`U+D800`–`U+DFFF`) to be encoded. The

utf-32* decoders no longer decode byte sequences that correspond to surrogate code points.

Changed in version 3.8: `cp65001` is now an alias to `utf_8`.

Python Specific Encodings

A number of predefined codecs are specific to Python, so their codec names have no meaning outside Python. These are listed in the tables below based on the expected input and output types (note that while text encodings are the most common use case for codecs, the underlying codec infrastructure supports arbitrary data transforms rather than just text encodings). For asymmetric codecs, the stated meaning describes the encoding direction.

Text Encodings

The following codecs provide **`str`** to **`bytes`** encoding and bytes-like object to **`str`** decoding, similar to the Unicode text encodings.

Codec	Aliases	Meaning
`idna`		Implement RFC 3490, see also **`encodings.idna`**. Only `errors='strict'` is supported.
`mbcs`	`ansi`, `dbcs`	Windows only: Encode the operand according to the ANSI codepage (CP_ACP).
`oem`		Windows only: Encode the operand according to the OEM codepage (CP_OEMCP). *New in version 3.6.*
`palmos`		Encoding of PalmOS 3.5.
`punycode`		Implement RFC 3492. Stateful codecs are not supported.
`raw_unicode_escape`		Latin-1 encoding with `\uXXXX` and `\UXXXXXXXX` for other code points. Existing backslashes are not escaped in any way. It is used in the Python pickle protocol.
`undefined`		Raise an exception for all conversions, even empty strings. The error handler is ignored.
`unicode_escape`		Encoding suitable as the contents of a Unicode literal in ASCII-encoded Python source code, except that quotes are not escaped. Decode from Latin-1 source code. Beware that Python source code actually uses UTF-8 by default.

Changed in version 3.8: “unicode_internal” codec is removed.

Binary Transforms

The following codecs provide binary transforms: bytes-like object to **bytes** mappings. They are not supported by **bytes.decode()** (which only produces **str** output).

Codec	Aliases	Meaning / decoder
base64_codec[1]	base64	Convert the operand to multiline MIME base64 (the result always includes a trailing '\n'). *Changed in version 3.4:* accepts any bytes-like object as input for encoding and decoding
bz2_codec	bz2	Compress the operand using bz2.
hex_codec	hex	Convert the operand to hexadecimal representation, with two digits per byte.
quopri_codec	quopri, quoted-printable, quotable	Convert the operand to quoted-printable.
uu_codec	uu	Convert the operand using uuencode.
zlib_codec	zip, zlib	Compress the operand using gzip.

1 In addition to bytes-like objects, 'base64_codec' also accepts ASCII-only instances of **str** for decoding

New in version 3.2: Restoration of the binary transforms.

Changed in version 3.4: Restoration of the aliases for the binary transforms.

Text Transforms

The following codec provides a text transform: a **str** to **str** mapping. It is not supported by **str.encode()** (which only produces **bytes** output).

Codec	Aliases	Meaning
rot_13	rot13	Return the Caesar-cypher encryption of the operand.

New in version 3.2: Restoration of the rot_13 text transform.

Changed in version 3.4: Restoration of the `rot13` alias.

`encodings.idna` — Internationalized Domain Names in Applications

This module implements **RFC 3490** [https://datatracker.ietf.org/doc/html/rfc3490.html] (Internationalized Domain Names in Applications) and **RFC 3492** [https://datatracker.ietf.org/doc/html/rfc3492.html] (Nameprep: A Stringprep Profile for Internationalized Domain Names (IDN)). It builds upon the `punycode` encoding and **`stringprep`**.

If you need the IDNA 2008 standard from **RFC 5891** [https://datatracker.ietf.org/doc/html/rfc5891.html] and **RFC 5895** [https://datatracker.ietf.org/doc/html/rfc5895.html], use the third-party idna module [https://pypi.org/project/idna/].

These RFCs together define a protocol to support non-ASCII characters in domain names. A domain name containing non-ASCII characters (such as `www.Alliancefrançaise.nu`) is converted into an ASCII-compatible encoding (ACE, such as `www.xn--alliancefranaise-npb.nu`). The ACE form of the domain name is then used in all places where arbitrary characters are not allowed by the protocol, such as DNS queries, HTTP *Host* fields, and so on. This conversion is carried out in the application; if possible invisible to the user: The application should transparently convert Unicode domain labels to IDNA on the wire, and convert back ACE labels to Unicode before presenting them to the user.

Python supports this conversion in several ways: the `idna` codec performs conversion between Unicode and ACE, separating an input string into labels based on the separator characters defined in **section 3.1 of RFC 3490** [https://datatracker.ietf.org/doc/html/rfc3490.html#section-3.1] and converting each label to ACE as required, and conversely separating an input byte string into labels based on the `.` separator and converting any ACE labels found into unicode. Furthermore, the **`socket`** module transparently converts Unicode host names to ACE, so that applications need not be concerned about converting host names themselves when they pass them to the socket module. On top of that, modules that have host names as

function parameters, such as **http.client** and **ftplib**, accept Unicode host names (**http.client** then also transparently sends an IDNA hostname in the *Host* field if it sends that field at all).

When receiving host names from the wire (such as in reverse name lookup), no automatic conversion to Unicode is performed: applications wishing to present such host names to the user should decode them to Unicode.

The module **encodings.idna** also implements the nameprep procedure, which performs certain normalizations on host names, to achieve case-insensitivity of international domain names, and to unify similar characters. The nameprep functions can be used directly if desired.

encodings.idna.nameprep(*label*)

Return the nameprepped version of *label*. The implementation currently assumes query strings, so `AllowUnassigned` is true.

encodings.idna.ToASCII(*label*)

Convert a label to ASCII, as specified in **RFC 3490** [https://datatracker.ietf.org/doc/html/rfc3490.html]. `UseSTD3ASCIIRules` is assumed to be false.

encodings.idna.ToUnicode(*label*)

Convert a label to Unicode, as specified in **RFC 3490** [https://datatracker.ietf.org/doc/html/rfc3490.html].

encodings.mbcs — Windows ANSI codepage

This module implements the ANSI codepage (CP_ACP).

Availability: Windows.

Changed in version 3.3: Support any error handler.

Changed in version 3.2: Before 3.2, the *errors* argument was ignored; `'replace'` was always used to encode, and `'ignore'` to decode.

`encodings.utf_8_sig` — UTF-8 codec with BOM signature

This module implements a variant of the UTF-8 codec. On encoding, a UTF-8 encoded BOM will be prepended to the UTF-8 encoded bytes. For the stateful encoder this is only done once (on the first write to the byte stream). On decoding, an optional UTF-8 encoded BOM at the start of the data will be skipped.

Data Types

The modules described in this chapter provide a variety of specialized data types such as dates and times, fixed-type arrays, heap queues, double-ended queues, and enumerations.

Python also provides some built-in data types, in particular, `dict`, `list`, `set` and `frozenset`, and `tuple`. The `str` class is used to hold Unicode strings, and the `bytes` and `bytearray` classes are used to hold binary data.

The following modules are documented in this chapter:

- `datetime` — Basic date and time types
  - Aware and Naive Objects
  - Constants
  - Available Types
    - Common Properties
    - Determining if an Object is Aware or Naive
  - `timedelta` Objects
    - Examples of usage: `timedelta`
  - `date` Objects
    - Examples of Usage: `date`
  - `datetime` Objects
    - Examples of Usage: `datetime`
  - `time` Objects
    - Examples of Usage: `time`

- `tzinfo` Objects
- `timezone` Objects
- `strftime()` and `strptime()` Behavior
  - `strftime()` and `strptime()` Format Codes
  - Technical Detail

- `zoneinfo` — IANA time zone support
  - Using `ZoneInfo`
  - Data sources
    - Configuring the data sources
      - Compile-time configuration
      - Environment configuration
      - Runtime configuration
  - The `ZoneInfo` class
    - String representations
    - Pickle serialization
  - Functions
  - Globals
  - Exceptions and warnings
- `calendar` — General calendar-related functions
- `collections` — Container datatypes
  - `ChainMap` objects
    - `ChainMap` Examples and Recipes
  - `Counter` objects
  - `deque` objects
    - `deque` Recipes
  - `defaultdict` objects
    - `defaultdict` Examples

    - **namedtuple()** Factory Function for Tuples with Named Fields
    - **OrderedDict** objects
        - **OrderedDict** Examples and Recipes
    - **UserDict** objects
    - **UserList** objects
    - **UserString** objects

- **collections.abc** — Abstract Base Classes for Containers
    - Collections Abstract Base Classes
    - Collections Abstract Base Classes – Detailed Descriptions
    - Examples and Recipes

- **heapq** — Heap queue algorithm
    - Basic Examples
    - Priority Queue Implementation Notes
    - Theory

- **bisect** — Array bisection algorithm
    - Performance Notes
    - Searching Sorted Lists
    - Examples

- **array** — Efficient arrays of numeric values
- **weakref** — Weak references
    - Weak Reference Objects
    - Example
    - Finalizer Objects
    - Comparing finalizers with **__del__()** methods

- **types** — Dynamic type creation and names for built-in types
    - Dynamic Type Creation
    - Standard Interpreter Types
    - Additional Utility Classes and Functions

    - Coroutine Utility Functions

- **copy** — Shallow and deep copy operations
- **pprint** — Data pretty printer

    - PrettyPrinter Objects
    - Example

- **reprlib** — Alternate **repr()** implementation

    - Repr Objects
    - Subclassing Repr Objects

- **enum** — Support for enumerations

    - Module Contents
    - Data Types

        - Supported **__dunder__** names
        - Supported **_sunder_** names

    - Utilities and Decorators
    - Notes

- **graphlib** — Functionality to operate with graph-like structures

    - Exceptions

`datetime` — Basic date and time types

Source code: Lib/datetime.py [https://github.com/python/cpython/tree/3.11/Lib/datetime.py]

The `datetime` module supplies classes for manipulating dates and times.

While date and time arithmetic is supported, the focus of the implementation is on efficient attribute extraction for output formatting and manipulation.

See also

Module `calendar`
General calendar related functions.

Module `time`
Time access and conversions.

Module `zoneinfo`
Concrete time zones representing the IANA time zone database.

Package dateutil [https://dateutil.readthedocs.io/en/stable/]
Third-party library with expanded time zone and parsing support.

Aware and Naive Objects

Date and time objects may be categorized as “aware” or “naive” depending on whether or not they include timezone information.

With sufficient knowledge of applicable algorithmic and political time adjustments, such as time zone and daylight saving time information, an **aware** object can locate itself relative to other aware objects. An aware object represents a specific moment in time that is not open to interpretation. 1

A **naive** object does not contain enough information to unambiguously locate itself relative to other date/time objects. Whether a naive object represents Coordinated Universal Time (UTC), local time, or time in some other timezone is purely up to the program, just like it is up to the program whether a particular number represents metres, miles, or mass. Naive objects are easy to understand and to work with, at the cost of ignoring some aspects of reality.

For applications requiring aware objects, **datetime** and **time** objects have an optional time zone information attribute, **tzinfo**, that can be set to an instance of a subclass of the abstract **tzinfo** class. These **tzinfo** objects capture information about the offset from UTC time, the time zone name, and whether daylight saving time is in effect.

Only one concrete **tzinfo** class, the **timezone** class, is supplied by the **datetime** module. The **timezone** class can represent simple timezones with fixed offsets from UTC, such as UTC itself or North American EST and EDT timezones. Supporting timezones at deeper levels of detail is up to the application. The rules for time adjustment across the world are more political than rational, change frequently, and there is no standard suitable for every application aside from UTC.

Constants

The **datetime** module exports the following constants:

datetime.MINYEAR

> The smallest year number allowed in a **date** or **datetime** object. **MINYEAR** is `1`.

datetime.MAXYEAR

The largest year number allowed in a **date** or **datetime** object. **MAXYEAR** is `9999`.

datetime.UTC

Alias for the UTC timezone singleton **datetime.timezone.utc**.

New in version 3.11.

Available Types

class datetime.date

An idealized naive date, assuming the current Gregorian calendar always was, and always will be, in effect. Attributes: **year**, **month**, and **day**.

class datetime.time

An idealized time, independent of any particular day, assuming that every day has exactly 24*60*60 seconds. (There is no notion of "leap seconds" here.) Attributes: **hour**, **minute**, **second**, **microsecond**, and **tzinfo**.

class datetime.datetime

A combination of a date and a time. Attributes: **year**, **month**, **day**, **hour**, **minute**, **second**, **microsecond**, and **tzinfo**.

class datetime.timedelta

A duration expressing the difference between two **date**, **time**, or **datetime** instances to microsecond resolution.

class datetime.tzinfo

An abstract base class for time zone information objects. These are used by the **datetime** and **time** classes to provide a customizable notion of time adjustment (for example, to account for time zone and/or daylight saving time).

class datetime.timezone

A class that implements the **tzinfo** abstract base class as a fixed offset from the UTC.

New in version 3.2.

Objects of these types are immutable.

Subclass relationships:

```
object
    timedelta
    tzinfo
        timezone
    time
    date
        datetime
```

Common Properties

The **date**, **datetime**, **time**, and **timezone** types share these common features:

- Objects of these types are immutable.
- Objects of these types are hashable, meaning that they can be used as dictionary keys.
- Objects of these types support efficient pickling via the **pickle** module.

Determining if an Object is Aware or Naive

Objects of the **date** type are always naive.

An object of type **time** or **datetime** may be aware or naive.

A **datetime** object *d* is aware if both of the following hold:

1. `d.tzinfo` is not `None`
2. `d.tzinfo.utcoffset(d)` does not return `None`

Otherwise, *d* is naive.

A **`time`** object *t* is aware if both of the following hold:

1. `t.tzinfo` is not `None`
2. `t.tzinfo.utcoffset(None)` does not return `None`.

Otherwise, *t* is naive.

The distinction between aware and naive doesn't apply to **`timedelta`** objects.

`timedelta` Objects

A **`timedelta`** object represents a duration, the difference between two dates or times.

class datetime.timedelta(*days=0*, *seconds=0*, *microseconds=0*, *milliseconds=0*, *minutes=0*, *hours=0*, *weeks=0*)

All arguments are optional and default to `0`. Arguments may be integers or floats, and may be positive or negative.

Only *days*, *seconds* and *microseconds* are stored internally. Arguments are converted to those units:

- A millisecond is converted to 1000 microseconds.
- A minute is converted to 60 seconds.
- An hour is converted to 3600 seconds.
- A week is converted to 7 days.

and days, seconds and microseconds are then normalized so that the representation is unique, with

- `0 <= microseconds < 1000000`
- `0 <= seconds < 3600*24` (the number of seconds in one day)
- `-999999999 <= days <= 999999999`

The following example illustrates how any arguments besides *days*, *seconds* and *microseconds* are "merged" and normalized into those three resulting attributes:

```
>>> from datetime import timedelta
>>> delta = timedelta(
...     days=50,
...     seconds=27,
...     microseconds=10,
...     milliseconds=29000,
...     minutes=5,
...     hours=8,
...     weeks=2
... )
>>> # Only days, seconds, and microseconds remain
>>> delta
datetime.timedelta(days=64, seconds=29156, microsec
```

If any argument is a float and there are fractional microseconds, the fractional microseconds left over from all arguments are combined and their sum is rounded to the nearest microsecond using round-half-to-even tiebreaker. If no argument is a float, the conversion and normalization processes are exact (no information is lost).

If the normalized value of days lies outside the indicated range, **`OverflowError`** is raised.

Note that normalization of negative values may be surprising at first. For example:

```
>>> from datetime import timedelta
>>> d = timedelta(microseconds=-1)
>>> (d.days, d.seconds, d.microseconds)
(-1, 86399, 999999)
```

Class attributes:

timedelta.min

The most negative **`timedelta`** object, `timedelta(-999999999)`.

timedelta.max

The most positive **timedelta** object, `timedelta(days=999999999, hours=23, minutes=59, seconds=59, microseconds=999999)`.

timedelta.resolution

The smallest possible difference between non-equal **timedelta** objects, `timedelta(microseconds=1)`.

Note that, because of normalization, `timedelta.max` > `-timedelta.min`. `-timedelta.max` is not representable as a **timedelta** object.

Instance attributes (read-only):

Attribute	Value
days	Between -999999999 and 999999999 inclusive
seconds	Between 0 and 86399 inclusive
microseconds	Between 0 and 999999 inclusive

Supported operations:

Operation	Result
t1 + t2	Sum of *t2* and *t3*. Afterwards *t1*-*t2* == *t3* and *t1*-*t3* == *t2* are true. (1)
t1 - t2	Difference of *t2* and *t3*. Afterwards *t1* == *t2* - *t3* and *t2* == *t1* + *t3* are true. (1)(6)
t1 * i	Delta multiplied by an integer. Afterwards *t1* // i == *t2* is true, provided `i != 0`. In general, *t1* * i == *t1* * (i-1) + *t1* is true. (1)
t1 * f	Delta multiplied by a float. The result is rounded to the nearest multiple of timedelta.resolution using round-half-to-even.
t1 / t2	Division (3) of overall duration *t2* by interval unit *t3*. Returns a **float** object.
t1 / f	Delta divided by a float or an int. The result is rounded to the nearest multiple of timedelta.resolution using round-half-to-even.
t1 // t2	The floor is computed and the remainder (if any) is thrown away. In the second case, an integer is returned. (3)
t1 % t2	The remainder is computed as a **timedelta** object. (3)
q, r = divmod(t1, t2)	Computes the quotient and the remainder: `q = t1 // t2` (3) and `r = t1 % t2`. q is an integer and r is a **timedelta**

object.

`+t`	Returns a `timedelta` object with the same value. (2)
`-t`	equivalent to `timedelta`(*-t1.days*, *-t1.seconds*, *-t1.microseconds*), and to *t1** -1. (1)(4)
`abs(t)`	equivalent to +*t* when `t.days >= 0`, and to *-t* when `t.days < 0`. (2)
`str(t)`	Returns a string in the form `[D day[s], ][H]H:MM:SS[.UUUUUU]`, where D is negative for negative `t`. (5)
`repr(t)`	Returns a string representation of the `timedelta` object as a constructor call with canonical attribute values.

Notes:

1. This is exact but may overflow.

2. This is exact and cannot overflow.

3. Division by 0 raises `ZeroDivisionError`.

4. *-timedelta.max* is not representable as a `timedelta` object.

5. String representations of `timedelta` objects are normalized similarly to their internal representation. This leads to somewhat unusual results for negative timedeltas. For example:

   ```
   >>> timedelta(hours=-5)
   datetime.timedelta(days=-1, seconds=68400)
   >>> print(_)
   -1 day, 19:00:00
   ```

6. The expression `t2 - t3` will always be equal to the expression `t2 + (-t3)` except when t3 is equal to `timedelta.max`; in that case the former will produce a result while the latter will overflow.

In addition to the operations listed above, `timedelta` objects support certain additions and subtractions with `date` and `datetime` objects (see below).

Changed in version 3.2: Floor division and true division of a **timedelta** object by another **timedelta** object are now supported, as are remainder operations and the **divmod()** function. True division and multiplication of a **timedelta** object by a **float** object are now supported.

Comparisons of **timedelta** objects are supported, with some caveats.

The comparisons == or != *always* return a **bool**, no matter the type of the compared object:

```
>>> from datetime import timedelta
>>> delta1 = timedelta(seconds=57)
>>> delta2 = timedelta(hours=25, seconds=2)
>>> delta2 != delta1
True
>>> delta2 == 5
False
```

For all other comparisons (such as < and >), when a **timedelta** object is compared to an object of a different type, **TypeError** is raised:

```
>>> delta2 > delta1
True
>>> delta2 > 5
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: '>' not supported between instances of 'datet
```

In Boolean contexts, a **timedelta** object is considered to be true if and only if it isn't equal to `timedelta(0)`.

Instance methods:

timedelta.total_seconds()

Return the total number of seconds contained in the duration. Equivalent to `td / timedelta(seconds=1)`. For interval units other than seconds, use the division form directly (e.g.

`td / timedelta(microseconds=1)`).

Note that for very large time intervals (greater than 270 years on most platforms) this method will lose microsecond accuracy.

New in version 3.2.

Examples of usage: `timedelta`

An additional example of normalization:

```
>>> # Components of another_year add up to exactly 365 d
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> another_year = timedelta(weeks=40, days=84, hours=23
...                          minutes=50, seconds=600)
>>> year == another_year
True
>>> year.total_seconds()
31536000.0
```

Examples of `timedelta` arithmetic:

```
>>> from datetime import timedelta
>>> year = timedelta(days=365)
>>> ten_years = 10 * year
>>> ten_years
datetime.timedelta(days=3650)
>>> ten_years.days // 365
10
>>> nine_years = ten_years - year
>>> nine_years
datetime.timedelta(days=3285)
>>> three_years = nine_years // 3
>>> three_years, three_years.days // 365
(datetime.timedelta(days=1095), 3)
```

`date` Objects

A **date** object represents a date (year, month and day) in an idealized calendar, the current Gregorian calendar indefinitely extended in both directions.

January 1 of year 1 is called day number 1, January 2 of year 1 is called day number 2, and so on. 2

class datetime.date(*year*, *month*, *day*)

All arguments are required. Arguments must be integers, in the following ranges:

- `MINYEAR <= year <= MAXYEAR`
- `1 <= month <= 12`
- `1 <= day <= number of days in the given month and year`

If an argument outside those ranges is given, **ValueError** is raised.

Other constructors, all class methods:

classmethod date.today()

Return the current local date.

This is equivalent to `date.fromtimestamp(time.time())`.

classmethod date.fromtimestamp(*timestamp*)

Return the local date corresponding to the POSIX timestamp, such as is returned by **time.time()**.

This may raise **OverflowError**, if the timestamp is out of the range of values supported by the platform C **localtime()** function, and **OSError** on **localtime()** failure. It's common for this to be restricted to years from 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by **fromtimestamp()**.

Changed in version 3.3: Raise **OverflowError** instead of

ValueError if the timestamp is out of the range of values supported by the platform C **localtime()** function. Raise **OSError** instead of **ValueError** on **localtime()** failure.

classmethod date.fromordinal(*ordinal*)

Return the date corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1.

ValueError is raised unless `1 <= ordinal <= date.max.toordinal()`. For any date *d*, `date.fromordinal(d.toordinal()) == d`.

classmethod date.fromisoformat(*date_string*)

Return a **date** corresponding to a *date_string* given in any valid ISO 8601 format, except ordinal dates (e.g. `YYYY-DDD`):

```
>>> from datetime import date
>>> date.fromisoformat('2019-12-04')
datetime.date(2019, 12, 4)
>>> date.fromisoformat('20191204')
datetime.date(2019, 12, 4)
>>> date.fromisoformat('2021-W01-1')
datetime.date(2021, 1, 4)
```

New in version 3.7.

Changed in version 3.11: Previously, this method only supported the format `YYYY-MM-DD`.

classmethod date.fromisocalendar(*year*, *week*, *day*)

Return a **date** corresponding to the ISO calendar date specified by year, week and day. This is the inverse of the function **date.isocalendar()**.

New in version 3.8.

Class attributes:

date.min

The earliest representable date, `date(MINYEAR, 1, 1)`.

date.max

The latest representable date, `date(MAXYEAR, 12, 31)`.

date.resolution

The smallest possible difference between non-equal date objects, `timedelta(days=1)`.

Instance attributes (read-only):

date.year

Between **MINYEAR** and **MAXYEAR** inclusive.

date.month

Between 1 and 12 inclusive.

date.day

Between 1 and the number of days in the given month of the given year.

Supported operations:

Operation	Result
`date2 = date1 + timedelta`	*date2* will be `timedelta.days` days after *date1*. (1)
`date2 = date1 - timedelta`	Computes *date2* such that `date2 + timedelta == date1`. (2)
`timedelta = date1 - date2`	(3)
`date1 < date2`	*date1* is considered less than *date2* when *date1* precedes *date2* in time. (4)

Notes:

1. *date2* is moved forward in time if `timedelta.days > 0`, or backward if `timedelta.days < 0`. Afterward `date2 - date1 == timedelta.days`. `timedelta.seconds` and `timedelta.microseconds` are ignored.

OverflowError is raised if `date2.year` would be smaller than **MINYEAR** or larger than **MAXYEAR**.

2. `timedelta.seconds` and `timedelta.microseconds` are ignored.
3. This is exact, and cannot overflow. timedelta.seconds and timedelta.microseconds are 0, and date2 + timedelta == date1 after.
4. In other words, `date1 < date2` if and only if `date1.toordinal() < date2.toordinal()`. Date comparison raises **TypeError** if the other comparand isn't also a **date** object. However, `NotImplemented` is returned instead if the other comparand has a **timetuple()** attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a **date** object is compared to an object of a different type, **TypeError** is raised unless the comparison is `==` or `!=`. The latter cases return **False** or **True**, respectively.

In Boolean contexts, all **date** objects are considered to be true.

Instance methods:

date.replace(*year*=*self.year*, *month*=*self.month*, *day*=*self.day*)

Return a date with the same value, except for those parameters given new values by whichever keyword arguments are specified.

Example:

```
>>> from datetime import date
>>> d = date(2002, 12, 31)
>>> d.replace(day=26)
datetime.date(2002, 12, 26)
```

date.timetuple()

Return a **time.struct_time** such as returned by **time.localtime()**.

The hours, minutes and seconds are 0, and the DST flag is -1.

`d.timetuple()` is equivalent to:

```
time.struct_time((d.year, d.month, d.day, 0, 0, 0,
```

where `yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1` is the day number within the current year starting with `1` for January 1st.

date.toordinal()

Return the proleptic Gregorian ordinal of the date, where January 1 of year 1 has ordinal 1. For any **`date`** object *d*, `date.fromordinal(d.toordinal()) == d`.

date.weekday()

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. For example, `date(2002, 12, 4).weekday() == 2`, a Wednesday. See also **`isoweekday()`**.

date.isoweekday()

Return the day of the week as an integer, where Monday is 1 and Sunday is 7. For example, `date(2002, 12, 4).isoweekday() == 3`, a Wednesday. See also **`weekday()`**, **`isocalendar()`**.

date.isocalendar()

Return a named tuple object with three components: `year`, `week` and `weekday`.

The ISO calendar is a widely used variant of the Gregorian calendar. 3

The ISO year consists of 52 or 53 full weeks, and where a week starts on a Monday and ends on a Sunday. The first week of an ISO year is the first (Gregorian) calendar week of a year containing a Thursday. This is called week number 1, and the ISO year of that Thursday is the same as its Gregorian year.

For example, 2004 begins on a Thursday, so the first week of ISO year 2004 begins on Monday, 29 Dec 2003 and ends on Sunday, 4 Jan 2004:

```
>>> from datetime import date
>>> date(2003, 12, 29).isocalendar()
datetime.IsoCalendarDate(year=2004, week=1, weekday
>>> date(2004, 1, 4).isocalendar()
datetime.IsoCalendarDate(year=2004, week=1, weekday
```

Changed in version 3.9: Result changed from a tuple to a named tuple.

date.isoformat()

Return a string representing the date in ISO 8601 format, `YYYY-MM-DD`:

```
>>> from datetime import date
>>> date(2002, 12, 4).isoformat()
'2002-12-04'
```

date.__str__()

For a date *d*, `str(d)` is equivalent to `d.isoformat()`.

date.ctime()

Return a string representing the date:

```
>>> from datetime import date
>>> date(2002, 12, 4).ctime()
'Wed Dec  4 00:00:00 2002'
```

`d.ctime()` is equivalent to:

```
time.ctime(time.mktime(d.timetuple()))
```

on platforms where the native C **`ctime()`** function (which **`time.ctime()`** invokes, but which **`date.ctime()`** does not invoke) conforms to the C standard.

date.strftime(*format*)

Return a string representing the date, controlled by an explicit format string. Format codes referring to hours, minutes or seconds will see 0 values. For a complete list of formatting directives, see strftime() and strptime() Behavior.

date._format_(*format*)

Same as **`date.strftime()`**. This makes it possible to specify a format string for a **`date`** object in formatted string literals and when using **`str.format()`**. For a complete list of formatting directives, see strftime() and strptime() Behavior.

Examples of Usage: **`date`**

Example of counting days to an event:

```
>>> import time
>>> from datetime import date
>>> today = date.today()
>>> today
datetime.date(2007, 12, 5)
>>> today == date.fromtimestamp(time.time())
True
>>> my_birthday = date(today.year, 6, 24)
>>> if my_birthday < today:
...     my_birthday = my_birthday.replace(year=today.yea
>>> my_birthday
datetime.date(2008, 6, 24)
>>> time_to_birthday = abs(my_birthday - today)
>>> time_to_birthday.days
202
```

More examples of working with **`date`**:

```
>>> from datetime import date
>>> d = date.fromordinal(730920) # 730920th day after 1.
>>> d
```

```
datetime.date(2002, 3, 11)

>>> # Methods related to formatting string output
>>> d.isoformat()
'2002-03-11'
>>> d.strftime("%d/%m/%y")
'11/03/02'
>>> d.strftime("%A %d. %B %Y")
'Monday 11. March 2002'
>>> d.ctime()
'Mon Mar 11 00:00:00 2002'
>>> 'The {1} is {0:%d}, the {2} is {0:%B}.'.format(d, "c
'The day is 11, the month is March.'

>>> # Methods for to extracting 'components' under diffe
>>> t = d.timetuple()
>>> for i in t:
...     print(i)
2002                # year
3                   # month
11                  # day
0
0
0
0                   # weekday (0 = Monday)
70                  # 70th day in the year
-1
>>> ic = d.isocalendar()
>>> for i in ic:
...     print(i)
2002                # ISO year
11                  # ISO week number
1                   # ISO day number ( 1 = Monday )

>>> # A date object is immutable; all operations produce
>>> d.replace(year=2005)
datetime.date(2005, 3, 11)
```

`datetime` Objects

A `datetime` object is a single object containing all the information from a `date` object and a `time` object.

Like a `date` object, `datetime` assumes the current Gregorian calendar extended in both directions; like a `time` object, `datetime` assumes there are exactly 3600*24 seconds in every day.

Constructor:

class datetime.datetime(*year*, *month*, *day*, *hour*=*0*, *minute*=*0*, *second*=*0*, *microsecond*=*0*, *tzinfo*=*None*, *, *fold*=*0*)

The *year*, *month* and *day* arguments are required. *tzinfo* may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments must be integers in the following ranges:

- `MINYEAR <= year <= MAXYEAR`,
- `1 <= month <= 12`,
- `1 <= day <= number of days in the given month and year`,
- `0 <= hour < 24`,
- `0 <= minute < 60`,
- `0 <= second < 60`,
- `0 <= microsecond < 1000000`,
- `fold in [0, 1]`.

If an argument outside those ranges is given, `ValueError` is raised.

New in version 3.6: Added the `fold` argument.

Other constructors, all class methods:

classmethod datetime.today()

Return the current local datetime, with `tzinfo` `None`.

Equivalent to:

`datetime.fromtimestamp(time.time())`

See also **`now()`**, **`fromtimestamp()`**.

This method is functionally equivalent to **`now()`**, but without a `tz` parameter.

classmethod datetime.now(*tz=None*)

Return the current local date and time.

If optional argument *tz* is `None` or not specified, this is like **`today()`**, but, if possible, supplies more precision than can be gotten from going through a **`time.time()`** timestamp (for example, this may be possible on platforms supplying the C **`gettimeofday()`** function).

If *tz* is not `None`, it must be an instance of a **`tzinfo`** subclass, and the current date and time are converted to *tz*'s time zone.

This function is preferred over **`today()`** and **`utcnow()`**.

classmethod datetime.utcnow()

Return the current UTC date and time, with **`tzinfo`** `None`.

This is like **`now()`**, but returns the current UTC date and time, as a naive **`datetime`** object. An aware current UTC datetime can be obtained by calling `datetime.now(timezone.utc)`. See also **`now()`**.

Warning

Because naive `datetime` objects are treated by many `datetime` methods as local times, it is preferred to use aware datetimes to represent times in UTC. As such, the recommended way to create an object representing the current time in UTC is by calling `datetime.now(timezone.utc)`.

classmethod datetime.fromtimestamp(*timestamp*, *tz=None*)

Return the local date and time corresponding to the POSIX timestamp, such as is returned by **time.time()**. If optional argument *tz* is `None` or not specified, the timestamp is converted to the platform's local date and time, and the returned **datetime** object is naive.

If *tz* is not `None`, it must be an instance of a **tzinfo** subclass, and the timestamp is converted to *tz*'s time zone.

fromtimestamp() may raise **OverflowError**, if the timestamp is out of the range of values supported by the platform C **localtime()** or **gmtime()** functions, and **OSError** on **localtime()** or **gmtime()** failure. It's common for this to be restricted to years in 1970 through 2038. Note that on non-POSIX systems that include leap seconds in their notion of a timestamp, leap seconds are ignored by **fromtimestamp()**, and then it's possible to have two timestamps differing by a second that yield identical **datetime** objects. This method is preferred over **utcfromtimestamp()**.

Changed in version 3.3: Raise **OverflowError** instead of **ValueError** if the timestamp is out of the range of values supported by the platform C **localtime()** or **gmtime()** functions. Raise **OSError** instead of **ValueError** on **localtime()** or **gmtime()** failure.

Changed in version 3.6: **fromtimestamp()** may return instances with **fold** set to 1.

classmethod datetime.utcfromtimestamp(*timestamp*)

Return the UTC **datetime** corresponding to the POSIX timestamp, with **tzinfo** `None`. (The resulting object is naive.)

This may raise **OverflowError**, if the timestamp is out of the range of values supported by the platform C **gmtime()** function, and **OSError** on **gmtime()** failure. It's common for this to be restricted to years in 1970 through 2038.

To get an aware **datetime** object, call **fromtimestamp()**:

```
datetime.fromtimestamp(timestamp, timezone.utc)
```

On the POSIX compliant platforms, it is equivalent to the following expression:

```
datetime(1970, 1, 1, tzinfo=timezone.utc) + timedel
```

except the latter formula always supports the full years range: between **MINYEAR** and **MAXYEAR** inclusive.

Warning

Because naive `datetime` objects are treated by many `datetime` methods as local times, it is preferred to use aware datetimes to represent times in UTC. As such, the recommended way to create an object representing a specific timestamp in UTC is by calling `datetime.fromtimestamp(timestamp, tz=timezone.utc)`.

Changed in version 3.3: Raise **OverflowError** instead of **ValueError** if the timestamp is out of the range of values supported by the platform C **gmtime()** function. Raise **OSError** instead of **ValueError** on **gmtime()** failure.

classmethod datetime.fromordinal(*ordinal*)

Return the **datetime** corresponding to the proleptic Gregorian ordinal, where January 1 of year 1 has ordinal 1. **ValueError** is raised unless `1 <= ordinal <= datetime.max.toordinal()`. The hour, minute, second and microsecond of the result are all 0, and **tzinfo** is `None`.

classmethod datetime.combine(*date*, *time*, *tzinfo*=*self.tzinfo*)

Return a new **datetime** object whose date components are equal to the given **date** object's, and whose time components are equal to the given **time** object's. If the *tzinfo*

argument is provided, its value is used to set the **tzinfo** attribute of the result, otherwise the **tzinfo** attribute of the *time* argument is used.

For any **datetime** object *d*, `d == datetime.combine(d.date(), d.time(), d.tzinfo)`. If date is a **datetime** object, its time components and **tzinfo** attributes are ignored.

Changed in version 3.6: Added the *tzinfo* argument.

classmethod datetime.fromisoformat(*date_string*)

Return a **datetime** corresponding to a *date_string* in any valid ISO 8601 format, with the following exceptions:

1. Time zone offsets may have fractional seconds.
2. The `T` separator may be replaced by any single unicode character.
3. Ordinal dates are not currently supported.
4. Fractional hours and minutes are not supported.

Examples:

```
>>> from datetime import datetime
>>> datetime.fromisoformat('2011-11-04')
datetime.datetime(2011, 11, 4, 0, 0)
>>> datetime.fromisoformat('20111104')
datetime.datetime(2011, 11, 4, 0, 0)
>>> datetime.fromisoformat('2011-11-04T00:05:23')
datetime.datetime(2011, 11, 4, 0, 5, 23)
>>> datetime.fromisoformat('2011-11-04T00:05:23Z')
datetime.datetime(2011, 11, 4, 0, 5, 23, tzinfo=dat
>>> datetime.fromisoformat('20111104T000523')
datetime.datetime(2011, 11, 4, 0, 5, 23)
>>> datetime.fromisoformat('2011-W01-2T00:05:23.283
datetime.datetime(2011, 1, 4, 0, 5, 23, 283000)
>>> datetime.fromisoformat('2011-11-04 00:05:23.283
datetime.datetime(2011, 11, 4, 0, 5, 23, 283000)
>>> datetime.fromisoformat('2011-11-04 00:05:23.283
datetime.datetime(2011, 11, 4, 0, 5, 23, 283000, tz
```

```
>>> datetime.fromisoformat('2011-11-04T00:05:23+04:
datetime.datetime(2011, 11, 4, 0, 5, 23,
    tzinfo=datetime.timezone(datetime.timedelta(sec
```

New in version 3.7.

Changed in version 3.11: Previously, this method only supported formats that could be emitted by **`date.isoformat()`** or **`datetime.isoformat()`**.

classmethod datetime.fromisocalendar(*year*, *week*, *day*)

Return a **`datetime`** corresponding to the ISO calendar date specified by year, week and day. The non-date components of the datetime are populated with their normal default values. This is the inverse of the function **`datetime.isocalendar()`**.

New in version 3.8.

classmethod datetime.strptime(*date_string*, *format*)

Return a **`datetime`** corresponding to *date_string*, parsed according to *format*.

This is equivalent to:

```
datetime(*(time.strptime(date_string, format)[0:6]))
```

`ValueError` is raised if the date_string and format can't be parsed by **`time.strptime()`** or if it returns a value which isn't a time tuple. For a complete list of formatting directives, see strftime() and strptime() Behavior.

Class attributes:

datetime.min

The earliest representable **`datetime`**, `datetime(MINYEAR, 1, 1, tzinfo=None)`.

datetime.max

The latest representable **datetime**, `datetime(MAXYEAR, 12, 31, 23, 59, 59, 999999, tzinfo=None)`.

datetime.resolution

The smallest possible difference between non-equal **datetime** objects, `timedelta(microseconds=1)`.

Instance attributes (read-only):

datetime.year

Between **MINYEAR** and **MAXYEAR** inclusive.

datetime.month

Between 1 and 12 inclusive.

datetime.day

Between 1 and the number of days in the given month of the given year.

datetime.hour

In `range(24)`.

datetime.minute

In `range(60)`.

datetime.second

In `range(60)`.

datetime.microsecond

In `range(1000000)`.

datetime.tzinfo

The object passed as the *tzinfo* argument to the **datetime** constructor, or `None` if none was passed.

datetime.fold

In `[0, 1]`. Used to disambiguate wall times during a repeated interval. (A repeated interval occurs when clocks are rolled back at the end of daylight saving time or when the UTC offset for the current zone is decreased for political reasons.) The value 0 (1) represents the earlier (later) of the two moments with the same wall time representation.

New in version 3.6.

Supported operations:

Operation	Result
(1)	`datetime2 = datetime1 + timedelta`
(2)	`datetime2 = datetime1 - timedelta`
(3)	`timedelta = datetime1 - datetime2`
(4)	Compares **datetime** to **datetime**.

1. datetime2 is a duration of timedelta removed from datetime1, moving forward in time if `timedelta.days` > 0, or backward if `timedelta.days` < 0. The result has the same **tzinfo** attribute as the input datetime, and datetime2 - datetime1 == timedelta after. **OverflowError** is raised if datetime2.year would be smaller than **MINYEAR** or larger than **MAXYEAR**. Note that no time zone adjustments are done even if the input is an aware object.

2. Computes the datetime2 such that datetime2 + timedelta == datetime1. As for addition, the result has the same **tzinfo** attribute as the input datetime, and no time zone adjustments are done even if the input is aware.

3. Subtraction of a **datetime** from a **datetime** is defined only if both operands are naive, or if both are aware. If one is aware and the other is naive, **TypeError** is raised.

   If both are naive, or both are aware and have the same **tzinfo** attribute, the **tzinfo** attributes are ignored, and the result is a **timedelta** object *t* such that `datetime2 + t == datetime1`. No time zone adjustments are done in this case.

If both are aware and have different **tzinfo** attributes, `a-b` acts as if *a* and *b* were first converted to naive UTC datetimes first. The result is `(a.replace(tzinfo=None) - a.utcoffset()) - (b.replace(tzinfo=None) - b.utcoffset())` except that the implementation never overflows.

4. *datetime1* is considered less than *datetime2* when *datetime1* precedes *datetime2* in time.

   If one comparand is naive and the other is aware, **TypeError** is raised if an order comparison is attempted. For equality comparisons, naive instances are never equal to aware instances.

   If both comparands are aware, and have the same **tzinfo** attribute, the common **tzinfo** attribute is ignored and the base datetimes are compared. If both comparands are aware and have different **tzinfo** attributes, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`).

   Changed in version 3.3: Equality comparisons between aware and naive **datetime** instances don't raise **TypeError**.

   Note

   In order to stop comparison from falling back to the default scheme of comparing object addresses, datetime comparison normally raises **TypeError** if the other comparand isn't also a **datetime** object. However, `NotImplemented` is returned instead if the other comparand has a **timetuple()** attribute. This hook gives other kinds of date objects a chance at implementing mixed-type comparison. If not, when a **datetime** object is compared to an object of a different type, **TypeError** is raised unless the comparison is `==` or `!=`. The latter cases return **False** or **True**, respectively.

Instance methods:

datetime.date()

Return **date** object with same year, month and day.

datetime.time()

Return **time** object with same hour, minute, second, microsecond and fold. **tzinfo** is `None`. See also method **timetz()**.

Changed in version 3.6: The fold value is copied to the returned **time** object.

datetime.timetz()

Return **time** object with same hour, minute, second, microsecond, fold, and tzinfo attributes. See also method **time()**.

Changed in version 3.6: The fold value is copied to the returned **time** object.

datetime.replace(*year*=*self.year*, *month*=*self.month*, *day*=*self.day*, *hour*=*self.hour*, *minute*=*self.minute*, *second*=*self.second*, *microsecond*=*self.microsecond*, *tzinfo*=*self.tzinfo*, *, *fold*=*0*)

Return a datetime with the same attributes, except for those attributes given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive datetime from an aware datetime with no conversion of date and time data.

New in version 3.6: Added the `fold` argument.

datetime.astimezone(*tz*=*None*)

Return a **datetime** object with new **tzinfo** attribute *tz*, adjusting the date and time data so the result is the same UTC time as *self*, but in *tz*'s local time.

If provided, *tz* must be an instance of a **tzinfo** subclass, and

its **`utcoffset()`** and **`dst()`** methods must not return `None`. If *self* is naive, it is presumed to represent time in the system timezone.

If called without arguments (or with `tz=None`) the system local timezone is assumed for the target timezone. The `.tzinfo` attribute of the converted datetime instance will be set to an instance of **`timezone`** with the zone name and offset obtained from the OS.

If `self.tzinfo` is *tz*, `self.astimezone(tz)` is equal to *self*: no adjustment of date or time data is performed. Else the result is local time in the timezone *tz*, representing the same UTC time as *self*: after `astz = dt.astimezone(tz)`, `astz - astz.utcoffset()` will have the same date and time data as `dt - dt.utcoffset()`.

If you merely want to attach a time zone object *tz* to a datetime *dt* without adjustment of date and time data, use `dt.replace(tzinfo=tz)`. If you merely want to remove the time zone object from an aware datetime *dt* without conversion of date and time data, use `dt.replace(tzinfo=None)`.

Note that the default **`tzinfo.fromutc()`** method can be overridden in a **`tzinfo`** subclass to affect the result returned by **`astimezone()`**. Ignoring error cases, **`astimezone()`** acts like:

```
def astimezone(self, tz):
    if self.tzinfo is tz:
        return self
    # Convert self to UTC, and attach the new time
    utc = (self - self.utcoffset()).replace(tzinfo=
    # Convert from UTC to tz's local time.
    return tz.fromutc(utc)
```

Changed in version 3.3: *tz* now can be omitted.

Changed in version 3.6: The **`astimezone()`** method can now be called on naive instances that are presumed to represent

system local time.

datetime.utcoffset()

If **tzinfo** is `None`, returns `None`, else returns `self.tzinfo.utcoffset(self)`, and raises an exception if the latter doesn't return `None` or a **timedelta** object with magnitude less than one day.

Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

datetime.dst()

If **tzinfo** is `None`, returns `None`, else returns `self.tzinfo.dst(self)`, and raises an exception if the latter doesn't return `None` or a **timedelta** object with magnitude less than one day.

Changed in version 3.7: The DST offset is not restricted to a whole number of minutes.

datetime.tzname()

If **tzinfo** is `None`, returns `None`, else returns `self.tzinfo.tzname(self)`, raises an exception if the latter doesn't return `None` or a string object,

datetime.timetuple()

Return a **time.struct_time** such as returned by **time.localtime()**.

`d.timetuple()` is equivalent to:

```
time.struct_time((d.year, d.month, d.day,
                  d.hour, d.minute, d.second,
                  d.weekday(), yday, dst))
```

where `yday = d.toordinal() - date(d.year, 1, 1).toordinal() + 1` is the day number within the current year starting with `1` for January 1st. The **tm_isdst** flag of

the result is set according to the **dst()** method: **tzinfo** is None or **dst()** returns None, **tm_isdst** is set to -1; else if **dst()** returns a non-zero value, **tm_isdst** is set to 1; else **tm_isdst** is set to 0.

datetime.utctimetuple()

If **datetime** instance *d* is naive, this is the same as d.timetuple() except that **tm_isdst** is forced to 0 regardless of what d.dst() returns. DST is never in effect for a UTC time.

If *d* is aware, *d* is normalized to UTC time, by subtracting d.utcoffset(), and a **time.struct_time** for the normalized time is returned. **tm_isdst** is forced to 0. Note that an **OverflowError** may be raised if *d*.year was MINYEAR or MAXYEAR and UTC adjustment spills over a year boundary.

Warning

Because naive datetime objects are treated by many datetime methods as local times, it is preferred to use aware datetimes to represent times in UTC; as a result, using utcfromtimetuple may give misleading results. If you have a naive datetime representing UTC, use datetime.replace(tzinfo=timezone.utc) to make it aware, at which point you can use **datetime.timetuple()**.

datetime.toordinal()

Return the proleptic Gregorian ordinal of the date. The same as self.date().toordinal().

datetime.timestamp()

Return POSIX timestamp corresponding to the **datetime** instance. The return value is a **float** similar to that returned by **time.time()**.

Naive **datetime** instances are assumed to represent local time and this method relies on the platform C **mktime()** function to perform the conversion. Since **datetime** supports wider range of values than **mktime()** on many platforms, this method may raise **OverflowError** for times far in the past or far in the future.

For aware **datetime** instances, the return value is computed as:

```
(dt - datetime(1970, 1, 1, tzinfo=timezone.utc)).to
```

New in version 3.3.

Changed in version 3.6: The **timestamp()** method uses the **fold** attribute to disambiguate the times during a repeated interval.

Note

There is no method to obtain the POSIX timestamp directly from a naive **datetime** instance representing UTC time. If your application uses this convention and your system timezone is not set to UTC, you can obtain the POSIX timestamp by supplying `tzinfo=timezone.utc`:

```
timestamp = dt.replace(tzinfo=timezone.utc).timest
```

or by calculating the timestamp directly:

```
timestamp = (dt - datetime(1970, 1, 1)) / timedelt
```

datetime.weekday()

Return the day of the week as an integer, where Monday is 0 and Sunday is 6. The same as `self.date().weekday()`. See also **isoweekday()**.

datetime.isoweekday()

Return the day of the week as an integer, where Monday is 1

and Sunday is 7. The same as `self.date().isoweekday()`. See also **`weekday()`**, **`isocalendar()`**.

datetime.isocalendar()

Return a named tuple with three components: `year`, `week` and `weekday`. The same as `self.date().isocalendar()`.

datetime.isoformat(*sep* = *'T'*, *timespec* = *'auto'*)

Return a string representing the date and time in ISO 8601 format:

- `YYYY-MM-DDTHH:MM:SS.ffffff`, if **`microsecond`** is not 0
- `YYYY-MM-DDTHH:MM:SS`, if **`microsecond`** is 0

If **`utcoffset()`** does not return `None`, a string is appended, giving the UTC offset:

- `YYYY-MM-DDTHH:MM:SS.ffffff` `+HH:MM[:SS[.ffffff]]`, if **`microsecond`** is not 0
- `YYYY-MM-DDTHH:MM:SS+HH:MM[:SS[.ffffff]]`, if **`microsecond`** is 0

Examples:

```
>>> from datetime import datetime, timezone
>>> datetime(2019, 5, 18, 15, 17, 8, 132263).isofor
'2019-05-18T15:17:08.132263'
>>> datetime(2019, 5, 18, 15, 17, tzinfo=timezone.u
'2019-05-18T15:17:00+00:00'
```

The optional argument *sep* (default `'T'`) is a one-character separator, placed between the date and time portions of the result. For example:

```
>>> from datetime import tzinfo, timedelta, datetim
>>> class TZ(tzinfo):
...     """A time zone with an arbitrary, constant
```

```
...     def utcoffset(self, dt):
...         return timedelta(hours=-6, minutes=-39)
...
>>> datetime(2002, 12, 25, tzinfo=TZ()).isoformat('
'2002-12-25 00:00:00-06:39'
>>> datetime(2009, 11, 27, microsecond=100, tzinfo=
'2009-11-27T00:00:00.000100-06:39'
```

The optional argument *timespec* specifies the number of additional components of the time to include (the default is `'auto'`). It can be one of the following:

- `'auto'`: Same as `'seconds'` if **`microsecond`** is 0, same as `'microseconds'` otherwise.
- `'hours'`: Include the **`hour`** in the two-digit `HH` format.
- `'minutes'`: Include **`hour`** and **`minute`** in `HH:MM` format.
- `'seconds'`: Include **`hour`**, **`minute`**, and **`second`** in `HH:MM:SS` format.
- `'milliseconds'`: Include full time, but truncate fractional second part to milliseconds. `HH:MM:SS.sss` format.
- `'microseconds'`: Include full time in `HH:MM:SS.ffffff` format.

Note

Excluded time components are truncated, not rounded.

`ValueError` will be raised on an invalid *timespec* argument:

```
>>> from datetime import datetime
>>> datetime.now().isoformat(timespec='minutes')
'2002-12-25T00:00'
>>> dt = datetime(2015, 1, 1, 12, 30, 59, 0)
>>> dt.isoformat(timespec='microseconds')
'2015-01-01T12:30:59.000000'
```

New in version 3.6: Added the *timespec* argument.

datetime._str_()

For a **`datetime`** instance *d*, `str(d)` is equivalent to `d.isoformat(' ')`.

datetime.ctime()

Return a string representing the date and time:

```
>>> from datetime import datetime
>>> datetime(2002, 12, 4, 20, 30, 40).ctime()
'Wed Dec  4 20:30:40 2002'
```

The output string will *not* include time zone information, regardless of whether the input is aware or naive.

`d.ctime()` is equivalent to:

```
time.ctime(time.mktime(d.timetuple()))
```

on platforms where the native C **`ctime()`** function (which **`time.ctime()`** invokes, but which **`datetime.ctime()`** does not invoke) conforms to the C standard.

datetime.strftime(*format*)

Return a string representing the date and time, controlled by an explicit format string. For a complete list of formatting directives, see strftime() and strptime() Behavior.

datetime._format_(*format*)

Same as **`datetime.strftime()`**. This makes it possible to specify a format string for a **`datetime`** object in formatted string literals and when using **`str.format()`**. For a complete list of formatting directives, see strftime() and strptime() Behavior.

Examples of Usage: **`datetime`**

Examples of working with **`datetime`** objects:

```
>>> from datetime import datetime, date, time, timezone

>>> # Using datetime.combine()
>>> d = date(2005, 7, 14)
>>> t = time(12, 30)
>>> datetime.combine(d, t)
datetime.datetime(2005, 7, 14, 12, 30)

>>> # Using datetime.now()
>>> datetime.now()
datetime.datetime(2007, 12, 6, 16, 29, 43, 79043)   # GM
>>> datetime.now(timezone.utc)
datetime.datetime(2007, 12, 6, 15, 29, 43, 79060, tzinfo

>>> # Using datetime.strptime()
>>> dt = datetime.strptime("21/11/06 16:30", "%d/%m/%y %
>>> dt
datetime.datetime(2006, 11, 21, 16, 30)

>>> # Using datetime.timetuple() to get tuple of all att
>>> tt = dt.timetuple()
>>> for it in tt:
...     print(it)
...
2006    # year
11      # month
21      # day
16      # hour
30      # minute
0       # second
1       # weekday (0 = Monday)
325     # number of days since 1st January
-1      # dst - method tzinfo.dst() returned None

>>> # Date in ISO format
>>> ic = dt.isocalendar()
>>> for it in ic:
...     print(it)
```

```
...
2006    # ISO year
47      # ISO week
2       # ISO weekday

>>> # Formatting a datetime
>>> dt.strftime("%A, %d. %B %Y %I:%M%p")
'Tuesday, 21. November 2006 04:30PM'
>>> 'The {1} is {0:%d}, the {2} is {0:%B}, the {3} is {0
'The day is 21, the month is November, the time is 04:30
```

The example below defines a **`tzinfo`** subclass capturing time zone information for Kabul, Afghanistan, which used +4 UTC until 1945 and then +4:30 UTC thereafter:

```
from datetime import timedelta, datetime, tzinfo, timezo

class KabulTz(tzinfo):
    # Kabul used +4 until 1945, when they moved to +4:30
    UTC_MOVE_DATE = datetime(1944, 12, 31, 20, tzinfo=ti

    def utcoffset(self, dt):
        if dt.year < 1945:
            return timedelta(hours=4)
        elif (1945, 1, 1, 0, 0) <= dt.timetuple()[:5] <
            # An ambiguous ("imaginary") half-hour range
            # a 'fold' in time due to the shift from +4
            # If dt falls in the imaginary range, use fo
            # to resolve. See PEP495.
            return timedelta(hours=4, minutes=(30 if dt.
        else:
            return timedelta(hours=4, minutes=30)

    def fromutc(self, dt):
        # Follow same validations as in datetime.tzinfo
        if not isinstance(dt, datetime):
            raise TypeError("fromutc() requires a dateti
        if dt.tzinfo is not self:
            raise ValueError("dt.tzinfo is not self")
```

```
        # A custom implementation is required for fromut
        # the input to this function is a datetime with
        # but with a tzinfo set to self.
        # See datetime.astimezone or fromtimestamp.
        if dt.replace(tzinfo=timezone.utc) >= self.UTC_M
            return dt + timedelta(hours=4, minutes=30)
        else:
            return dt + timedelta(hours=4)

    def dst(self, dt):
        # Kabul does not observe daylight saving time.
        return timedelta(0)

    def tzname(self, dt):
        if dt >= self.UTC_MOVE_DATE:
            return "+04:30"
        return "+04"
```

Usage of `KabulTz` from above:

```
>>> tz1 = KabulTz()

>>> # Datetime before the change
>>> dt1 = datetime(1900, 11, 21, 16, 30, tzinfo=tz1)
>>> print(dt1.utcoffset())
4:00:00

>>> # Datetime after the change
>>> dt2 = datetime(2006, 6, 14, 13, 0, tzinfo=tz1)
>>> print(dt2.utcoffset())
4:30:00

>>> # Convert datetime to another time zone
>>> dt3 = dt2.astimezone(timezone.utc)
>>> dt3
datetime.datetime(2006, 6, 14, 8, 30, tzinfo=datetime.ti
>>> dt2
datetime.datetime(2006, 6, 14, 13, 0, tzinfo=KabulTz())
```

```
>>> dt2 == dt3
True
```

`time` Objects

A `time` object represents a (local) time of day, independent of any particular day, and subject to adjustment via a `tzinfo` object.

class datetime.time(*hour* = *0*, *minute* = *0*, *second* = *0*, *microsecond* = *0*, *tzinfo* = *None*, ***, *fold* = *0*)

All arguments are optional. *tzinfo* may be `None`, or an instance of a `tzinfo` subclass. The remaining arguments must be integers in the following ranges:

- `0 <= hour < 24`,
- `0 <= minute < 60`,
- `0 <= second < 60`,
- `0 <= microsecond < 1000000`,
- `fold in [0, 1]`.

If an argument outside those ranges is given, `ValueError` is raised. All default to `0` except *tzinfo*, which defaults to `None`.

Class attributes:

time.min

The earliest representable `time`, `time(0, 0, 0, 0)`.

time.max

The latest representable `time`, `time(23, 59, 59, 999999)`.

time.resolution

The smallest possible difference between non-equal `time` objects, `timedelta(microseconds=1)`, although note that arithmetic on `time` objects is not supported.

Instance attributes (read-only):

time.hour

In `range(24)`.

time.minute

In `range(60)`.

time.second

In `range(60)`.

time.microsecond

In `range(1000000)`.

time.tzinfo

The object passed as the tzinfo argument to the **`time`** constructor, or `None` if none was passed.

time.fold

In `[0, 1]`. Used to disambiguate wall times during a repeated interval. (A repeated interval occurs when clocks are rolled back at the end of daylight saving time or when the UTC offset for the current zone is decreased for political reasons.) The value 0 (1) represents the earlier (later) of the two moments with the same wall time representation.

New in version 3.6.

`time` objects support comparison of **`time`** to **`time`**, where *a* is considered less than *b* when *a* precedes *b* in time. If one comparand is naive and the other is aware, **`TypeError`** is raised if an order comparison is attempted. For equality comparisons, naive instances are never equal to aware instances.

If both comparands are aware, and have the same **`tzinfo`** attribute, the common **`tzinfo`** attribute is ignored and the base times are compared. If both comparands are aware and have different **`tzinfo`** attributes, the comparands are first adjusted by subtracting their UTC offsets (obtained from `self.utcoffset()`). In order to stop mixed-type comparisons

from falling back to the default comparison by object address, when a **time** object is compared to an object of a different type, **TypeError** is raised unless the comparison is == or !=. The latter cases return **False** or **True**, respectively.

Changed in version 3.3: Equality comparisons between aware and naive **time** instances don't raise **TypeError**.

In Boolean contexts, a **time** object is always considered to be true.

Changed in version 3.5: Before Python 3.5, a **time** object was considered to be false if it represented midnight in UTC. This behavior was considered obscure and error-prone and has been removed in Python 3.5. See bpo-13936 [https://bugs.python.org/issue?@action=redirect&bpo=13936] for full details.

Other constructor:

classmethod time.fromisoformat(*time_string*)

Return a **time** corresponding to a *time_string* in any valid ISO 8601 format, with the following exceptions:

1. Time zone offsets may have fractional seconds.
2. The leading `T`, normally required in cases where there may be ambiguity between a date and a time, is not required.
3. Fractional seconds may have any number of digits (anything beyond 6 will be truncated).
4. Fractional hours and minutes are not supported.

Examples:

```
>>> from datetime import time
>>> time.fromisoformat('04:23:01')
datetime.time(4, 23, 1)
>>> time.fromisoformat('T04:23:01')
datetime.time(4, 23, 1)
>>> time.fromisoformat('T042301')
datetime.time(4, 23, 1)
>>> time.fromisoformat('04:23:01.000384')
```

```
datetime.time(4, 23, 1, 384)
>>> time.fromisoformat('04:23:01,000')
datetime.time(4, 23, 1, 384)
>>> time.fromisoformat('04:23:01+04:00')
datetime.time(4, 23, 1, tzinfo=datetime.timezone(da
>>> time.fromisoformat('04:23:01Z')
datetime.time(4, 23, 1, tzinfo=datetime.timezone.ut
>>> time.fromisoformat('04:23:01+00:00')
datetime.time(4, 23, 1, tzinfo=datetime.timezone.ut
```

New in version 3.7.

Changed in version 3.11: Previously, this method only supported formats that could be emitted by **`time.isoformat()`**.

Instance methods:

time.replace(*hour=self.hour*, *minute=self.minute*, *second=self.second*, *microsecond=self.microsecond*, *tzinfo=self.tzinfo*, ***, *fold=0*)

Return a **`time`** with the same value, except for those attributes given new values by whichever keyword arguments are specified. Note that `tzinfo=None` can be specified to create a naive **`time`** from an aware **`time`**, without conversion of the time data.

New in version 3.6: Added the `fold` argument.

time.isoformat(*timespec='auto'*)

Return a string representing the time in ISO 8601 format, one of:

- `HH:MM:SS.ffffff`, if **`microsecond`** is not 0
- `HH:MM:SS`, if **`microsecond`** is 0
- `HH:MM:SS.ffffff+HH:MM[:SS[.ffffff]]`, if **`utcoffset()`** does not return `None`
- `HH:MM:SS+HH:MM[:SS[.ffffff]]`, if **`microsecond`** is 0 and **`utcoffset()`** does not return

None

The optional argument *timespec* specifies the number of additional components of the time to include (the default is `'auto'`). It can be one of the following:

- `'auto'`: Same as `'seconds'` if **`microsecond`** is 0, same as `'microseconds'` otherwise.
- `'hours'`: Include the **`hour`** in the two-digit `HH` format.
- `'minutes'`: Include **`hour`** and **`minute`** in `HH:MM` format.
- `'seconds'`: Include **`hour`**, **`minute`**, and **`second`** in `HH:MM:SS` format.
- `'milliseconds'`: Include full time, but truncate fractional second part to milliseconds. `HH:MM:SS.sss` format.
- `'microseconds'`: Include full time in `HH:MM:SS.ffffff` format.

Note

Excluded time components are truncated, not rounded.

`ValueError` will be raised on an invalid *timespec* argument.

Example:

```
>>> from datetime import time
>>> time(hour=12, minute=34, second=56, microsecond
'12:34'
>>> dt = time(hour=12, minute=34, second=56, micros
>>> dt.isoformat(timespec='microseconds')
'12:34:56.000000'
>>> dt.isoformat(timespec='auto')
'12:34:56'
```

New in version 3.6: Added the *timespec* argument.

time._str_()

For a time *t*, `str(t)` is equivalent to `t.isoformat()`.

time.strftime(*format*)

Return a string representing the time, controlled by an explicit format string. For a complete list of formatting directives, see strftime() and strptime() Behavior.

time._format_(*format*)

Same as **`time.strftime()`**. This makes it possible to specify a format string for a **`time`** object in formatted string literals and when using **`str.format()`**. For a complete list of formatting directives, see strftime() and strptime() Behavior.

time.utcoffset()

If **`tzinfo`** is `None`, returns `None`, else returns `self.tzinfo.utcoffset(None)`, and raises an exception if the latter doesn't return `None` or a **`timedelta`** object with magnitude less than one day.

Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

time.dst()

If **`tzinfo`** is `None`, returns `None`, else returns `self.tzinfo.dst(None)`, and raises an exception if the latter doesn't return `None`, or a **`timedelta`** object with magnitude less than one day.

Changed in version 3.7: The DST offset is not restricted to a whole number of minutes.

time.tzname()

If **`tzinfo`** is `None`, returns `None`, else returns `self.tzinfo.tzname(None)`, or raises an exception if the latter doesn't return `None` or a string object.

Examples of Usage: `time`

Examples of working with a `time` object:

```
>>> from datetime import time, tzinfo, timedelta
>>> class TZ1(tzinfo):
...     def utcoffset(self, dt):
...         return timedelta(hours=1)
...     def dst(self, dt):
...         return timedelta(0)
...     def tzname(self,dt):
...         return "+01:00"
...     def  __repr__(self):
...         return f"{self.__class__.__name__}()"
...
>>> t = time(12, 10, 30, tzinfo=TZ1())
>>> t
datetime.time(12, 10, 30, tzinfo=TZ1())
>>> t.isoformat()
'12:10:30+01:00'
>>> t.dst()
datetime.timedelta(0)
>>> t.tzname()
'+01:00'
>>> t.strftime("%H:%M:%S %Z")
'12:10:30 +01:00'
>>> 'The {} is {:%H:%M}.'.format("time", t)
'The time is 12:10.'
```

`tzinfo` Objects

class datetime.tzinfo

This is an abstract base class, meaning that this class should not be instantiated directly. Define a subclass of `tzinfo` to capture information about a particular time zone.

An instance of (a concrete subclass of) `tzinfo` can be passed to the constructors for `datetime` and `time` objects. The

latter objects view their attributes as being in local time, and the **tzinfo** object supports methods revealing offset of local time from UTC, the name of the time zone, and DST offset, all relative to a date or time object passed to them.

You need to derive a concrete subclass, and (at least) supply implementations of the standard **tzinfo** methods needed by the **datetime** methods you use. The **datetime** module provides **timezone**, a simple concrete subclass of **tzinfo** which can represent timezones with fixed offset from UTC such as UTC itself or North American EST and EDT.

Special requirement for pickling: A **tzinfo** subclass must have an **__init__()** method that can be called with no arguments, otherwise it can be pickled but possibly not unpickled again. This is a technical requirement that may be relaxed in the future.

A concrete subclass of **tzinfo** may need to implement the following methods. Exactly which methods are needed depends on the uses made of aware **datetime** objects. If in doubt, simply implement all of them.

tzinfo.utcoffset(*dt*)

Return offset of local time from UTC, as a **timedelta** object that is positive east of UTC. If local time is west of UTC, this should be negative.

This represents the *total* offset from UTC; for example, if a **tzinfo** object represents both time zone and DST adjustments, **utcoffset()** should return their sum. If the UTC offset isn't known, return `None`. Else the value returned must be a **timedelta** object strictly between `-timedelta(hours=24)` and `timedelta(hours=24)` (the magnitude of the offset must be less than one day). Most implementations of **utcoffset()** will probably look like one of these two:

```
return CONSTANT                 # fixed-offset clas
return CONSTANT + self.dst(dt)  # daylight-aware cl
```

If **utcoffset()** does not return `None`, **dst()** should not return `None` either.

The default implementation of **utcoffset()** raises **NotImplementedError**.

Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

tzinfo.dst(*dt*)

Return the daylight saving time (DST) adjustment, as a **timedelta** object or `None` if DST information isn't known.

Return `timedelta(0)` if DST is not in effect. If DST is in effect, return the offset as a **timedelta** object (see **utcoffset()** for details). Note that DST offset, if applicable, has already been added to the UTC offset returned by **utcoffset()**, so there's no need to consult **dst()** unless you're interested in obtaining DST info separately. For example, **datetime.timetuple()** calls its **tzinfo** attribute's **dst()** method to determine how the **tm_isdst** flag should be set, and **tzinfo.fromutc()** calls **dst()** to account for DST changes when crossing time zones.

An instance *tz* of a **tzinfo** subclass that models both standard and daylight times must be consistent in this sense:

```
tz.utcoffset(dt) - tz.dst(dt)
```

must return the same result for every **datetime** *dt* with `dt.tzinfo == tz` For sane **tzinfo** subclasses, this expression yields the time zone's "standard offset", which should not depend on the date or the time, but only on geographic location. The implementation of **datetime.astimezone()** relies on this, but cannot detect violations; it's the programmer's responsibility to ensure it. If a **tzinfo** subclass cannot guarantee this, it may be able to override the default implementation of **tzinfo.fromutc()** to work correctly with **astimezone()** regardless.

Most implementations of **dst()** will probably look like one

of these two:

```
def dst(self, dt):
    # a fixed-offset class:  doesn't account for DS
    return timedelta(0)
```

or:

```
def dst(self, dt):
    # Code to set dston and dstoff to the time zone
    # transition times based on the input dt.year,
    # in standard local time.

    if dston <= dt.replace(tzinfo=None) < dstoff:
        return timedelta(hours=1)
    else:
        return timedelta(0)
```

The default implementation of **dst()** raises **NotImplementedError**.

Changed in version 3.7: The DST offset is not restricted to a whole number of minutes.

tzinfo.tzname(*dt*)

Return the time zone name corresponding to the **datetime** object *dt*, as a string. Nothing about string names is defined by the **datetime** module, and there's no requirement that it mean anything in particular. For example, "GMT", "UTC", "-500", "-5:00", "EDT", "US/Eastern", "America/New York" are all valid replies. Return `None` if a string name isn't known. Note that this is a method rather than a fixed string primarily because some **tzinfo** subclasses will wish to return different names depending on the specific value of *dt* passed, especially if the **tzinfo** class is accounting for daylight time.

The default implementation of **tzname()** raises **NotImplementedError**.

These methods are called by a **datetime** or **time** object, in response to their methods of the same names. A **datetime** object passes itself as the argument, and a **time** object passes `None` as the argument. A **tzinfo** subclass's methods should therefore be prepared to accept a *dt* argument of `None`, or of class **datetime**.

When `None` is passed, it's up to the class designer to decide the best response. For example, returning `None` is appropriate if the class wishes to say that time objects don't participate in the **tzinfo** protocols. It may be more useful for `utcoffset(None)` to return the standard UTC offset, as there is no other convention for discovering the standard offset.

When a **datetime** object is passed in response to a **datetime** method, `dt.tzinfo` is the same object as *self*. **tzinfo** methods can rely on this, unless user code calls **tzinfo** methods directly. The intent is that the **tzinfo** methods interpret *dt* as being in local time, and not need worry about objects in other timezones.

There is one more **tzinfo** method that a subclass may wish to override:

tzinfo.fromutc(*dt*)

> This is called from the default **datetime.astimezone()** implementation. When called from that, `dt.tzinfo` is *self*, and *dt*'s date and time data are to be viewed as expressing a UTC time. The purpose of **fromutc()** is to adjust the date and time data, returning an equivalent datetime in *self*'s local time.
>
> Most **tzinfo** subclasses should be able to inherit the default **fromutc()** implementation without problems. It's strong enough to handle fixed-offset time zones, and time zones accounting for both standard and daylight time, and the latter even if the DST transition times differ in different years. An example of a time zone the default **fromutc()** implementation may not handle correctly in all cases is one where the standard offset (from UTC) depends on the specific date and time passed, which can happen for political reasons. The default implementations of **astimezone()** and

fromutc() may not produce the result you want if the result is one of the hours straddling the moment the standard offset changes.

Skipping code for error cases, the default **fromutc()** implementation acts like:

```
def fromutc(self, dt):
    # raise ValueError error if dt.tzinfo is not se
    dtoff = dt.utcoffset()
    dtdst = dt.dst()
    # raise ValueError if dtoff is None or dtdst is
    delta = dtoff - dtdst  # this is self's standar
    if delta:
        dt += delta   # convert to standard local t
        dtdst = dt.dst()
        # raise ValueError if dtdst is None
    if dtdst:
        return dt + dtdst
    else:
        return dt
```

In the following **tzinfo_examples.py** file there are some examples of **tzinfo** classes:

```
from datetime import tzinfo, timedelta, datetime

ZERO = timedelta(0)
HOUR = timedelta(hours=1)
SECOND = timedelta(seconds=1)

# A class capturing the platform's idea of local time.
# (May result in wrong values on historical times in
#  timezones where UTC offset and/or the DST rules had
#  changed in the past.)
import time as _time

STDOFFSET = timedelta(seconds = -_time.timezone)
if _time.daylight:
```

```
    DSTOFFSET = timedelta(seconds = -_time.altzone)
else:
    DSTOFFSET = STDOFFSET

DSTDIFF = DSTOFFSET - STDOFFSET

class LocalTimezone(tzinfo):

    def fromutc(self, dt):
        assert dt.tzinfo is self
        stamp = (dt - datetime(1970, 1, 1, tzinfo=self))
        args = _time.localtime(stamp)[:6]
        dst_diff = DSTDIFF // SECOND
        # Detect fold
        fold = (args == _time.localtime(stamp - dst_diff
        return datetime(*args, microsecond=dt.microsecon
                        tzinfo=self, fold=fold)

            return dst_time

Eastern  = USTimeZone(-5, "Eastern",  "EST", "EDT")
Central  = USTimeZone(-6, "Central",  "CST", "CDT")
Mountain = USTimeZone(-7, "Mountain", "MST", "MDT")
Pacific  = USTimeZone(-8, "Pacific",  "PST", "PDT")
```

Note that there are unavoidable subtleties twice per year in a **`tzinfo`** subclass accounting for both standard and daylight time, at the DST transition points. For concreteness, consider US Eastern (UTC -0500), where EDT begins the minute after 1:59 (EST) on the second Sunday in March, and ends the minute after 1:59 (EDT) on the first Sunday in November:

```
  UTC   3:MM  4:MM  5:MM  6:MM  7:MM  8:MM
  EST  22:MM 23:MM  0:MM  1:MM  2:MM  3:MM
  EDT  23:MM  0:MM  1:MM  2:MM  3:MM  4:MM

start  22:MM 23:MM  0:MM  1:MM  3:MM  4:MM

  end  23:MM  0:MM  1:MM  1:MM  2:MM  3:MM
```

When DST starts (the “start” line), the local wall clock leaps from 1:59 to 3:00. A wall time of the form 2:MM doesn’t really make sense on that day, so `astimezone(Eastern)` won’t deliver a result with `hour == 2` on the day DST begins. For example, at the Spring forward transition of 2016, we get:

```
>>> from datetime import datetime, timezone
>>> from tzinfo_examples import HOUR, Eastern
>>> u0 = datetime(2016, 3, 13, 5, tzinfo=timezone.utc)
>>> for i in range(4):
...     u = u0 + i*HOUR
...     t = u.astimezone(Eastern)
...     print(u.time(), 'UTC =', t.time(), t.tzname())
...
05:00:00 UTC = 00:00:00 EST
```

```
06:00:00 UTC = 01:00:00 EST
07:00:00 UTC = 03:00:00 EDT
08:00:00 UTC = 04:00:00 EDT
```

When DST ends (the “end” line), there’s a potentially worse problem: there’s an hour that can’t be spelled unambiguously in local wall time: the last hour of daylight time. In Eastern, that’s times of the form 5:MM UTC on the day daylight time ends. The local wall clock leaps from 1:59 (daylight time) back to 1:00 (standard time) again. Local times of the form 1:MM are ambiguous. **`astimezone()`** mimics the local clock’s behavior by mapping two adjacent UTC hours into the same local hour then. In the Eastern example, UTC times of the form 5:MM and 6:MM both map to 1:MM when converted to Eastern, but earlier times have the **`fold`** attribute set to 0 and the later times have it set to 1. For example, at the Fall back transition of 2016, we get:

```
>>> u0 = datetime(2016, 11, 6, 4, tzinfo=timezone.utc)
>>> for i in range(4):
...     u = u0 + i*HOUR
...     t = u.astimezone(Eastern)
...     print(u.time(), 'UTC =', t.time(), t.tzname(), t
...
04:00:00 UTC = 00:00:00 EDT 0
05:00:00 UTC = 01:00:00 EDT 0
06:00:00 UTC = 01:00:00 EST 1
07:00:00 UTC = 02:00:00 EST 0
```

Note that the **`datetime`** instances that differ only by the value of the **`fold`** attribute are considered equal in comparisons.

Applications that can’t bear wall-time ambiguities should explicitly check the value of the **`fold`** attribute or avoid using hybrid **`tzinfo`** subclasses; there are no ambiguities when using **`timezone`**, or any other fixed-offset **`tzinfo`** subclass (such as a class representing only EST (fixed offset -5 hours), or only EDT (fixed offset -4 hours)).

See also

zoneinfo

The **datetime** module has a basic **timezone** class (for handling arbitrary fixed offsets from UTC) and its **timezone.utc** attribute (a UTC timezone instance).

`zoneinfo` brings the *IANA timezone database* (also known as the Olson database) to Python, and its usage is recommended.

IANA timezone database **[https://www.iana.org/time-zones]**
The Time Zone Database (often called tz, tzdata or zoneinfo) contains code and data that represent the history of local time for many representative locations around the globe. It is updated periodically to reflect changes made by political bodies to time zone boundaries, UTC offsets, and daylight-saving rules.

timezone Objects

The **timezone** class is a subclass of **tzinfo**, each instance of which represents a timezone defined by a fixed offset from UTC.

Objects of this class cannot be used to represent timezone information in the locations where different offsets are used in different days of the year or where historical changes have been made to civil time.

class datetime.timezone(*offset*, *name*=*None*)

The *offset* argument must be specified as a **timedelta** object representing the difference between the local time and UTC. It must be strictly between `-timedelta(hours=24)` and `timedelta(hours=24)`, otherwise **ValueError** is raised.

The *name* argument is optional. If specified it must be a string that will be used as the value returned by the

datetime.tzname() method.

New in version 3.2.

Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

timezone.utcoffset(*dt*)

Return the fixed value specified when the **timezone** instance is constructed.

The *dt* argument is ignored. The return value is a **timedelta** instance equal to the difference between the local time and UTC.

Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

timezone.tzname(*dt*)

Return the fixed value specified when the **timezone** instance is constructed.

If *name* is not provided in the constructor, the name returned by `tzname(dt)` is generated from the value of the `offset` as follows. If *offset* is `timedelta(0)`, the name is "UTC", otherwise it is a string in the format `UTC±HH:MM`, where ± is the sign of `offset`, HH and MM are two digits of `offset.hours` and `offset.minutes` respectively.

Changed in version 3.6: Name generated from `offset=timedelta(0)` is now plain `'UTC'`, not `'UTC+00:00'`.

timezone.dst(*dt*)

Always returns `None`.

timezone.fromutc(*dt*)

Return `dt + offset`. The *dt* argument must be an aware **datetime** instance, with `tzinfo` set to `self`.

Class attributes:

timezone.utc

The UTC timezone, `timezone(timedelta(0))`.

`strftime()` and `strptime()` Behavior

`date`, `datetime`, and `time` objects all support a `strftime(format)` method, to create a string representing the time under the control of an explicit format string.

Conversely, the `datetime.strptime()` class method creates a `datetime` object from a string representing a date and time and a corresponding format string.

The table below provides a high-level comparison of `strftime()` versus `strptime()`:

`strftime`	`strptime`
Usage: Convert object to a string according to a given format	Usage: Parse a string into a `datetime` object given a corresponding format
Type of method: Instance method	Type of method: Class method
Method of: `date`; `datetime`; `time`	Method of: `datetime`
Signature: `strftime(format)`	Signature: `strptime(date_string, format)`

`strftime()` and `strptime()` Format Codes

The following is a list of all the format codes that the 1989 C standard requires, and these work on all platforms with a standard C implementation.

Directive	Meaning	Notes
`%a`	Weekday as locale's abbreviated name.	(1)
`%A`	Weekday as locale's full name.	(1)
`%w`	Weekday as a decimal number, where 0 is Sunday and 6 is Saturday.	
`%d`	Day of the month as a zero-padded decimal number.	
`%b`	Month as locale's abbreviated name.	(1)
`%B`	Month as locale's full name.	(1)

Sat, Sa (en_US);
So, Mo, …, Sa (de_DE)
Saturday, Sunday (en_US);
Sonntag, Montag, …, Samstag (de_DE)
0, 1, …, 6
01, 02, …, 31
Jan, Feb, …, Dec (en_US);

	Jan, Feb, …, Dez (de_DE)
	Month as locale's full name. December (en_US); Januar, Februar, …, Dezember (de_DE)
	Month as a zero-padded decimal number.
	Day of the month as a zero-padded decimal number.
	Year without century as a zero-padded decimal number.
	Year with century as a decimal number.
	Hour (24-hour clock) as a zero-padded decimal number.
	Hour (12-hour clock) as a zero-padded decimal number.
	Locale's equivalent of either AM or PM.
	am, pm (de_DE)
	Minute as a zero-padded decimal number.
	Second as a zero-padded decimal number.
	Microsecond as a decimal number, zero-padded to 6 digits.
	UTC offset in the form ±HHMM[SS[.ffffff]] (empty string if the object is naive).
	Time zone name (empty string if the object is naive).
	Day of the year as a zero-padded decimal number.
	Week number of the year (Sunday as the first day of the week) as a zero-padded decimal number. All days in a new year preceding the first Sunday are considered to be in week 0.
	Week number of the year (Monday as the first day of the week) as a zero-padded decimal number. All days in a new year preceding the first Monday are considered to be in week 0.
	Locale's appropriate date and time representation. Di 16 Aug 21:30:00 1988 (de_DE)
	Locale's appropriate date representation. 08/16/1988 (en_US); 16.08.1988 (de_DE)
	Locale's appropriate time representation. 21:30:00 (de_DE)
	A literal '%' character.

Several additional directives not required by the C89 standard are included for convenience. These parameters all correspond to ISO 8601 date values.

	ISO 8601 year with century representing the year that contains the greater part of the ISO week (%V).
	ISO 8601 weekday as a decimal number where 1 is Monday.

%G	ISO 8601 year with century representing the year that contains the greatest part of the ISO week (see %V).
%u	ISO 8601 weekday as a decimal number where 1 is Monday.
%V	ISO 8601 week as a decimal number with Monday as the first day of the week. Week 01 is the week containing Jan 4.

These may not be available on all platforms when used with the **`strftime()`** method. The ISO 8601 year and ISO 8601 week directives are not interchangeable with the year and week number directives above. Calling **`strptime()`** with incomplete or ambiguous ISO 8601 directives will raise a **`ValueError`**.

The full set of format codes supported varies across platforms, because Python calls the platform C library's **`strftime()`** function, and platform variations are common. To see the full set of format codes supported on your platform, consult the *strftime(3)* documentation. There are also differences between platforms in handling of unsupported format specifiers.

New in version 3.6: `%G`, `%u` and `%V` were added.

Technical Detail

Broadly speaking, `d.strftime(fmt)` acts like the **`time`** module's `time.strftime(fmt, d.timetuple())` although not all objects support a **`timetuple()`** method.

For the **`datetime.strptime()`** class method, the default value is `1900-01-01T00:00:00.000`: any components not specified in the format string will be pulled from the default value. 4

Using `datetime.strptime(date_string, format)` is equivalent to:

```
datetime(*(time.strptime(date_string, format)[0:6]))
```

except when the format includes sub-second components or timezone offset information, which are supported in `datetime.strptime` but are discarded by `time.strptime`.

For **`time`** objects, the format codes for year, month, and day should not be used, as **`time`** objects have no such values. If they're used anyway, `1900` is substituted for the year, and `1` for the month and day.

For **date** objects, the format codes for hours, minutes, seconds, and microseconds should not be used, as **date** objects have no such values. If they're used anyway, `0` is substituted for them.

For the same reason, handling of format strings containing Unicode code points that can't be represented in the charset of the current locale is also platform-dependent. On some platforms such code points are preserved intact in the output, while on others `strftime` may raise **UnicodeError** or return an empty string instead.

Notes:

1. Because the format depends on the current locale, care should be taken when making assumptions about the output value. Field orderings will vary (for example, "month/day/year" versus "day/month/year"), and the output may contain Unicode characters encoded using the locale's default encoding (for example, if the current locale is `ja_JP`, the default encoding could be any one of `eucJP`, `SJIS`, or `utf-8`; use **locale.getlocale()** to determine the current locale's encoding).

2. The **strptime()** method can parse years in the full [1, 9999] range, but years < 1000 must be zero-filled to 4-digit width.

   Changed in version 3.2: In previous versions, **strftime()** method was restricted to years >= 1900.

   Changed in version 3.3: In version 3.2, **strftime()** method was restricted to years >= 1000.

3. When used with the **strptime()** method, the `%p` directive only affects the output hour field if the `%I` directive is used to parse the hour.

4. Unlike the **time** module, the **datetime** module does not support leap seconds.

5. When used with the **strptime()** method, the `%f` directive

accepts from one to six digits and zero pads on the right. `%f` is an extension to the set of format characters in the C standard (but implemented separately in datetime objects, and therefore always available).

6. For a naive object, the `%z` and `%Z` format codes are replaced by empty strings.

   For an aware object:

   `%z`

   > **`utcoffset()`** is transformed into a string of the form `±HHMM[SS[.ffffff]]`, where `HH` is a 2-digit string giving the number of UTC offset hours, `MM` is a 2-digit string giving the number of UTC offset minutes, `SS` is a 2-digit string giving the number of UTC offset seconds and `ffffff` is a 6-digit string giving the number of UTC offset microseconds. The `ffffff` part is omitted when the offset is a whole number of seconds and both the `ffffff` and the `SS` part is omitted when the offset is a whole number of minutes. For example, if **`utcoffset()`** returns `timedelta(hours=-3, minutes=-30)`, `%z` is replaced with the string `'-0330'`.

   Changed in version 3.7: The UTC offset is not restricted to a whole number of minutes.

   Changed in version 3.7: When the `%z` directive is provided to the **`strptime()`** method, the UTC offsets can have a colon as a separator between hours, minutes and seconds. For example, `'+01:00:00'` will be parsed as an offset of one hour. In addition, providing `'Z'` is identical to `'+00:00'`.

   `%Z`

   > In **`strftime()`**, `%Z` is replaced by an empty string if **`tzname()`** returns `None`; otherwise `%Z` is replaced by the returned value, which must be a string.
   >
   > **`strptime()`** only accepts certain values for `%Z`:

1. any value in `time.tzname` for your machine's locale
2. the hard-coded values `UTC` and `GMT`

So someone living in Japan may have `JST`, `UTC`, and `GMT` as valid values, but probably not `EST`. It will raise `ValueError` for invalid values.

Changed in version 3.2: When the `%z` directive is provided to the **`strptime()`** method, an aware **`datetime`** object will be produced. The `tzinfo` of the result will be set to a **`timezone`** instance.

7. When used with the **`strptime()`** method, `%U` and `%W` are only used in calculations when the day of the week and the calendar year (`%Y`) are specified.

8. Similar to `%U` and `%W`, `%V` is only used in calculations when the day of the week and the ISO year (`%G`) are specified in a **`strptime()`** format string. Also note that `%G` and `%Y` are not interchangeable.

9. When used with the **`strptime()`** method, the leading zero is optional for formats `%d`, `%m`, `%H`, `%I`, `%M`, `%S`, `%j`, `%U`, `%W`, and `%V`. Format `%y` does require a leading zero.

See R. H. van Gent's guide to the mathematics of the ISO 8601 calendar [https://web.archive.org/web/20220531051136/https://webspace.science.uu.nl/~gent0113/calendar/isocalendar.htm] for a good explanation.

4

Passing `datetime.strptime('Feb 29', '%b %d')` will fail since `1900` is not a leap year.

`zoneinfo` — IANA time zone support

New in version 3.9.

Source code: Lib/zoneinfo [https://github.com/python/cpython/tree/3.11/Lib/zoneinfo]

The `zoneinfo` module provides a concrete time zone implementation to support the IANA time zone database as originally specified in **PEP 615** [https://peps.python.org/pep-0615/]. By default, `zoneinfo` uses the system's time zone data if available; if no system time zone data is available, the library will fall back to using the first-party tzdata [https://pypi.org/project/tzdata/] package available on PyPI.

See also

Module: `datetime`
: Provides the `time` and `datetime` types with which the `ZoneInfo` class is designed to be used.

Package tzdata **[https://pypi.org/project/tzdata/]**
: First-party package maintained by the CPython core developers to supply time zone data via PyPI.

Availability: not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See WebAssembly platforms for more information.

Using `ZoneInfo`

`ZoneInfo` is a concrete implementation of the **`datetime.tzinfo`** abstract base class, and is intended to be attached to `tzinfo`, either via the constructor, the **`datetime.replace`** method or **`datetime.astimezone`**:

```
>>> from zoneinfo import ZoneInfo
>>> from datetime import datetime, timedelta

>>> dt = datetime(2020, 10, 31, 12, tzinfo=ZoneInfo("Ame
>>> print(dt)
2020-10-31 12:00:00-07:00

>>> dt.tzname()
'PDT'
```

Datetimes constructed in this way are compatible with datetime arithmetic and handle daylight saving time transitions with no further intervention:

```
>>> dt_add = dt + timedelta(days=1)

>>> print(dt_add)
2020-11-01 12:00:00-08:00

>>> dt_add.tzname()
'PST'
```

These time zones also support the **`fold`** attribute introduced in **PEP 495** [https://peps.python.org/pep-0495/]. During offset transitions which induce ambiguous times (such as a daylight saving time to standard time transition), the offset from *before* the transition is used when `fold=0`, and the offset *after* the transition is used when `fold=1`, for example:

```
>>> dt = datetime(2020, 11, 1, 1, tzinfo=ZoneInfo("Ameri
>>> print(dt)
2020-11-01 01:00:00-07:00

>>> print(dt.replace(fold=1))
2020-11-01 01:00:00-08:00
```

When converting from another time zone, the fold will be set to the correct value:

```
>>> from datetime import timezone
>>> LOS_ANGELES = ZoneInfo("America/Los_Angeles")
>>> dt_utc = datetime(2020, 11, 1, 8, tzinfo=timezone.ut

>>> # Before the PDT -> PST transition
>>> print(dt_utc.astimezone(LOS_ANGELES))
2020-11-01 01:00:00-07:00

>>> # After the PDT -> PST transition
>>> print((dt_utc + timedelta(hours=1)).astimezone(LOS_A
2020-11-01 01:00:00-08:00
```

Data sources

The `zoneinfo` module does not directly provide time zone data, and instead pulls time zone information from the system time zone database or the first-party PyPI package tzdata [https://pypi.org/project/tzdata/], if available. Some systems, including notably Windows systems, do not have an IANA database available, and so for projects targeting cross-platform compatibility that require time zone data, it is recommended to declare a dependency on tzdata. If neither system data nor tzdata are available, all calls to **`ZoneInfo`** will raise **`ZoneInfoNotFoundError`**.

Configuring the data sources

When `ZoneInfo(key)` is called, the constructor first searches the directories specified in **`TZPATH`** for a file matching `key`, and on failure looks for a match in the tzdata package. This behavior can be configured in three ways:

1. The default **`TZPATH`** when not otherwise specified can be configured at compile time.
2. **`TZPATH`** can be configured using an environment variable.
3. At runtime, the search path can be manipulated using the **`reset_tzpath()`** function.

Compile-time configuration

The default **TZPATH** includes several common deployment locations for the time zone database (except on Windows, where there are no “well-known” locations for time zone data). On POSIX systems, downstream distributors and those building Python from source who know where their system time zone data is deployed may change the default time zone path by specifying the compile-time option `TZPATH` (or, more likely, the **configure flag --with-tzpath**), which should be a string delimited by **os.pathsep**.

On all platforms, the configured value is available as the `TZPATH` key in **sysconfig.get_config_var()**.

Environment configuration

When initializing **TZPATH** (either at import time or whenever **reset_tzpath()** is called with no arguments), the `zoneinfo` module will use the environment variable `PYTHONTZPATH`, if it exists, to set the search path.

PYTHONTZPATH

> This is an **os.pathsep**-separated string containing the time zone search path to use. It must consist of only absolute rather than relative paths. Relative components specified in `PYTHONTZPATH` will not be used, but otherwise the behavior when a relative path is specified is implementation-defined; CPython will raise **InvalidTZPathWarning**, but other implementations are free to silently ignore the erroneous component or raise an exception.

To set the system to ignore the system data and use the tzdata package instead, set `PYTHONTZPATH=""`.

Runtime configuration

The TZ search path can also be configured at runtime using the **reset_tzpath()** function. This is generally not an advisable

operation, though it is reasonable to use it in test functions that require the use of a specific time zone path (or require disabling access to the system time zones).

The `ZoneInfo` class

class zoneinfo.ZoneInfo(*key*)

A concrete **`datetime.tzinfo`** subclass that represents an IANA time zone specified by the string `key`. Calls to the primary constructor will always return objects that compare identically; put another way, barring cache invalidation via **`ZoneInfo.clear_cache()`**, for all values of `key`, the following assertion will always be true:

```
a = ZoneInfo(key)
b = ZoneInfo(key)
assert a is b
```

`key` must be in the form of a relative, normalized POSIX path, with no up-level references. The constructor will raise **`ValueError`** if a non-conforming key is passed.

If no file matching `key` is found, the constructor will raise **`ZoneInfoNotFoundError`**.

The `ZoneInfo` class has two alternate constructors:

classmethod ZoneInfo.from_file(*fobj*, */*, *key=None*)

Constructs a `ZoneInfo` object from a file-like object returning bytes (e.g. a file opened in binary mode or an **`io.BytesIO`** object). Unlike the primary constructor, this always constructs a new object.

The `key` parameter sets the name of the zone for the purposes of **`__str__()`** and **`__repr__()`**.

Objects created via this constructor cannot be pickled (see pickling).

classmethod ZoneInfo.no_cache(*key*)

An alternate constructor that bypasses the constructor's cache. It is identical to the primary constructor, but returns a new object on each call. This is most likely to be useful for testing or demonstration purposes, but it can also be used to create a system with a different cache invalidation strategy.

Objects created via this constructor will also bypass the cache of a deserializing process when unpickled.

Caution

Using this constructor may change the semantics of your datetimes in surprising ways, only use it if you know that you need to.

The following class methods are also available:

classmethod ZoneInfo.clear_cache(**, only_keys=None*)

A method for invalidating the cache on the `ZoneInfo` class. If no arguments are passed, all caches are invalidated and the next call to the primary constructor for each key will return a new instance.

If an iterable of key names is passed to the `only_keys` parameter, only the specified keys will be removed from the cache. Keys passed to `only_keys` but not found in the cache are ignored.

Warning

Invoking this function may change the semantics of datetimes using `ZoneInfo` in surprising ways; this modifies process-wide global state and thus may have wide-ranging effects. Only use it if you know that you need to.

The class has one attribute:

ZoneInfo.key

This is a read-only attribute that returns the value of `key` passed to the constructor, which should be a lookup key in the IANA time zone database (e.g. `America/New_York`, `Europe/Paris` or `Asia/Tokyo`).

For zones constructed from file without specifying a `key` parameter, this will be set to `None`.

Note

Although it is a somewhat common practice to expose these to end users, these values are designed to be primary keys for representing the relevant zones and not necessarily user-facing elements. Projects like CLDR (the Unicode Common Locale Data Repository) can be used to get more user-friendly strings from these keys.

String representations

The string representation returned when calling **`str`** on a **`ZoneInfo`** object defaults to using the **`ZoneInfo.key`** attribute (see the note on usage in the attribute documentation):

```
>>> zone = ZoneInfo("Pacific/Kwajalein")
>>> str(zone)
'Pacific/Kwajalein'

>>> dt = datetime(2020, 4, 1, 3, 15, tzinfo=zone)
>>> f"{dt.isoformat()} [{dt.tzinfo}]"
'2020-04-01T03:15:00+12:00 [Pacific/Kwajalein]'
```

For objects constructed from a file without specifying a `key` parameter, `str` falls back to calling **`repr()`**. `ZoneInfo`'s `repr` is implementation-defined and not necessarily stable between versions, but it is guaranteed not to be a valid `ZoneInfo` key.

Pickle serialization

Rather than serializing all transition data, `ZoneInfo` objects are serialized by key, and `ZoneInfo` objects constructed from files (even those with a value for `key` specified) cannot be pickled.

The behavior of a `ZoneInfo` file depends on how it was constructed:

1. `ZoneInfo(key)`: When constructed with the primary constructor, a `ZoneInfo` object is serialized by key, and when deserialized, the deserializing process uses the primary and thus it is expected that these are expected to be the same object as other references to the same time zone. For example, if `europe_berlin_pkl` is a string containing a pickle constructed from `ZoneInfo("Europe/Berlin")`, one would expect the following behavior:

   ```
   >>> a = ZoneInfo("Europe/Berlin")
   >>> b = pickle.loads(europe_berlin_pkl)
   >>> a is b
   True
   ```

2. `ZoneInfo.no_cache(key)`: When constructed from the cache-bypassing constructor, the `ZoneInfo` object is also serialized by key, but when deserialized, the deserializing process uses the cache bypassing constructor. If `europe_berlin_pkl_nc` is a string containing a pickle constructed from `ZoneInfo.no_cache("Europe/Berlin")`, one would expect the following behavior:

   ```
   >>> a = ZoneInfo("Europe/Berlin")
   >>> b = pickle.loads(europe_berlin_pkl_nc)
   >>> a is b
   False
   ```

3. `ZoneInfo.from_file(fobj, /, key=None)`: When constructed from a file, the `ZoneInfo` object raises an exception on pickling. If an end user wants to pickle a `ZoneInfo` constructed from a file, it is recommended that

they use a wrapper type or a custom serialization function: either serializing by key or storing the contents of the file object and serializing that.

This method of serialization requires that the time zone data for the required key be available on both the serializing and deserializing side, similar to the way that references to classes and functions are expected to exist in both the serializing and deserializing environments. It also means that no guarantees are made about the consistency of results when unpickling a `ZoneInfo` pickled in an environment with a different version of the time zone data.

Functions

zoneinfo.available_timezones()

Get a set containing all the valid keys for IANA time zones available anywhere on the time zone path. This is recalculated on every call to the function.

This function only includes canonical zone names and does not include "special" zones such as those under the `posix/` and `right/` directories, or the `posixrules` zone.

Caution

This function may open a large number of files, as the best way to determine if a file on the time zone path is a valid time zone is to read the "magic string" at the beginning.

Note

These values are not designed to be exposed to end-users; for user facing elements, applications should use something like CLDR (the Unicode Common Locale Data Repository) to get more user-friendly strings. See also the cautionary note on **`ZoneInfo.key`**.

zoneinfo.reset_tzpath(*to=None*)

Sets or resets the time zone search path (**`TZPATH`**) for the module. When called with no arguments, **`TZPATH`** is set to the default value.

Calling `reset_tzpath` will not invalidate the **`ZoneInfo`** cache, and so calls to the primary `ZoneInfo` constructor will only use the new `TZPATH` in the case of a cache miss.

The `to` parameter must be a sequence of strings or **`os.PathLike`** and not a string, all of which must be absolute paths. **`ValueError`** will be raised if something other than an absolute path is passed.

Globals

zoneinfo.TZPATH

A read-only sequence representing the time zone search path – when constructing a `ZoneInfo` from a key, the key is joined to each entry in the `TZPATH`, and the first file found is used.

`TZPATH` may contain only absolute paths, never relative paths, regardless of how it is configured.

The object that `zoneinfo.TZPATH` points to may change in response to a call to **`reset_tzpath()`**, so it is recommended to use `zoneinfo.TZPATH` rather than importing `TZPATH` from `zoneinfo` or assigning a long-lived variable to `zoneinfo.TZPATH`.

For more information on configuring the time zone search path, see Configuring the data sources.

Exceptions and warnings

exception zoneinfo.ZoneInfoNotFoundError

Raised when construction of a **`ZoneInfo`** object fails because the specified key could not be found on the system. This is a subclass of **`KeyError`**.

exception zoneinfo.InvalidTZPathWarning

Raised when **PYTHONTZPATH** contains an invalid component that will be filtered out, such as a relative path.

`calendar` — General calendar-related functions

Source code: Lib/calendar.py [https://github.com/python/cpython/tree/3.11/Lib/calendar.py]

This module allows you to output calendars like the Unix **cal** program, and provides additional useful functions related to the calendar. By default, these calendars have Monday as the first day of the week, and Sunday as the last (the European convention). Use `setfirstweekday()` to set the first day of the week to Sunday (6) or to any other weekday. Parameters that specify dates are given as integers. For related functionality, see also the `datetime` and `time` modules.

The functions and classes defined in this module use an idealized calendar, the current Gregorian calendar extended indefinitely in both directions. This matches the definition of the "proleptic Gregorian" calendar in Dershowitz and Reingold's book "Calendrical Calculations", where it's the base calendar for all computations. Zero and negative years are interpreted as prescribed by the ISO 8601 standard. Year 0 is 1 BC, year -1 is 2 BC, and so on.

class calendar.Calendar(*firstweekday=0*)

Creates a `Calendar` object. *firstweekday* is an integer specifying the first day of the week. `MONDAY` is `0` (the default), `SUNDAY` is `6`.

A `Calendar` object provides several methods that can be used for preparing the calendar data for formatting. This class doesn't do any formatting itself. This is the job of subclasses.

`Calendar` instances have the following methods:

iterweekdays()

Return an iterator for the week day numbers that will be used for one week. The first value from the iterator will be the same as the value of the **`firstweekday`** property.

itermonthdates(*year*, *month*)

Return an iterator for the month *month* (1–12) in the year *year*. This iterator will return all days (as **`datetime.date`** objects) for the month and all days before the start of the month or after the end of the month that are required to get a complete week.

itermonthdays(*year*, *month*)

Return an iterator for the month *month* in the year *year* similar to **`itermonthdates()`**, but not restricted by the **`datetime.date`** range. Days returned will simply be day of the month numbers. For the days outside of the specified month, the day number is `0`.

itermonthdays2(*year*, *month*)

Return an iterator for the month *month* in the year *year* similar to **`itermonthdates()`**, but not restricted by the **`datetime.date`** range. Days returned will be tuples consisting of a day of the month number and a week day number.

itermonthdays3(*year*, *month*)

Return an iterator for the month *month* in the year *year* similar to **`itermonthdates()`**, but not restricted by the **`datetime.date`** range. Days returned will be tuples consisting of a year, a month and a day of the month numbers.

New in version 3.7.

itermonthdays4(*year*, *month*)

Return an iterator for the month *month* in the year *year* similar to `itermonthdates()`, but not restricted by the `datetime.date` range. Days returned will be tuples consisting of a year, a month, a day of the month, and a day of the week numbers.

New in version 3.7.

monthdatescalendar(*year*, *month*)

Return a list of the weeks in the month *month* of the *year* as full weeks. Weeks are lists of seven `datetime.date` objects.

monthdays2calendar(*year*, *month*)

Return a list of the weeks in the month *month* of the *year* as full weeks. Weeks are lists of seven tuples of day numbers and weekday numbers.

monthdayscalendar(*year*, *month*)

Return a list of the weeks in the month *month* of the *year* as full weeks. Weeks are lists of seven day numbers.

yeardatescalendar(*year*, *width*=*3*)

Return the data for the specified year ready for formatting. The return value is a list of month rows. Each month row contains up to *width* months (defaulting to 3). Each month contains between 4 and 6 weeks and each week contains 1–7 days. Days are `datetime.date` objects.

yeardays2calendar(*year*, *width*=*3*)

Return the data for the specified year ready for formatting (similar to `yeardatescalendar()`). Entries in the week lists are tuples of day numbers and weekday numbers. Day numbers outside this month are zero.

yeardayscalendar(*year*, *width*=*3*)

Return the data for the specified year ready for formatting (similar to **yeardatescalendar()**). Entries in the week lists are day numbers. Day numbers outside this month are zero.

class calendar.TextCalendar(*firstweekday*=*0*)

This class can be used to generate plain text calendars.

TextCalendar instances have the following methods:

formatmonth(*theyear*, *themonth*, *w*=*0*, *l*=*0*)

Return a month's calendar in a multi-line string. If *w* is provided, it specifies the width of the date columns, which are centered. If *l* is given, it specifies the number of lines that each week will use. Depends on the first weekday as specified in the constructor or set by the **setfirstweekday()** method.

prmonth(*theyear*, *themonth*, *w*=*0*, *l*=*0*)

Print a month's calendar as returned by **formatmonth()**.

formatyear(*theyear*, *w*=*2*, *l*=*1*, *c*=*6*, *m*=*3*)

Return a *m*-column calendar for an entire year as a multi-line string. Optional parameters *w*, *l*, and *c* are for date column width, lines per week, and number of spaces between month columns, respectively. Depends on the first weekday as specified in the constructor or set by the **setfirstweekday()** method. The earliest year for which a calendar can be generated is platform-dependent.

pryear(*theyear*, *w*=*2*, *l*=*1*, *c*=*6*, *m*=*3*)

Print the calendar for an entire year as returned by **formatyear()**.

class calendar.HTMLCalendar(*firstweekday=0*)

This class can be used to generate HTML calendars.

HTMLCalendar instances have the following methods:

formatmonth(*theyear*, *themonth*, *withyear=True*)

Return a month's calendar as an HTML table. If *withyear* is true the year will be included in the header, otherwise just the month name will be used.

formatyear(*theyear*, *width=3*)

Return a year's calendar as an HTML table. *width* (defaulting to 3) specifies the number of months per row.

formatyearpage(*theyear*, *width=3*, *css='calendar.css'*, *encoding=None*)

Return a year's calendar as a complete HTML page. *width* (defaulting to 3) specifies the number of months per row. *css* is the name for the cascading style sheet to be used. **None** can be passed if no style sheet should be used. *encoding* specifies the encoding to be used for the output (defaulting to the system default encoding).

HTMLCalendar has the following attributes you can override to customize the CSS classes used by the calendar:

cssclasses

A list of CSS classes used for each weekday. The default class list is:

```
cssclasses = ["mon", "tue", "wed", "thu", "fri"
```

more styles can be added for each day:

```
cssclasses = ["mon text-bold", "tue", "wed", "t
```

Note that the length of this list must be seven items.

cssclass_noday

The CSS class for a weekday occurring in the previous or coming month.

New in version 3.7.

cssclasses_weekday_head

A list of CSS classes used for weekday names in the header row. The default is the same as **cssclasses**.

New in version 3.7.

cssclass_month_head

The month's head CSS class (used by **formatmonthname()**). The default value is `"month"`.

New in version 3.7.

cssclass_month

The CSS class for the whole month's table (used by **formatmonth()**). The default value is `"month"`.

New in version 3.7.

cssclass_year

The CSS class for the whole year's table of tables (used by **formatyear()**). The default value is `"year"`.

New in version 3.7.

cssclass_year_head

The CSS class for the table head for the whole year (used by **formatyear()**). The default value is `"year"`.

New in version 3.7.

Note that although the naming for the above described class

attributes is singular (e.g. `cssclass_month` `cssclass_noday`), one can replace the single CSS class with a space separated list of CSS classes, for example:

```
"text-bold text-red"
```

Here is an example how **`HTMLCalendar`** can be customized:

```
class CustomHTMLCal(calendar.HTMLCalendar):
    cssclasses = [style + " text-nowrap" for style
                  calendar.HTMLCalendar.cssclasses]
    cssclass_month_head = "text-center month-head"
    cssclass_month = "text-center month"
    cssclass_year = "text-italic lead"
```

class calendar.LocaleTextCalendar(*firstweekday=0*, *locale=None*)

This subclass of **`TextCalendar`** can be passed a locale name in the constructor and will return month and weekday names in the specified locale.

class calendar.LocaleHTMLCalendar(*firstweekday=0*, *locale=None*)

This subclass of **`HTMLCalendar`** can be passed a locale name in the constructor and will return month and weekday names in the specified locale.

Note

The constructor, **`formatweekday()`** and **`formatmonthname()`** methods of these two classes temporarily change the `LC_TIME` locale to the given *locale*. Because the current locale is a process-wide setting, they are not thread-safe.

For simple text calendars this module provides the following functions.

calendar.setfirstweekday(*weekday*)

Sets the weekday (`0` is Monday, `6` is Sunday) to start each week. The values **`MONDAY`**, **`TUESDAY`**, **`WEDNESDAY`**,

THURSDAY, **FRIDAY**, **SATURDAY**, and **SUNDAY** are provided for convenience. For example, to set the first weekday to Sunday:

```
import calendar
calendar.setfirstweekday(calendar.SUNDAY)
```

calendar.firstweekday()

Returns the current setting for the weekday to start each week.

calendar.isleap(*year*)

Returns **True** if *year* is a leap year, otherwise **False**.

calendar.leapdays(*y1*, *y2*)

Returns the number of leap years in the range from *y1* to *y2* (exclusive), where *y1* and *y2* are years.

This function works for ranges spanning a century change.

calendar.weekday(*year*, *month*, *day*)

Returns the day of the week (`0` is Monday) for *year* (`1970`–…), *month* (`1`–`12`), *day* (`1`–`31`).

calendar.weekheader(*n*)

Return a header containing abbreviated weekday names. *n* specifies the width in characters for one weekday.

calendar.monthrange(*year*, *month*)

Returns weekday of first day of the month and number of days in month, for the specified *year* and *month*.

calendar.monthcalendar(*year*, *month*)

Returns a matrix representing a month's calendar. Each row represents a week; days outside of the month are represented by zeros. Each week begins with Monday unless set by

setfirstweekday().

calendar.prmonth(*theyear*, *themonth*, *w*=*0*, *l*=*0*)

Prints a month's calendar as returned by **month()**.

calendar.month(*theyear*, *themonth*, *w*=*0*, *l*=*0*)

Returns a month's calendar in a multi-line string using the **formatmonth()** of the **TextCalendar** class.

calendar.prcal(*year*, *w*=*0*, *l*=*0*, *c*=*6*, *m*=*3*)

Prints the calendar for an entire year as returned by **calendar()**.

calendar.calendar(*year*, *w*=*2*, *l*=*1*, *c*=*6*, *m*=*3*)

Returns a 3-column calendar for an entire year as a multi-line string using the **formatyear()** of the **TextCalendar** class.

calendar.timegm(*tuple*)

An unrelated but handy function that takes a time tuple such as returned by the **gmtime()** function in the **time** module, and returns the corresponding Unix timestamp value, assuming an epoch of 1970, and the POSIX encoding. In fact, **time.gmtime()** and **timegm()** are each others' inverse.

The **calendar** module exports the following data attributes:

calendar.day_name

An array that represents the days of the week in the current locale.

calendar.day_abbr

An array that represents the abbreviated days of the week in the current locale.

calendar.month_name

An array that represents the months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_name[0]` is the empty string.

calendar.month_abbr

An array that represents the abbreviated months of the year in the current locale. This follows normal convention of January being month number 1, so it has a length of 13 and `month_abbr[0]` is the empty string.

calendar.MONDAY
calendar.TUESDAY
calendar.WEDNESDAY
calendar.THURSDAY
calendar.FRIDAY
calendar.SATURDAY
calendar.SUNDAY

Aliases for day numbers, where `MONDAY` is `0` and `SUNDAY` is `6`.

See also

Module `datetime`

Object-oriented interface to dates and times with similar functionality to the `time` module.

Module `time`

Low-level time related functions.

`collections` — Container datatypes

Source code: Lib/collections/__init__.py [https://github.com/python/cpython/tree/3.11/Lib/collections/__init__.py]

This module implements specialized container datatypes providing alternatives to Python's general purpose built-in containers, `dict`, `list`, `set`, and `tuple`.

namedtuple()	factory function for creating tuple subclasses with named fields
deque	list-like container with fast appends and pops on either end
ChainMap	dict-like class for creating a single view of multiple mappings
Counter	dict subclass for counting hashable objects
OrderedDict	dict subclass that remembers the order entries were added
defaultdict	dict subclass that calls a factory function to supply missing values
UserDict	wrapper around dictionary objects for easier dict subclassing
UserList	wrapper around list objects for easier list subclassing
UserString	wrapper around string objects for easier string subclassing

`ChainMap` objects

New in version 3.3.

A `ChainMap` class is provided for quickly linking a number of mappings so they can be treated as a single unit. It is often much faster than creating a new dictionary and running multiple `update()` calls.

The class can be used to simulate nested scopes and is useful in templating.

class collections.ChainMap(**maps*)

A `ChainMap` groups multiple dicts or other mappings

together to create a single, updateable view. If no *maps* are specified, a single empty dictionary is provided so that a new chain always has at least one mapping.

The underlying mappings are stored in a list. That list is public and can be accessed or updated using the *maps* attribute. There is no other state.

Lookups search the underlying mappings successively until a key is found. In contrast, writes, updates, and deletions only operate on the first mapping.

A **ChainMap** incorporates the underlying mappings by reference. So, if one of the underlying mappings gets updated, those changes will be reflected in **ChainMap**.

All of the usual dictionary methods are supported. In addition, there is a *maps* attribute, a method for creating new subcontexts, and a property for accessing all but the first mapping:

maps

A user updateable list of mappings. The list is ordered from first-searched to last-searched. It is the only stored state and can be modified to change which mappings are searched. The list should always contain at least one mapping.

new_child(*m=None*, ***kwargs*)

Returns a new **ChainMap** containing a new map followed by all of the maps in the current instance. If `m` is specified, it becomes the new map at the front of the list of mappings; if not specified, an empty dict is used, so that a call to `d.new_child()` is equivalent to: `ChainMap({}, *d.maps)`. If any keyword arguments are specified, they update passed map or new empty dict. This method is used for creating subcontexts that can be updated without altering values in any of the parent mappings.

Changed in version 3.4: The optional `m` parameter was added.

Changed in version 3.10: Keyword arguments support was added.

parents

Property returning a new **`ChainMap`** containing all of the maps in the current instance except the first one. This is useful for skipping the first map in the search. Use cases are similar to those for the **`nonlocal`** keyword used in nested scopes. The use cases also parallel those for the built-in **`super()`** function. A reference to `d.parents` is equivalent to: `ChainMap(*d.maps[1:])`.

Note, the iteration order of a **`ChainMap()`** is determined by scanning the mappings last to first:

```
>>> baseline = {'music': 'bach', 'art': 'rembrandt'
>>> adjustments = {'art': 'van gogh', 'opera': 'car
>>> list(ChainMap(adjustments, baseline))
['music', 'art', 'opera']
```

This gives the same ordering as a series of **`dict.update()`** calls starting with the last mapping:

```
>>> combined = baseline.copy()
>>> combined.update(adjustments)
>>> list(combined)
['music', 'art', 'opera']
```

Changed in version 3.9: Added support for `|` and `|=` operators, specified in **PEP 584** [https://peps.python.org/pep-0584/].

- The MultiContext class [https://github.com/enthought/codetools/

blob/4.0.0/codetools/contexts/multi_context.py] in the Enthought CodeTools package [https://github.com/enthought/codetools] has options to support writing to any mapping in the chain.

- Django's Context class [https://github.com/django/django/blob/main/django/template/context.py] for templating is a read-only chain of mappings. It also features pushing and popping of contexts similar to the `new_child()` method and the `parents` property.
- The Nested Contexts recipe [https://code.activestate.com/recipes/577434/] has options to control whether writes and other mutations apply only to the first mapping or to any mapping in the chain.
- A greatly simplified read-only version of Chainmap [https://code.activestate.com/recipes/305268/].

`ChainMap` Examples and Recipes

This section shows various approaches to working with chained maps.

Example of simulating Python's internal lookup chain:

```
import builtins
pylookup = ChainMap(locals(), globals(), vars(builtins))
```

Example of letting user specified command-line arguments take precedence over environment variables which in turn take precedence over default values:

```
import os, argparse

defaults = {'color': 'red', 'user': 'guest'}

parser = argparse.ArgumentParser()
parser.add_argument('-u', '--user')
parser.add_argument('-c', '--color')
namespace = parser.parse_args()
command_line_args = {k: v for k, v in vars(namespace).it
```

```
combined = ChainMap(command_line_args, os.environ, defau
print(combined['color'])
print(combined['user'])
```

Example patterns for using the **ChainMap** class to simulate nested contexts:

```
c = ChainMap()          # Create root context
d = c.new_child()       # Create nested child context
e = c.new_child()       # Child of c, independent from d
e.maps[0]               # Current context dictionary -- li
e.maps[-1]              # Root context -- like Python's gl
e.parents               # Enclosing context chain -- like

d['x'] = 1              # Set value in current context
d['x']                  # Get first key in the chain of co
del d['x']              # Delete from current context
list(d)                 # All nested values
k in d                  # Check all nested values
len(d)                  # Number of nested values
d.items()               # All nested items
dict(d)                 # Flatten into a regular dictionar
```

The **ChainMap** class only makes updates (writes and deletions) to the first mapping in the chain while lookups will search the full chain. However, if deep writes and deletions are desired, it is easy to make a subclass that updates keys found deeper in the chain:

```
class DeepChainMap(ChainMap):
    'Variant of ChainMap that allows direct updates to i

    def __setitem__(self, key, value):
        for mapping in self.maps:
            if key in mapping:
                mapping[key] = value
                return
        self.maps[0][key] = value

    def __delitem__(self, key):
```

```
        for mapping in self.maps:
            if key in mapping:
                del mapping[key]
                return
        raise KeyError(key)

>>> d = DeepChainMap({'zebra': 'black'}, {'elephant': 'b
>>> d['lion'] = 'orange'         # update an existing ke
>>> d['snake'] = 'red'           # new keys get added to
>>> del d['elephant']            # remove an existing ke
>>> d                            # display result
DeepChainMap({'zebra': 'black', 'snake': 'red'}, {}, {'l
```

`Counter` objects

A counter tool is provided to support convenient and rapid tallies. For example:

```
>>> # Tally occurrences of words in a list
>>> cnt = Counter()
>>> for word in ['red', 'blue', 'red', 'green', 'blue',
...     cnt[word] += 1
>>> cnt
Counter({'blue': 3, 'red': 2, 'green': 1})

>>> # Find the ten most common words in Hamlet
>>> import re
>>> words = re.findall(r'\w+', open('hamlet.txt').read()
>>> Counter(words).most_common(10)
[('the', 1143), ('and', 966), ('to', 762), ('of', 669),
 ('you', 554),  ('a', 546), ('my', 514), ('hamlet', 471)
```

class collections.Counter([*iterable-or-mapping*])

A `Counter` is a `dict` subclass for counting hashable objects. It is a collection where elements are stored as dictionary keys and their counts are stored as dictionary values. Counts are allowed to be any integer value including zero or negative counts. The `Counter` class is similar to bags

or multisets in other languages.

Elements are counted from an *iterable* or initialized from another *mapping* (or counter):

```
>>> c = Counter()                           # a new
>>> c = Counter('gallahad')                 # a new
>>> c = Counter({'red': 4, 'blue': 2})      # a new
>>> c = Counter(cats=4, dogs=8)             # a new
```

Counter objects have a dictionary interface except that they return a zero count for missing items instead of raising a **KeyError**:

```
>>> c = Counter(['eggs', 'ham'])
>>> c['bacon']                              # count
0
```

Setting a count to zero does not remove an element from a counter. Use `del` to remove it entirely:

```
>>> c['sausage'] = 0                        # count
>>> del c['sausage']                        # del a
```

New in version 3.1.

Changed in version 3.7: As a **dict** subclass, **Counter** inherited the capability to remember insertion order. Math operations on *Counter* objects also preserve order. Results are ordered according to when an element is first encountered in the left operand and then by the order encountered in the right operand.

Counter objects support additional methods beyond those available for all dictionaries:

elements()

> Return an iterator over elements repeating each as many times as its count. Elements are returned in the order first encountered. If an element's count is less than one, **elements()** will ignore it.

```
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> sorted(c.elements())
['a', 'a', 'a', 'a', 'b', 'b']
```

most_common([*n*])

Return a list of the *n* most common elements and their counts from the most common to the least. If *n* is omitted or `None`, **`most_common()`** returns *all* elements in the counter. Elements with equal counts are ordered in the order first encountered:

```
>>> Counter('abracadabra').most_common(3)
[('a', 5), ('b', 2), ('r', 2)]
```

subtract([*iterable-or-mapping*])

Elements are subtracted from an *iterable* or from another *mapping* (or counter). Like **`dict.update()`** but subtracts counts instead of replacing them. Both inputs and outputs may be zero or negative.

```
>>> c = Counter(a=4, b=2, c=0, d=-2)
>>> d = Counter(a=1, b=2, c=3, d=4)
>>> c.subtract(d)
>>> c
Counter({'a': 3, 'b': 0, 'c': -3, 'd': -6})
```

New in version 3.2.

total()

Compute the sum of the counts.

```
>>> c = Counter(a=10, b=5, c=0)
>>> c.total()
15
```

New in version 3.10.

The usual dictionary methods are available for **`Counter`**

objects except for two which work differently for counters.

fromkeys(*iterable*)

This class method is not implemented for **Counter** objects.

update([*iterable-or-mapping*])

Elements are counted from an *iterable* or added-in from another *mapping* (or counter). Like **dict.update()** but adds counts instead of replacing them. Also, the *iterable* is expected to be a sequence of elements, not a sequence of `(key, value)` pairs.

Counters support rich comparison operators for equality, subset, and superset relationships: `==`, `!=`, `<`, `<=`, `>`, `>=`. All of those tests treat missing elements as having zero counts so that `Counter(a=1) == Counter(a=1, b=0)` returns true.

New in version 3.10: Rich comparison operations were added.

Changed in version 3.10: In equality tests, missing elements are treated as having zero counts. Formerly, `Counter(a=3)` and `Counter(a=3, b=0)` were considered distinct.

Common patterns for working with **Counter** objects:

```
c.total()                       # total of all counts
c.clear()                       # reset all counts
list(c)                         # list unique elements
set(c)                          # convert to a set
dict(c)                         # convert to a regular d
c.items()                       # convert to a list of (
Counter(dict(list_of_pairs))    # convert from a list of
c.most_common()[:-n-1:-1]       # n least common element
+c                              # remove zero and negati
```

Several mathematical operations are provided for combining **Counter** objects to produce multisets (counters that have counts greater than zero). Addition and subtraction combine counters by

adding or subtracting the counts of corresponding elements. Intersection and union return the minimum and maximum of corresponding counts. Equality and inclusion compare corresponding counts. Each operation can accept inputs with signed counts, but the output will exclude results with counts of zero or less.

```
>>> c = Counter(a=3, b=1)
>>> d = Counter(a=1, b=2)
>>> c + d                       # add two counters toget
Counter({'a': 4, 'b': 3})
>>> c - d                       # subtract (keeping only
Counter({'a': 2})
>>> c & d                       # intersection:  min(c[x
Counter({'a': 1, 'b': 1})
>>> c | d                       # union:  max(c[x], d[x]
Counter({'a': 3, 'b': 2})
>>> c == d                      # equality:  c[x] == d[x
False
>>> c <= d                      # inclusion:  c[x] <= d[
False
```

Unary addition and subtraction are shortcuts for adding an empty counter or subtracting from an empty counter.

```
>>> c = Counter(a=2, b=-4)
>>> +c
Counter({'a': 2})
>>> -c
Counter({'b': 4})
```

New in version 3.3: Added support for unary plus, unary minus, and in-place multiset operations.

Note

Counters were primarily designed to work with positive integers to represent running counts; however, care was taken to not unnecessarily preclude use cases needing other types or negative values. To help with those use cases, this section documents the

minimum range and type restrictions.

- The `Counter` class itself is a dictionary subclass with no restrictions on its keys and values. The values are intended to be numbers representing counts, but you *could* store anything in the value field.
- The `most_common()` method requires only that the values be orderable.
- For in-place operations such as `c[key] += 1`, the value type need only support addition and subtraction. So fractions, floats, and decimals would work and negative values are supported. The same is also true for `update()` and `subtract()` which allow negative and zero values for both inputs and outputs.
- The multiset methods are designed only for use cases with positive values. The inputs may be negative or zero, but only outputs with positive values are created. There are no type restrictions, but the value type needs to support addition, subtraction, and comparison.
- The `elements()` method requires integer counts. It ignores zero and negative counts.

```

`deque` objects

class collections.deque([*iterable*[, *maxlen*]])

Returns a new deque object initialized left-to-right (using `append()`) with data from *iterable*. If *iterable* is not specified, the new deque is empty.

Deques are a generalization of stacks and queues (the name is pronounced “deck” and is short for “double-ended queue”). Deques support thread-safe, memory efficient appends and pops from either side of the deque with approximately the same O(1) performance in either direction.

Though `list` objects support similar operations, they are optimized for fast fixed-length operations and incur O(n) memory movement costs for `pop(0)` and `insert(0, v)` operations which change both the size and position of the underlying data representation.

If *maxlen* is not specified or is `None`, deques may grow to an arbitrary length. Otherwise, the deque is bounded to the specified maximum length. Once a bounded length deque is full, when new items are added, a corresponding number of items are discarded from the opposite end. Bounded length deques provide functionality similar to the `tail` filter in Unix. They are also useful for tracking transactions and other pools of data where only the most recent activity is of interest.

Deque objects support the following methods:

append(*x*)

Add *x* to the right side of the deque.

appendleft(*x*)

Add *x* to the left side of the deque.

clear()

Remove all elements from the deque leaving it with length 0.

copy()

Create a shallow copy of the deque.

New in version 3.5.

count(*x*)

Count the number of deque elements equal to *x*.

New in version 3.2.

extend(*iterable*)

Extend the right side of the deque by appending elements from the iterable argument.

extendleft(*iterable*)

Extend the left side of the deque by appending elements from *iterable*. Note, the series of left appends results in reversing the order of elements in the iterable argument.

index(*x*[, *start*[, *stop*]])

Return the position of *x* in the deque (at or after index *start* and before index *stop*). Returns the first match or raises `ValueError` if not found.

New in version 3.5.

insert(*i*, *x*)

Insert *x* into the deque at position *i*.

If the insertion would cause a bounded deque to grow beyond *maxlen*, an `IndexError` is raised.

New in version 3.5.

pop()

Remove and return an element from the right side of the deque. If no elements are present, raises an **IndexError**.

popleft()

Remove and return an element from the left side of the deque. If no elements are present, raises an **IndexError**.

remove(*value*)

Remove the first occurrence of *value*. If not found, raises a **ValueError**.

reverse()

Reverse the elements of the deque in-place and then return `None`.

New in version 3.2.

rotate(*n=1*)

Rotate the deque *n* steps to the right. If *n* is negative, rotate to the left.

When the deque is not empty, rotating one step to the right is equivalent to `d.appendleft(d.pop())`, and rotating one step to the left is equivalent to `d.append(d.popleft())`.

Deque objects also provide one read-only attribute:

maxlen

Maximum size of a deque or `None` if unbounded.

New in version 3.1.

In addition to the above, deques support iteration, pickling, `len(d)`, `reversed(d)`, `copy.copy(d)`, `copy.deepcopy(d)`, membership testing with the **`in`** operator, and subscript references such as `d[0]` to access the first element. Indexed access is O(1) at both ends but slows to O(n) in the middle. For fast random access, use lists instead.

Starting in version 3.5, deques support `__add__()`, `__mul__()`, and `__imul__()`.

Example:

```
>>> from collections import deque
>>> d = deque('ghi')                 # make a new deque
>>> for elem in d:                   # iterate over the
...     print(elem.upper())
G
H
I

>>> d.append('j')                    # add a new entry t
>>> d.appendleft('f')                # add a new entry t
>>> d                                # show the represen
deque(['f', 'g', 'h', 'i', 'j'])

>>> d.pop()                          # return and remove
'j'
>>> d.popleft()                      # return and remove
'f'
>>> list(d)                          # list the contents
['g', 'h', 'i']
>>> d[0]                             # peek at leftmost
'g'
>>> d[-1]                            # peek at rightmost
'i'

>>> list(reversed(d))                # list the contents
['i', 'h', 'g']
>>> 'h' in d                         # search the deque
```

```
True
>>> d.extend('jkl')                    # add multiple elem
>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])
>>> d.rotate(1)                        # right rotation
>>> d
deque(['l', 'g', 'h', 'i', 'j', 'k'])
>>> d.rotate(-1)                       # left rotation
>>> d
deque(['g', 'h', 'i', 'j', 'k', 'l'])

>>> deque(reversed(d))                 # make a new deque
deque(['l', 'k', 'j', 'i', 'h', 'g'])
>>> d.clear()                          # empty the deque
>>> d.pop()                            # cannot pop from a

>>> d.extendleft('abc')                # extendleft() reve
>>> d
deque(['c', 'b', 'a'])
```

`deque` Recipes

This section shows various approaches to working with deques.

Bounded length deques provide functionality similar to the `tail` filter in Unix:

```
def tail(filename, n=10):
    'Return the last n lines of a file'
    with open(filename) as f:
        return deque(f, n)
```

Another approach to using deques is to maintain a sequence of recently added elements by appending to the right and popping to the left:

```
def moving_average(iterable, n=3):
    # moving_average([40, 30, 50, 46, 39, 44]) --> 40.0
    # https://en.wikipedia.org/wiki/Moving_average
    it = iter(iterable)
    d = deque(itertools.islice(it, n-1))
    d.appendleft(0)
    s = sum(d)
    for elem in it:
        s += elem - d.popleft()
        d.append(elem)
        yield s / n
```

A round-robin scheduler [https://en.wikipedia.org/wiki/Round-robin_scheduling] can be implemented with input iterators stored in a **`deque`**. Values are yielded from the active iterator in position zero. If that iterator is exhausted, it can be removed with **`popleft()`**; otherwise, it can be cycled back to the end with the **`rotate()`** method:

```
def roundrobin(*iterables):
    "roundrobin('ABC', 'D', 'EF') --> A D E B F C"
    iterators = deque(map(iter, iterables))
    while iterators:
        try:
            while True:
                yield next(iterators[0])
                iterators.rotate(-1)
        except StopIteration:
            # Remove an exhausted iterator.
            iterators.popleft()
```

The **`rotate()`** method provides a way to implement **`deque`** slicing and deletion. For example, a pure Python implementation of `del d[n]` relies on the `rotate()` method to position elements to be popped:

```
def delete_nth(d, n):
    d.rotate(-n)
    d.popleft()
    d.rotate(n)
```

To implement **deque** slicing, use a similar approach applying **rotate()** to bring a target element to the left side of the deque. Remove old entries with **popleft()**, add new entries with **extend()**, and then reverse the rotation. With minor variations on that approach, it is easy to implement Forth style stack manipulations such as `dup`, `drop`, `swap`, `over`, `pick`, `rot`, and `roll`.

defaultdict objects

class collections.defaultdict(*default_factory* = *None*, */*[, ...])

Return a new dictionary-like object. **defaultdict** is a subclass of the built-in **dict** class. It overrides one method and adds one writable instance variable. The remaining functionality is the same as for the **dict** class and is not documented here.

The first argument provides the initial value for the **default_factory** attribute; it defaults to `None`. All remaining arguments are treated the same as if they were passed to the **dict** constructor, including keyword arguments.

defaultdict objects support the following method in addition to the standard **dict** operations:

missing(*key*)

If the **default_factory** attribute is `None`, this raises a **KeyError** exception with the *key* as argument.

If **default_factory** is not `None`, it is called without arguments to provide a default value for the given *key*, this value is inserted in the dictionary for the *key*, and returned.

If calling **default_factory** raises an exception this exception is propagated unchanged.

This method is called by the **__getitem__()** method of the **dict** class when the requested key is not found; whatever it returns or raises is then returned or raised by **__getitem__()**.

Note that **__missing__()** is *not* called for any operations besides **__getitem__()**. This means that **get()** will, like normal dictionaries, return `None` as a default rather than using **default_factory**.

defaultdict objects support the following instance variable:

default_factory

This attribute is used by the **__missing__()** method; it is initialized from the first argument to the constructor, if present, or to `None`, if absent.

Changed in version 3.9: Added merge (`|`) and update (`|=`) operators, specified in **PEP 584** [https://peps.python.org/pep-0584/].

defaultdict Examples

Using **list** as the **default_factory**, it is easy to group a sequence of key-value pairs into a dictionary of lists:

```
>>> s = [('yellow', 1), ('blue', 2), ('yellow', 3), ('bl
>>> d = defaultdict(list)
>>> for k, v in s:
...     d[k].append(v)
...
>>> sorted(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

When each key is encountered for the first time, it is not already in the mapping; so an entry is automatically created using the **default_factory** function which returns an empty **list**. The **list.append()** operation then attaches the value to the new list. When keys are encountered again, the look-up proceeds normally

(returning the list for that key) and the **`list.append()`** operation adds another value to the list. This technique is simpler and faster than an equivalent technique using **`dict.setdefault()`**:

```
>>> d = {}
>>> for k, v in s:
...     d.setdefault(k, []).append(v)
...
>>> sorted(d.items())
[('blue', [2, 4]), ('red', [1]), ('yellow', [1, 3])]
```

Setting the **`default_factory`** to **`int`** makes the **`defaultdict`** useful for counting (like a bag or multiset in other languages):

```
>>> s = 'mississippi'
>>> d = defaultdict(int)
>>> for k in s:
...     d[k] += 1
...
>>> sorted(d.items())
[('i', 4), ('m', 1), ('p', 2), ('s', 4)]
```

When a letter is first encountered, it is missing from the mapping, so the **`default_factory`** function calls **`int()`** to supply a default count of zero. The increment operation then builds up the count for each letter.

The function **`int()`** which always returns zero is just a special case of constant functions. A faster and more flexible way to create constant functions is to use a lambda function which can supply any constant value (not just zero):

```
>>> def constant_factory(value):
...     return lambda: value
>>> d = defaultdict(constant_factory('<missing>'))
>>> d.update(name='John', action='ran')
>>> '%(name)s %(action)s to %(object)s' % d
'John ran to <missing>'
```

Setting the **`default_factory`** to **`set`** makes the **`defaultdict`**

useful for building a dictionary of sets:

```
>>> s = [('red', 1), ('blue', 2), ('red', 3), ('blue', 4
>>> d = defaultdict(set)
>>> for k, v in s:
...     d[k].add(v)
...
>>> sorted(d.items())
[('blue', {2, 4}), ('red', {1, 3})]
```

`namedtuple()` Factory Function for Tuples with Named Fields

Named tuples assign meaning to each position in a tuple and allow for more readable, self-documenting code. They can be used wherever regular tuples are used, and they add the ability to access fields by name instead of position index.

collections.namedtuple(*typename*, *field_names*, *, *rename*=*False*, *defaults*=*None*, *module*=*None*)

> Returns a new tuple subclass named *typename*. The new subclass is used to create tuple-like objects that have fields accessible by attribute lookup as well as being indexable and iterable. Instances of the subclass also have a helpful docstring (with typename and field_names) and a helpful **`__repr__()`** method which lists the tuple contents in a `name=value` format.
>
> The *field_names* are a sequence of strings such as `['x', 'y']`. Alternatively, *field_names* can be a single string with each fieldname separated by whitespace and/or commas, for example `'x y'` or `'x, y'`.
>
> Any valid Python identifier may be used for a fieldname except for names starting with an underscore. Valid identifiers consist of letters, digits, and underscores but do not start with a digit or underscore and cannot be a **`keyword`** such as *class*, *for*, *return*, *global*, *pass*, or *raise*.

If *rename* is true, invalid fieldnames are automatically replaced with positional names. For example, `['abc', 'def', 'ghi', 'abc']` is converted to `['abc', '_1', 'ghi', '_3']`, eliminating the keyword `def` and the duplicate fieldname `abc`.

defaults can be `None` or an iterable of default values. Since fields with a default value must come after any fields without a default, the *defaults* are applied to the rightmost parameters. For example, if the fieldnames are `['x', 'y', 'z']` and the defaults are `(1, 2)`, then `x` will be a required argument, `y` will default to `1`, and `z` will default to `2`.

If *module* is defined, the `__module__` attribute of the named tuple is set to that value.

Named tuple instances do not have per-instance dictionaries, so they are lightweight and require no more memory than regular tuples.

To support pickling, the named tuple class should be assigned to a variable that matches *typename*.

Changed in version 3.1: Added support for *rename*.

Changed in version 3.6: The *verbose* and *rename* parameters became keyword-only arguments.

Changed in version 3.6: Added the *module* parameter.

Changed in version 3.7: Removed the *verbose* parameter and the **`_source`** attribute.

Changed in version 3.7: Added the *defaults* parameter and the **`_field_defaults`** attribute.

```
>>> # Basic example
>>> Point = namedtuple('Point', ['x', 'y'])
>>> p = Point(11, y=22)     # instantiate with positiona
>>> p[0] + p[1]             # indexable like the plain t
33
```

```
>>> x, y = p                    # unpack like a regular tupl
>>> x, y
(11, 22)
>>> p.x + p.y                   # fields also accessible by
33
>>> p                           # readable __repr__ with a r
Point(x=11, y=22)
```

Named tuples are especially useful for assigning field names to result tuples returned by the **csv** or **sqlite3** modules:

```
EmployeeRecord = namedtuple('EmployeeRecord', 'name, age

import csv
for emp in map(EmployeeRecord._make, csv.reader(open("em
    print(emp.name, emp.title)

import sqlite3
conn = sqlite3.connect('/companydata')
cursor = conn.cursor()
cursor.execute('SELECT name, age, title, department, pay
for emp in map(EmployeeRecord._make, cursor.fetchall()):
    print(emp.name, emp.title)
```

In addition to the methods inherited from tuples, named tuples support three additional methods and two attributes. To prevent conflicts with field names, the method and attribute names start with an underscore.

classmethod somenamedtuple._make(*iterable*)

Class method that makes a new instance from an existing sequence or iterable.

```
>>> t = [11, 22]
>>> Point._make(t)
Point(x=11, y=22)
```

somenamedtuple._asdict()

Return a new **dict** which maps field names to their

corresponding values:

```
>>> p = Point(x=11, y=22)
>>> p._asdict()
{'x': 11, 'y': 22}
```

Changed in version 3.1: Returns an **OrderedDict** instead of a regular **dict**.

Changed in version 3.8: Returns a regular **dict** instead of an **OrderedDict**. As of Python 3.7, regular dicts are guaranteed to be ordered. If the extra features of **OrderedDict** are required, the suggested remediation is to cast the result to the desired type: `OrderedDict(nt._asdict())`.

somenamedtuple._replace(***kwargs*)

Return a new instance of the named tuple replacing specified fields with new values:

```
>>> p = Point(x=11, y=22)
>>> p._replace(x=33)
Point(x=33, y=22)

>>> for partnum, record in inventory.items():
...     inventory[partnum] = record._replace(price=
```

somenamedtuple._fields

Tuple of strings listing the field names. Useful for introspection and for creating new named tuple types from existing named tuples.

```
>>> p._fields            # view the field names
('x', 'y')

>>> Color = namedtuple('Color', 'red green blue')
>>> Pixel = namedtuple('Pixel', Point._fields + Col
>>> Pixel(11, 22, 128, 255, 0)
Pixel(x=11, y=22, red=128, green=255, blue=0)
```

somenamedtuple._field_defaults

Dictionary mapping field names to default values.

```
>>> Account = namedtuple('Account', ['type', 'balan
>>> Account._field_defaults
{'balance': 0}
>>> Account('premium')
Account(type='premium', balance=0)
```

To retrieve a field whose name is stored in a string, use the **`getattr()`** function:

```
>>> getattr(p, 'x')
11
```

To convert a dictionary to a named tuple, use the double-star-operator (as described in Unpacking Argument Lists):

```
>>> d = {'x': 11, 'y': 22}
>>> Point(**d)
Point(x=11, y=22)
```

Since a named tuple is a regular Python class, it is easy to add or change functionality with a subclass. Here is how to add a calculated field and a fixed-width print format:

```
>>> class Point(namedtuple('Point', ['x', 'y'])):
...     __slots__ = ()
...     @property
...     def hypot(self):
...         return (self.x ** 2 + self.y ** 2) ** 0.5
...     def __str__(self):
...         return 'Point: x=%6.3f  y=%6.3f  hypot=%6.3f

>>> for p in Point(3, 4), Point(14, 5/7):
...     print(p)
Point: x= 3.000  y= 4.000  hypot= 5.000
Point: x=14.000  y= 0.714  hypot=14.018
```

The subclass shown above sets `__slots__` to an empty tuple. This

helps keep memory requirements low by preventing the creation of instance dictionaries.

Subclassing is not useful for adding new, stored fields. Instead, simply create a new named tuple type from the **`_fields`** attribute:

```
>>> Point3D = namedtuple('Point3D', Point._fields + ('z'
```

Docstrings can be customized by making direct assignments to the `__doc__` fields:

```
>>> Book = namedtuple('Book', ['id', 'title', 'authors']
>>> Book.__doc__ += ': Hardcover book in active collecti
>>> Book.id.__doc__ = '13-digit ISBN'
>>> Book.title.__doc__ = 'Title of first printing'
>>> Book.authors.__doc__ = 'List of authors sorted by la
```

Changed in version 3.5: Property docstrings became writeable.

See also

- See **`typing.NamedTuple`** for a way to add type hints for named tuples. It also provides an elegant notation using the **`class`** keyword:

  ```
  class Component(NamedTuple):
      part_number: int
      weight: float
      description: Optional[str] = None
  ```

- See **`types.SimpleNamespace()`** for a mutable namespace based on an underlying dictionary instead of a tuple.

- The **`dataclasses`** module provides a decorator and functions for automatically adding generated special methods to user-defined classes.

`OrderedDict` objects

Ordered dictionaries are just like regular dictionaries but have some extra capabilities relating to ordering operations. They have become less important now that the built-in **`dict`** class gained the ability to remember insertion order (this new behavior became guaranteed in Python 3.7).

Some differences from **`dict`** still remain:

- The regular **`dict`** was designed to be very good at mapping operations. Tracking insertion order was secondary.
- The **`OrderedDict`** was designed to be good at reordering operations. Space efficiency, iteration speed, and the performance of update operations were secondary.
- The **`OrderedDict`** algorithm can handle frequent reordering operations better than **`dict`**. As shown in the recipes below, this makes it suitable for implementing various kinds of LRU caches.
- The equality operation for **`OrderedDict`** checks for matching order.

  A regular **`dict`** can emulate the order sensitive equality test with `p == q and all(k1 == k2 for k1, k2 in zip(p, q))`.
- The **`popitem()`** method of **`OrderedDict`** has a different signature. It accepts an optional argument to specify which item is popped.

  A regular **`dict`** can emulate OrderedDict's `od.popitem(last=True)` with `d.popitem()` which is guaranteed to pop the rightmost (last) item.

  A regular **`dict`** can emulate OrderedDict's `od.popitem(last=False)` with `(k := next(iter(d)), d.pop(k))` which will return and remove the leftmost (first) item if it exists.
- **`OrderedDict`** has a **`move_to_end()`** method to efficiently reposition an element to an endpoint.

A regular **dict** can emulate OrderedDict's `od.move_to_end(k, last=True)` with `d[k] = d.pop(k)` which will move the key and its associated value to the rightmost (last) position.

A regular **dict** does not have an efficient equivalent for OrderedDict's `od.move_to_end(k, last=False)` which moves the key and its associated value to the leftmost (first) position.

- Until Python 3.8, **dict** lacked a **__reversed__()** method.

class collections.OrderedDict([*items*])

Return an instance of a **dict** subclass that has methods specialized for rearranging dictionary order.

New in version 3.1.

popitem(*last=True*)

The **popitem()** method for ordered dictionaries returns and removes a (key, value) pair. The pairs are returned in LIFO order if *last* is true or FIFO order if false.

move_to_end(*key*, *last=True*)

Move an existing *key* to either end of an ordered dictionary. The item is moved to the right end if *last* is true (the default) or to the beginning if *last* is false. Raises **KeyError** if the *key* does not exist:

```
>>> d = OrderedDict.fromkeys('abcde')
>>> d.move_to_end('b')
>>> ''.join(d)
'acdeb'
>>> d.move_to_end('b', last=False)
>>> ''.join(d)
'bacde'
```

New in version 3.2.

In addition to the usual mapping methods, ordered dictionaries also support reverse iteration using **`reversed()`**.

Equality tests between **`OrderedDict`** objects are order-sensitive and are implemented as `list(od1.items())==list(od2.items())`. Equality tests between **`OrderedDict`** objects and other **`Mapping`** objects are order-insensitive like regular dictionaries. This allows **`OrderedDict`** objects to be substituted anywhere a regular dictionary is used.

Changed in version 3.5: The items, keys, and values views of **`OrderedDict`** now support reverse iteration using **`reversed()`**.

Changed in version 3.6: With the acceptance of **PEP 468** [https://peps.python.org/pep-0468/], order is retained for keyword arguments passed to the **`OrderedDict`** constructor and its **`update()`** method.

Changed in version 3.9: Added merge (`|`) and update (`|=`) operators, specified in **PEP 584** [https://peps.python.org/pep-0584/].

`OrderedDict` Examples and Recipes

It is straightforward to create an ordered dictionary variant that remembers the order the keys were *last* inserted. If a new entry overwrites an existing entry, the original insertion position is changed and moved to the end:

```
class LastUpdatedOrderedDict(OrderedDict):
    'Store items in the order the keys were last added'

    def __setitem__(self, key, value):
        super().__setitem__(key, value)
        self.move_to_end(key)
```

An **`OrderedDict`** would also be useful for implementing variants of **`functools.lru_cache()`**:

```
from time import time
```

```
class TimeBoundedLRU:
    "LRU Cache that invalidates and refreshes old entrie

    def __init__(self, func, maxsize=128, maxage=30):
        self.cache = OrderedDict()      # { args : (time
        self.func = func
        self.maxsize = maxsize
        self.maxage = maxage

    def __call__(self, *args):
        if args in self.cache:
            self.cache.move_to_end(args)
            timestamp, result = self.cache[args]
            if time() - timestamp <= self.maxage:
                return result
        result = self.func(*args)
        self.cache[args] = time(), result
        if len(self.cache) > self.maxsize:
            self.cache.popitem(0)
        return result

class MultiHitLRUCache:
    """ LRU cache that defers caching a result until
        it has been requested multiple times.

        To avoid flushing the LRU cache with one-time re
        we don't cache until a request has been made mor

    """

    def __init__(self, func, maxsize=128, maxrequests=40
        self.requests = OrderedDict()   # { uncached_key
        self.cache = OrderedDict()      # { cached_key :
        self.func = func
        self.maxrequests = maxrequests  # max number of
        self.maxsize = maxsize          # max number of
        self.cache_after = cache_after

    def __call__(self, *args):
```

```
        if args in self.cache:
            self.cache.move_to_end(args)
            return self.cache[args]
        result = self.func(*args)
        self.requests[args] = self.requests.get(args, 0)
        if self.requests[args] <= self.cache_after:
            self.requests.move_to_end(args)
            if len(self.requests) > self.maxrequests:
                self.requests.popitem(0)
        else:
            self.requests.pop(args, None)
            self.cache[args] = result
            if len(self.cache) > self.maxsize:
                self.cache.popitem(0)
        return result
```

`UserDict` objects

The class, `UserDict` acts as a wrapper around dictionary objects. The need for this class has been partially supplanted by the ability to subclass directly from `dict`; however, this class can be easier to work with because the underlying dictionary is accessible as an attribute.

class collections.UserDict([*initialdata*])

Class that simulates a dictionary. The instance's contents are kept in a regular dictionary, which is accessible via the `data` attribute of `UserDict` instances. If *initialdata* is provided, `data` is initialized with its contents; note that a reference to *initialdata* will not be kept, allowing it to be used for other purposes.

In addition to supporting the methods and operations of mappings, `UserDict` instances provide the following attribute:

data

A real dictionary used to store the contents of the `UserDict` class.

`UserList` objects

This class acts as a wrapper around list objects. It is a useful base class for your own list-like classes which can inherit from them and override existing methods or add new ones. In this way, one can add new behaviors to lists.

The need for this class has been partially supplanted by the ability to subclass directly from `list`; however, this class can be easier to work with because the underlying list is accessible as an attribute.

class collections.UserList([*list*])

Class that simulates a list. The instance's contents are kept in a regular list, which is accessible via the `data` attribute of `UserList` instances. The instance's contents are initially set to a copy of *list*, defaulting to the empty list `[]`. *list* can be any iterable, for example a real Python list or a `UserList` object.

In addition to supporting the methods and operations of mutable sequences, `UserList` instances provide the following attribute:

data

A real `list` object used to store the contents of the `UserList` class.

Subclassing requirements: Subclasses of `UserList` are expected to offer a constructor which can be called with either no arguments or one argument. List operations which return a new sequence attempt to create an instance of the actual implementation class. To do so, it assumes that the constructor can be called with a single parameter, which is a sequence object used as a data source.

If a derived class does not wish to comply with this requirement, all of the special methods supported by this class will need to be overridden; please consult the sources for information about the methods which need to be provided in that case.

`UserString` objects

The class, `UserString` acts as a wrapper around string objects. The need for this class has been partially supplanted by the ability to subclass directly from `str`; however, this class can be easier to work with because the underlying string is accessible as an attribute.

class collections.UserString(*seq*)

Class that simulates a string object. The instance's content is kept in a regular string object, which is accessible via the `data` attribute of `UserString` instances. The instance's contents are initially set to a copy of *seq*. The *seq* argument can be any object which can be converted into a string using the built-in `str()` function.

In addition to supporting the methods and operations of strings, `UserString` instances provide the following attribute:

data

A real `str` object used to store the contents of the `UserString` class.

Changed in version 3.5: New methods `__getnewargs__`, `__rmod__`, `casefold`, `format_map`, `isprintable`, and `maketrans`.

`collections.abc` — Abstract Base Classes for Containers

New in version 3.3: Formerly, this module was part of the `collections` module.

Source code: Lib/_collections_abc.py [https://github.com/python/cpython/tree/3.11/Lib/_collections_abc.py]

This module provides abstract base classes that can be used to test whether a class provides a particular interface; for example, whether it is hashable or whether it is a mapping.

An `issubclass()` or `isinstance()` test for an interface works in one of three ways.

1) A newly written class can inherit directly from one of the abstract base classes. The class must supply the required abstract methods. The remaining mixin methods come from inheritance and can be overridden if desired. Other methods may be added as needed:

```
class C(Sequence):                          # Direct inherit
    def __init__(self): ...                 # Extra method r
    def __getitem__(self, index):  ...      # Required abstr
    def __len__(self):  ...                 # Required abstr
    def count(self, value): ...             # Optionally ove
```

```
>>> issubclass(C, Sequence)
True
>>> isinstance(C(), Sequence)
True
```

2) Existing classes and built-in classes can be registered as “virtual subclasses” of the ABCs. Those classes should define the full API

including all of the abstract methods and all of the mixin methods. This lets users rely on **`issubclass()`** or **`isinstance()`** tests to determine whether the full interface is supported. The exception to this rule is for methods that are automatically inferred from the rest of the API:

```
class D:                                    # No inheritanc
    def __init__(self): ...                 # Extra method
    def __getitem__(self, index):  ...      # Abstract meth
    def __len__(self):  ...                 # Abstract meth
    def count(self, value): ...             # Mixin method
    def index(self, value): ...             # Mixin method

Sequence.register(D)                        # Register inst
```

```
>>> issubclass(D, Sequence)
True
>>> isinstance(D(), Sequence)
True
```

In this example, class **`D`** does not need to define `__contains__`, `__iter__`, and `__reversed__` because the in-operator, the iteration logic, and the **`reversed()`** function automatically fall back to using `__getitem__` and `__len__`.

3) Some simple interfaces are directly recognizable by the presence of the required methods (unless those methods have been set to **`None`**):

```
class E:
    def __iter__(self): ...
    def __next__(next): ...
```

```
>>> issubclass(E, Iterable)
True
>>> isinstance(E(), Iterable)
True
```

Complex interfaces do not support this last technique because an interface is more than just the presence of method names. Interfaces

specify semantics and relationships between methods that cannot be inferred solely from the presence of specific method names. For example, knowing that a class supplies `__getitem__`, `__len__`, and `__iter__` is insufficient for distinguishing a **Sequence** from a **Mapping**.

New in version 3.9: These abstract classes now support `[]`. See Generic Alias Type and **PEP 585** [https://peps.python.org/pep-0585/].

Collections Abstract Base Classes

The collections module offers the following ABCs:

ABC	Inherits from	Abstract Methods	Mixin Methods
Container		`__contains__`	
Hashable		`__hash__`	
Iterable [1] [2]		`__iter__`	
Iterator	Iterable		`__next__`
Reversible [1]	Iterable	`__reversed__`	
Generator [1]	Iterator	`send`, `throw`	`close`, `__iter__`, `__next__`
Sized [1]		`__len__`	
Callable [1]		`__call__`	
Collection	Sized, Iterable, Container	`__contains__`, `__iter__`, `__len__`	
Sequence	Reversible, Collection	`__getitem__`, `__len__`	`__contains__`, `__iter__`, `__reversed__`, `index`, and `count`
MutableSequence	Sequence	`__getitem__`, `__setitem__`, `__delitem__`, `__len__`, `insert`	Inherited Sequence methods and `append`, `reverse`, `extend`, `pop`, `remove`, and `__iadd__`
ByteString	Sequence	`__getitem__`, `__len__`	Inherited Sequence methods
Set	Collection	`__contains__`, `__iter__`, `__len__`	`__le__`, `__lt__`, `__eq__`, `__ne__`, `__gt__`, `__ge__`, `__and__`, `__or__`, `__sub__`, `__xor__`, and `isdisjoint`
MutableSet	Set	`__contains__`, `__iter__`, `__len__`, `add`, `discard`	Inherited Set methods and `clear`, `pop`, `remove`, `__ior__`, `__iand__`, `__ixor__`, and `__isub__`
Mapping	Collection	`__getitem__`, `__iter__`, `__len__`	`__contains__`, `keys`, `items`, `values`, `get`, `__eq__`, and `__ne__`
MutableMapping	Mapping	`__getitem__`, `__setitem__`, `__delitem__`, `__iter__`, `__len__`	Inherited Mapping methods and `pop`, `popitem`, `clear`, `update`, and `setdefault`
MappingView	Sized		`__len__`
ItemsView	MappingView, Set		`__contains__`, `__iter__`
KeysView	MappingView, Set		`__contains__`, `__iter__`
ValuesView	MappingView, Collection		`__contains__`, `__iter__`

Awaitable[1]	__await__
Coroutine[1]	send, throw
AsyncIterable[1]	__aiter__
AsyncIterator[1]	__anext__
AsyncGenerator[1]	asend, athrow

Footnotes

1([1](),[2](),[3](),[4](),[5](),[6](),[7](),[8](),[9](),[10](),[11](),[12](),[13](),[14]())

These ABCs override **`object.__subclasshook__()`** to support testing an interface by verifying the required methods are present and have not been set to **`None`**. This only works for simple interfaces. More complex interfaces require registration or direct subclassing.

2

Checking `isinstance(obj, Iterable)` detects classes that are registered as **`Iterable`** or that have an **`__iter__()`** method, but it does not detect classes that iterate with the **`__getitem__()`** method. The only reliable way to determine whether an object is iterable is to call `iter(obj)`.

Collections Abstract Base Classes – Detailed Descriptions

class collections.abc.Container

ABC for classes that provide the **`__contains__()`** method.

class collections.abc.Hashable

ABC for classes that provide the **`__hash__()`** method.

class collections.abc.Sized

ABC for classes that provide the **`__len__()`** method.

class collections.abc.Callable

ABC for classes that provide the **`__call__()`** method.

class collections.abc.Iterable

ABC for classes that provide the **__iter__()** method.

Checking `isinstance(obj, Iterable)` detects classes that are registered as **Iterable** or that have an **__iter__()** method, but it does not detect classes that iterate with the **__getitem__()** method. The only reliable way to determine whether an object is iterable is to call `iter(obj)`.

class collections.abc.Collection

ABC for sized iterable container classes.

New in version 3.6.

class collections.abc.Iterator

ABC for classes that provide the **__iter__()** and **__next__()** methods. See also the definition of iterator.

class collections.abc.Reversible

ABC for iterable classes that also provide the **__reversed__()** method.

New in version 3.6.

class collections.abc.Generator

ABC for generator classes that implement the protocol defined in **PEP 342** [https://peps.python.org/pep-0342/] that extends iterators with the **send()**, **throw()** and **close()** methods. See also the definition of generator.

New in version 3.5.

class collections.abc.Sequence
class collections.abc.MutableSequence
class collections.abc.ByteString

ABCs for read-only and mutable sequences.

Implementation note: Some of the mixin methods, such as

__iter__(), **__reversed__()** and **index()**, make repeated calls to the underlying **__getitem__()** method. Consequently, if **__getitem__()** is implemented with constant access speed, the mixin methods will have linear performance; however, if the underlying method is linear (as it would be with a linked list), the mixins will have quadratic performance and will likely need to be overridden.

Changed in version 3.5: The index() method added support for *stop* and *start* arguments.

class collections.abc.Set
class collections.abc.MutableSet

ABCs for read-only and mutable sets.

class collections.abc.Mapping
class collections.abc.MutableMapping

ABCs for read-only and mutable mappings.

class collections.abc.MappingView
class collections.abc.ItemsView
class collections.abc.KeysView
class collections.abc.ValuesView

ABCs for mapping, items, keys, and values views.

class collections.abc.Awaitable

ABC for awaitable objects, which can be used in **await** expressions. Custom implementations must provide the **__await__()** method.

Coroutine objects and instances of the **Coroutine** ABC are all instances of this ABC.

Note

In CPython, generator-based coroutines (generators decorated with **types.coroutine()**) are *awaitables*, even though they do not have an **__await__()** method. Using `isinstance(gencoro, Awaitable)` for them

will return `False`. Use **`inspect.isawaitable()`** to detect them.

New in version 3.5.

class collections.abc.Coroutine

ABC for coroutine compatible classes. These implement the following methods, defined in Coroutine Objects: **`send()`**, **`throw()`**, and **`close()`**. Custom implementations must also implement **`__await__()`**. All **`Coroutine`** instances are also instances of **`Awaitable`**. See also the definition of coroutine.

Note

In CPython, generator-based coroutines (generators decorated with **`types.coroutine()`**) are *awaitables*, even though they do not have an **`__await__()`** method. Using `isinstance(gencoro, Coroutine)` for them will return `False`. Use **`inspect.isawaitable()`** to detect them.

New in version 3.5.

class collections.abc.AsyncIterable

ABC for classes that provide `__aiter__` method. See also the definition of asynchronous iterable.

New in version 3.5.

class collections.abc.AsyncIterator

ABC for classes that provide `__aiter__` and `__anext__` methods. See also the definition of asynchronous iterator.

New in version 3.5.

class collections.abc.AsyncGenerator

ABC for asynchronous generator classes that implement the

protocol defined in **PEP 525** [https://peps.python.org/pep-0525/] and **PEP 492** [https://peps.python.org/pep-0492/].

New in version 3.6.

Examples and Recipes

ABCs allow us to ask classes or instances if they provide particular functionality, for example:

```
size = None
if isinstance(myvar, collections.abc.Sized):
    size = len(myvar)
```

Several of the ABCs are also useful as mixins that make it easier to develop classes supporting container APIs. For example, to write a class supporting the full **Set** API, it is only necessary to supply the three underlying abstract methods: **__contains__()**, **__iter__()**, and **__len__()**. The ABC supplies the remaining methods such as **__and__()** and **isdisjoint()**:

```
class ListBasedSet(collections.abc.Set):
    ''' Alternate set implementation favoring space over
        and not requiring the set elements to be hashabl
    def __init__(self, iterable):
        self.elements = lst = []
        for value in iterable:
            if value not in lst:
                lst.append(value)

    def __iter__(self):
        return iter(self.elements)

    def __contains__(self, value):
        return value in self.elements

    def __len__(self):
        return len(self.elements)
```

```
s1 = ListBasedSet('abcdef')
s2 = ListBasedSet('defghi')
overlap = s1 & s2                # The __and__() method is s
```

Notes on using **Set** and **MutableSet** as a mixin:

1. Since some set operations create new sets, the default mixin methods need a way to create new instances from an iterable. The class constructor is assumed to have a signature in the form `ClassName(iterable)`. That assumption is factored-out to an internal classmethod called **_from_iterable()** which calls `cls(iterable)` to produce a new set. If the **Set** mixin is being used in a class with a different constructor signature, you will need to override **_from_iterable()** with a classmethod or regular method that can construct new instances from an iterable argument.
2. To override the comparisons (presumably for speed, as the semantics are fixed), redefine **__le__()** and **__ge__()**, then the other operations will automatically follow suit.
3. The **Set** mixin provides a **_hash()** method to compute a hash value for the set; however, **__hash__()** is not defined because not all sets are hashable or immutable. To add set hashability using mixins, inherit from both **Set()** and **Hashable()**, then define `__hash__ = Set._hash`.

`heapq` — Heap queue algorithm

Source code: Lib/heapq.py [https://github.com/python/cpython/tree/3.11/Lib/heapq.py]

This module provides an implementation of the heap queue algorithm, also known as the priority queue algorithm.

Heaps are binary trees for which every parent node has a value less than or equal to any of its children. This implementation uses arrays for which `heap[k] <= heap[2*k+1]` and `heap[k] <= heap[2*k+2]` for all *k*, counting elements from zero. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that its smallest element is always the root, `heap[0]`.

The API below differs from textbook heap algorithms in two aspects: (a) We use zero-based indexing. This makes the relationship between the index for a node and the indexes for its children slightly less obvious, but is more suitable since Python uses zero-based indexing. (b) Our pop method returns the smallest item, not the largest (called a “min heap” in textbooks; a “max heap” is more common in texts because of its suitability for in-place sorting).

These two make it possible to view the heap as a regular Python list without surprises: `heap[0]` is the smallest item, and `heap.sort()` maintains the heap invariant!

To create a heap, use a list initialized to `[]`, or you can transform a populated list into a heap via function **`heapify()`**.

The following functions are provided:

heapq.heappush(*heap*, *item*)

Push the value *item* onto the *heap*, maintaining the heap invariant.

heapq.heappop(*heap*)

Pop and return the smallest item from the *heap*, maintaining the heap invariant. If the heap is empty, **IndexError** is raised. To access the smallest item without popping it, use `heap[0]`.

heapq.heappushpop(*heap*, *item*)

Push *item* on the heap, then pop and return the smallest item from the *heap*. The combined action runs more efficiently than **heappush()** followed by a separate call to **heappop()**.

heapq.heapify(*x*)

Transform list *x* into a heap, in-place, in linear time.

heapq.heapreplace(*heap*, *item*)

Pop and return the smallest item from the *heap*, and also push the new *item*. The heap size doesn't change. If the heap is empty, **IndexError** is raised.

This one step operation is more efficient than a **heappop()** followed by **heappush()** and can be more appropriate when using a fixed-size heap. The pop/push combination always returns an element from the heap and replaces it with *item*.

The value returned may be larger than the *item* added. If that isn't desired, consider using **heappushpop()** instead. Its push/pop combination returns the smaller of the two values, leaving the larger value on the heap.

The module also offers three general purpose functions based on heaps.

heapq.merge(**iterables*, *key*=*None*, *reverse*=*False*)

Merge multiple sorted inputs into a single sorted output (for example, merge timestamped entries from multiple log files). Returns an iterator over the sorted values.

Similar to `sorted(itertools.chain(*iterables))` but returns an iterable, does not pull the data into memory all at once, and assumes that each of the input streams is already sorted (smallest to largest).

Has two optional arguments which must be specified as keyword arguments.

key specifies a key function of one argument that is used to extract a comparison key from each input element. The default value is `None` (compare the elements directly).

reverse is a boolean value. If set to `True`, then the input elements are merged as if each comparison were reversed. To achieve behavior similar to `sorted(itertools.chain(*iterables), reverse=True)`, all iterables must be sorted from largest to smallest.

Changed in version 3.5: Added the optional *key* and *reverse* parameters.

heapq.nlargest(*n*, *iterable*, *key*=*None*)

Return a list with the *n* largest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in *iterable* (for example, `key=str.lower`). Equivalent to: `sorted(iterable, key=key, reverse=True)[:n]`.

heapq.nsmallest(*n*, *iterable*, *key*=*None*)

Return a list with the *n* smallest elements from the dataset defined by *iterable*. *key*, if provided, specifies a function of one argument that is used to extract a comparison key from each element in *iterable* (for example, `key=str.lower`). Equivalent to: `sorted(iterable, key=key)[:n]`.

The latter two functions perform best for smaller values of *n*. For larger values, it is more efficient to use the `sorted()` function. Also, when `n==1`, it is more efficient to use the built-in `min()` and `max()` functions. If repeated usage of these functions is required, consider turning the iterable into an actual heap.

Basic Examples

A heapsort [https://en.wikipedia.org/wiki/Heapsort] can be implemented by pushing all values onto a heap and then popping off the smallest values one at a time:

```
>>> def heapsort(iterable):
...     h = []
...     for value in iterable:
...         heappush(h, value)
...     return [heappop(h) for i in range(len(h))]
...
>>> heapsort([1, 3, 5, 7, 9, 2, 4, 6, 8, 0])
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
```

This is similar to `sorted(iterable)`, but unlike `sorted()`, this implementation is not stable.

Heap elements can be tuples. This is useful for assigning comparison values (such as task priorities) alongside the main record being tracked:

```
>>> h = []
>>> heappush(h, (5, 'write code'))
>>> heappush(h, (7, 'release product'))
>>> heappush(h, (1, 'write spec'))
>>> heappush(h, (3, 'create tests'))
>>> heappop(h)
(1, 'write spec')
```

Priority Queue Implementation Notes

A priority queue [https://en.wikipedia.org/wiki/Priority_queue] is common

use for a heap, and it presents several implementation challenges:

- Sort stability: how do you get two tasks with equal priorities to be returned in the order they were originally added?
- Tuple comparison breaks for (priority, task) pairs if the priorities are equal and the tasks do not have a default comparison order.
- If the priority of a task changes, how do you move it to a new position in the heap?
- Or if a pending task needs to be deleted, how do you find it and remove it from the queue?

A solution to the first two challenges is to store entries as 3-element list including the priority, an entry count, and the task. The entry count serves as a tie-breaker so that two tasks with the same priority are returned in the order they were added. And since no two entry counts are the same, the tuple comparison will never attempt to directly compare two tasks.

Another solution to the problem of non-comparable tasks is to create a wrapper class that ignores the task item and only compares the priority field:

```
from dataclasses import dataclass, field
from typing import Any

@dataclass(order=True)
class PrioritizedItem:
    priority: int
    item: Any=field(compare=False)
```

The remaining challenges revolve around finding a pending task and making changes to its priority or removing it entirely. Finding a task can be done with a dictionary pointing to an entry in the queue.

Removing the entry or changing its priority is more difficult because it would break the heap structure invariants. So, a possible solution is to mark the entry as removed and add a new entry with the revised priority:

```
pq = []                         # list of entries arrang
entry_finder = {}               # mapping of tasks to en
REMOVED = '<removed-task>'      # placeholder for a remo
counter = itertools.count()     # unique sequence count

def add_task(task, priority=0):
    'Add a new task or update the priority of an existin
    if task in entry_finder:
        remove_task(task)
    count = next(counter)
    entry = [priority, count, task]
    entry_finder[task] = entry
    heappush(pq, entry)

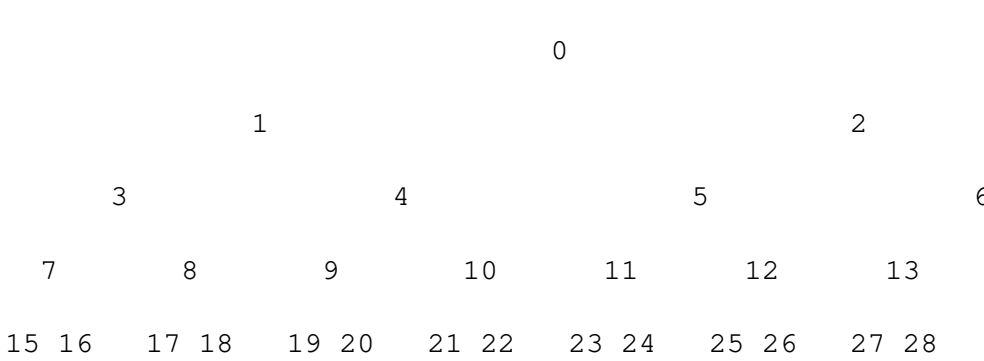
def remove_task(task):
    'Mark an existing task as REMOVED.  Raise KeyError i
    entry = entry_finder.pop(task)
    entry[-1] = REMOVED

def pop_task():
    'Remove and return the lowest priority task. Raise K
    while pq:
        priority, count, task = heappop(pq)
        if task is not REMOVED:
            del entry_finder[task]
            return task
    raise KeyError('pop from an empty priority queue')
```

Theory

Heaps are arrays for which `a[k] <= a[2*k+1]` and `a[k] <= a[2*k+2]` for all *k*, counting elements from 0. For the sake of comparison, non-existing elements are considered to be infinite. The interesting property of a heap is that `a[0]` is always its smallest element.

The strange invariant above is meant to be an efficient memory representation for a tournament. The numbers below are *k*, not



In the tree above, each cell *k* is topping `2*k+1` and `2*k+2`. In a usual binary tournament we see in sports, each cell is the winner over the two cells it tops, and we can trace the winner down the tree to see all opponents s/he had. However, in many computer applications of such tournaments, we do not need to trace the history of a winner. To be more memory efficient, when a winner is promoted, we try to replace it by something else at a lower level, and the rule becomes that a cell and the two cells it tops contain three different items, but the top cell "wins" over the two topped cells.

If this heap invariant is protected at all time, index 0 is clearly the overall winner. The simplest algorithmic way to remove it and find the "next" winner is to move some loser (let's say cell 30 in the diagram above) into the 0 position, and then percolate this new 0 down the tree, exchanging values, until the invariant is re-established. This is clearly logarithmic on the total number of items in the tree. By iterating over all items, you get an O(n log n) sort.

A nice feature of this sort is that you can efficiently insert new items while the sort is going on, provided that the inserted items are not "better" than the last 0'th element you extracted. This is especially useful in simulation contexts, where the tree holds all incoming events, and the "win" condition means the smallest scheduled time. When an event schedules other events for execution, they are scheduled into the future, so they can easily go into the heap. So, a heap is a good structure for implementing schedulers (this is what I used for my MIDI sequencer :-).

Various structures for implementing schedulers have been extensively studied, and heaps are good for this, as they are reasonably speedy, the speed is almost constant, and the worst case is not much different than the average case. However, there are other representations which are more efficient overall, yet the worst cases might be terrible.

Heaps are also very useful in big disk sorts. You most probably all know that a big sort implies producing “runs” (which are pre-sorted sequences, whose size is usually related to the amount of CPU memory), followed by a merging passes for these runs, which merging is often very cleverly organised 1. It is very important that the initial sort produces the longest runs possible. Tournaments are a good way to achieve that. If, using all the memory available to hold a tournament, you replace and percolate items that happen to fit the current run, you’ll produce runs which are twice the size of the memory for random input, and much better for input fuzzily ordered.

Moreover, if you output the 0’th item on disk and get an input which may not fit in the current tournament (because the value “wins” over the last output value), it cannot fit in the heap, so the size of the heap decreases. The freed memory could be cleverly reused immediately for progressively building a second heap, which grows at exactly the same rate the first heap is melting. When the first heap completely vanishes, you switch heaps and start a new run. Clever and quite effective!

In a word, heaps are useful memory structures to know. I use them in a few applications, and I think it is good to keep a ‘heap’ module around. :-)

Footnotes

1

The disk balancing algorithms which are current, nowadays, are more annoying than clever, and this is a consequence of the seeking capabilities of the disks. On devices which cannot seek, like big tape drives, the story was quite different, and one had

to be very clever to ensure (far in advance) that each tape movement will be the most effective possible (that is, will best participate at “progressing” the merge). Some tapes were even able to read backwards, and this was also used to avoid the rewinding time. Believe me, real good tape sorts were quite spectacular to watch! From all times, sorting has always been a Great Art! :-)

`bisect` — Array bisection algorithm

Source code: Lib/bisect.py [https://github.com/python/cpython/tree/3.11/Lib/bisect.py]

This module provides support for maintaining a list in sorted order without having to sort the list after each insertion. For long lists of items with expensive comparison operations, this can be an improvement over the more common approach. The module is called `bisect` because it uses a basic bisection algorithm to do its work. The source code may be most useful as a working example of the algorithm (the boundary conditions are already right!).

The following functions are provided:

bisect.bisect_left(*a*, *x*, *lo=0*, *hi=len(a)*, ***, *key=None*)

Locate the insertion point for *x* in *a* to maintain sorted order. The parameters *lo* and *hi* may be used to specify a subset of the list which should be considered; by default the entire list is used. If *x* is already present in *a*, the insertion point will be before (to the left of) any existing entries. The return value is suitable for use as the first parameter to `list.insert()` assuming that *a* is already sorted.

The returned insertion point *i* partitions the array *a* into two halves so that `all(val < x for val in a[lo : i])` for the left side and `all(val >= x for val in a[i : hi])` for the right side.

key specifies a key function of one argument that is used to extract a comparison key from each element in the array. To support searching complex records, the key function is not applied to the *x* value.

If *key* is `None`, the elements are compared directly with no intervening function call.

Changed in version 3.10: Added the *key* parameter.

bisect.bisect_right(*a*, *x*, *lo=0*, *hi=len(a)*, ***, *key=None*)
bisect.bisect(*a*, *x*, *lo=0*, *hi=len(a)*, ***, *key=None*)

Similar to **`bisect_left()`**, but returns an insertion point which comes after (to the right of) any existing entries of *x* in *a*.

The returned insertion point *i* partitions the array *a* into two halves so that `all(val <= x for val in a[lo : i])` for the left side and `all(val > x for val in a[i : hi])` for the right side.

key specifies a key function of one argument that is used to extract a comparison key from each element in the array. To support searching complex records, the key function is not applied to the *x* value.

If *key* is `None`, the elements are compared directly with no intervening function call.

Changed in version 3.10: Added the *key* parameter.

bisect.insort_left(*a*, *x*, *lo=0*, *hi=len(a)*, ***, *key=None*)

Insert *x* in *a* in sorted order.

This function first runs **`bisect_left()`** to locate an insertion point. Next, it runs the **`insert()`** method on *a* to insert *x* at the appropriate position to maintain sort order.

To support inserting records in a table, the *key* function (if any) is applied to *x* for the search step but not for the insertion step.

Keep in mind that the `O(log n)` search is dominated by the slow O(n) insertion step.

Changed in version 3.10: Added the *key* parameter.

bisect.insort_right(*a*, *x*, *lo*=*0*, *hi*=*len(a)*, *, *key*=*None*)
bisect.insort(*a*, *x*, *lo*=*0*, *hi*=*len(a)*, *, *key*=*None*)

Similar to **`insort_left()`**, but inserting *x* in *a* after any existing entries of *x*.

This function first runs **`bisect_right()`** to locate an insertion point. Next, it runs the **`insert()`** method on *a* to insert *x* at the appropriate position to maintain sort order.

To support inserting records in a table, the *key* function (if any) is applied to *x* for the search step but not for the insertion step.

Keep in mind that the `O(log n)` search is dominated by the slow O(n) insertion step.

Changed in version 3.10: Added the *key* parameter.

Performance Notes

When writing time sensitive code using *bisect()* and *insort()*, keep these thoughts in mind:

- Bisection is effective for searching ranges of values. For locating specific values, dictionaries are more performant.
- The *insort()* functions are `O(n)` because the logarithmic search step is dominated by the linear time insertion step.
- The search functions are stateless and discard key function results after they are used. Consequently, if the search functions are used in a loop, the key function may be called again and again on the same array elements. If the key function isn't fast, consider wrapping it with **`functools.cache()`** to avoid duplicate computations. Alternatively, consider searching an array of precomputed keys to locate the insertion point (as shown in the examples section below).

See also

- Sorted Collections [https://grantjenks.com/docs/sortedcollections/] is a high performance module that uses *bisect* to managed sorted collections of data.
- The SortedCollection recipe [https://code.activestate.com/recipes/577197-sortedcollection/] uses bisect to build a full-featured collection class with straight-forward search methods and support for a key-function. The keys are precomputed to save unnecessary calls to the key function during searches.

Searching Sorted Lists

The above **`bisect()`** functions are useful for finding insertion points but can be tricky or awkward to use for common searching tasks. The following five functions show how to transform them into the standard lookups for sorted lists:

```
def index(a, x):
    'Locate the leftmost value exactly equal to x'
    i = bisect_left(a, x)
    if i != len(a) and a[i] == x:
        return i
    raise ValueError

def find_lt(a, x):
    'Find rightmost value less than x'
    i = bisect_left(a, x)
    if i:
        return a[i-1]
    raise ValueError

def find_le(a, x):
    'Find rightmost value less than or equal to x'
    i = bisect_right(a, x)
    if i:
        return a[i-1]
```

```
    raise ValueError

def find_gt(a, x):
    'Find leftmost value greater than x'
    i = bisect_right(a, x)
    if i != len(a):
        return a[i]
    raise ValueError

def find_ge(a, x):
    'Find leftmost item greater than or equal to x'
    i = bisect_left(a, x)
    if i != len(a):
        return a[i]
    raise ValueError
```

Examples

The **`bisect()`** function can be useful for numeric table lookups. This example uses **`bisect()`** to look up a letter grade for an exam score (say) based on a set of ordered numeric breakpoints: 90 and up is an 'A', 80 to 89 is a 'B', and so on:

```
>>> def grade(score, breakpoints=[60, 70, 80, 90], grade
...     i = bisect(breakpoints, score)
...     return grades[i]
...
>>> [grade(score) for score in [33, 99, 77, 70, 89, 90,
['F', 'A', 'C', 'C', 'B', 'A', 'A']
```

The **`bisect()`** and **`insort()`** functions also work with lists of tuples. The *key* argument can serve to extract the field used for ordering records in a table:

```
>>> from collections import namedtuple
>>> from operator import attrgetter
>>> from bisect import bisect, insort
>>> from pprint import pprint
```

```
>>> Movie = namedtuple('Movie', ('name', 'released', 'di

>>> movies = [
...     Movie('Jaws', 1975, 'Speilberg'),
...     Movie('Titanic', 1997, 'Cameron'),
...     Movie('The Birds', 1963, 'Hitchcock'),
...     Movie('Aliens', 1986, 'Scott')
... ]

>>> # Find the first movie released after 1960
>>> by_year = attrgetter('released')
>>> movies.sort(key=by_year)
>>> movies[bisect(movies, 1960, key=by_year)]
Movie(name='The Birds', released=1963, director='Hitchco

>>> # Insert a movie while maintaining sort order
>>> romance = Movie('Love Story', 1970, 'Hiller')
>>> insort(movies, romance, key=by_year)
>>> pprint(movies)
[Movie(name='The Birds', released=1963, director='Hitcho
 Movie(name='Love Story', released=1970, director='Hille
 Movie(name='Jaws', released=1975, director='Speilberg')
 Movie(name='Aliens', released=1986, director='Scott'),
 Movie(name='Titanic', released=1997, director='Cameron'
```

If the key function is expensive, it is possible to avoid repeated function calls by searching a list of precomputed keys to find the index of a record:

```
>>> data = [('red', 5), ('blue', 1), ('yellow', 8), ('bl
>>> data.sort(key=lambda r: r[1])       # Or use operato
>>> keys = [r[1] for r in data]         # Precompute a l
>>> data[bisect_left(keys, 0)]
('black', 0)
>>> data[bisect_left(keys, 1)]
('blue', 1)
>>> data[bisect_left(keys, 5)]
('red', 5)
>>> data[bisect_left(keys, 8)]
```

```
('yellow', 8)
```

`array` — Efficient arrays of numeric values

This module defines an object type which can compactly represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a *type code*, which is a single character. The following type codes are defined:

Type code	C Type	Minimum size in bytes
`'b'`	signed char	1
`'B'`	unsigned char	1
`'u'`	Py_UNICODE	2
`'h'`	signed short	2
`'H'`	unsigned short	2
`'i'`	signed int	2
`'I'`	unsigned int	2
`'l'`	signed long	4
`'L'`	unsigned long	4
`'q'`	signed long long	8
`'Q'`	unsigned long long	8
`'f'`	float	4
`'d'`	double	8

Notes:

1. It can be 16 bits or 32 bits depending on the platform.

   Changed in version 3.9: `array('u')` now uses `wchar_t` as C type instead of deprecated `Py_UNICODE`. This change doesn't affect its behavior because `Py_UNICODE` is alias of `wchar_t` since Python 3.3.

   Deprecated since version 3.3, will be removed in version 4.0.

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the **itemsize** attribute.

The module defines the following type:

class array.array(*typecode*[, *initializer*])

A new array whose items are restricted by *typecode*, and initialized from the optional *initializer* value, which must be a list, a bytes-like object, or iterable over elements of the appropriate type.

If given a list or string, the initializer is passed to the new array's **fromlist()**, **frombytes()**, or **fromunicode()** method (see below) to add initial items to the array. Otherwise, the iterable initializer is passed to the **extend()** method.

Raises an auditing event `array.__new__` with arguments `typecode`, `initializer`.

array.typecodes

A string with all available type codes.

Array objects support the ordinary sequence operations of indexing, slicing, concatenation, and multiplication. When using slice assignment, the assigned value must be an array object with the same type code; in all other cases, **TypeError** is raised. Array objects also implement the buffer interface, and may be used wherever bytes-like objects are supported.

The following data items and methods are also supported:

array.typecode

The typecode character used to create the array.

array.itemsize

The length in bytes of one array item in the internal representation.

array.append(*x*)

Append a new item with value *x* to the end of the array.

array.buffer_info()

Return a tuple `(address, length)` giving the current memory address and the length in elements of the buffer used to hold array's contents. The size of the memory buffer in bytes can be computed as `array.buffer_info()[1] * array.itemsize`. This is occasionally useful when working with low-level (and inherently unsafe) I/O interfaces that require memory addresses, such as certain **`ioctl()`** operations. The returned numbers are valid as long as the array exists and no length-changing operations are applied to it.

Note

When using array objects from code written in C or C++ (the only way to effectively make use of this information), it makes more sense to use the buffer interface supported by array objects. This method is maintained for backward compatibility and should be avoided in new code. The buffer interface is documented in Buffer Protocol.

array.byteswap()

"Byteswap" all items of the array. This is only supported for values which are 1, 2, 4, or 8 bytes in size; for other types of values, **`RuntimeError`** is raised. It is useful when reading data from a file written on a machine with a different byte order.

array.count(*x*)

Return the number of occurrences of *x* in the array.

array.extend(*iterable*)

Append items from *iterable* to the end of the array. If *iterable*

is another array, it must have *exactly* the same type code; if not, **`TypeError`** will be raised. If *iterable* is not an array, it must be iterable and its elements must be the right type to be appended to the array.

array.frombytes(*s*)

Appends items from the string, interpreting the string as an array of machine values (as if it had been read from a file using the **`fromfile()`** method).

New in version 3.2: **`fromstring()`** is renamed to **`frombytes()`** for clarity.

array.fromfile(*f*, *n*)

Read *n* items (as machine values) from the file object *f* and append them to the end of the array. If less than *n* items are available, **`EOFError`** is raised, but the items that were available are still inserted into the array.

array.fromlist(*list*)

Append items from the list. This is equivalent to `for x in list: a.append(x)` except that if there is a type error, the array is unchanged.

array.fromunicode(*s*)

Extends this array with data from the given unicode string. The array must be a type `'u'` array; otherwise a **`ValueError`** is raised. Use `array.frombytes(unicodestring.encode(enc))` to append Unicode data to an array of some other type.

array.index(*x*[, *start*[, *stop*]])

Return the smallest *i* such that *i* is the index of the first occurrence of *x* in the array. The optional arguments *start* and *stop* can be specified to search for *x* within a subsection of the array. Raise **`ValueError`** if *x* is not found.

Changed in version 3.10: Added optional *start* and *stop* parameters.

array.insert(*i*, *x*)

Insert a new item with value *x* in the array before position *i*. Negative values are treated as being relative to the end of the array.

array.pop([*i*])

Removes the item with the index *i* from the array and returns it. The optional argument defaults to `-1`, so that by default the last item is removed and returned.

array.remove(*x*)

Remove the first occurrence of *x* from the array.

array.reverse()

Reverse the order of the items in the array.

array.tobytes()

Convert the array to an array of machine values and return the bytes representation (the same sequence of bytes that would be written to a file by the **`tofile()`** method.)

New in version 3.2: **`tostring()`** is renamed to **`tobytes()`** for clarity.

array.tofile(*f*)

Write all items (as machine values) to the file object *f*.

array.tolist()

Convert the array to an ordinary list with the same items.

array.tounicode()

Convert the array to a unicode string. The array must be a type `'u'` array; otherwise a **`ValueError`** is raised. Use

`array.tobytes().decode(enc)` to obtain a unicode string from an array of some other type.

When an array object is printed or converted to a string, it is represented as `array(typecode, initializer)`. The *initializer* is omitted if the array is empty, otherwise it is a string if the *typecode* is `'u'`, otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to an array with the same type and value using **`eval()`**, so long as the **`array`** class has been imported using `from array import array`. Examples:

```
array('l')
array('u', 'hello \u2641')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

`weakref` — Weak references

Source code: Lib/weakref.py [https://github.com/python/cpython/tree/3.11/Lib/weakref.py]

The `weakref` module allows the Python programmer to create *weak references* to objects.

In the following, the term *referent* means the object which is referred to by a weak reference.

A weak reference to an object is not enough to keep the object alive: when the only remaining references to a referent are weak references, garbage collection is free to destroy the referent and reuse its memory for something else. However, until the object is actually destroyed the weak reference may return the object even if there are no strong references to it.

A primary use for weak references is to implement caches or mappings holding large objects, where it's desired that a large object not be kept alive solely because it appears in a cache or mapping.

For example, if you have a number of large binary image objects, you may wish to associate a name with each. If you used a Python dictionary to map names to images, or images to names, the image objects would remain alive just because they appeared as values or keys in the dictionaries. The `WeakKeyDictionary` and `WeakValueDictionary` classes supplied by the `weakref` module are an alternative, using weak references to construct mappings that don't keep objects alive solely because they appear in the mapping objects. If, for example, an image object is a value in a `WeakValueDictionary`, then when the last remaining references to that image object are the weak references held by weak mappings, garbage collection can reclaim the object, and its corresponding entries in weak mappings are simply deleted.

`WeakKeyDictionary` and **`WeakValueDictionary`** use weak references in their implementation, setting up callback functions on the weak references that notify the weak dictionaries when a key or value has been reclaimed by garbage collection. **`WeakSet`** implements the **`set`** interface, but keeps weak references to its elements, just like a **`WeakKeyDictionary`** does.

`finalize` provides a straight forward way to register a cleanup function to be called when an object is garbage collected. This is simpler to use than setting up a callback function on a raw weak reference, since the module automatically ensures that the finalizer remains alive until the object is collected.

Most programs should find that using one of these weak container types or **`finalize`** is all they need – it's not usually necessary to create your own weak references directly. The low-level machinery is exposed by the **`weakref`** module for the benefit of advanced uses.

Not all objects can be weakly referenced. Objects which support weak references include class instances, functions written in Python (but not in C), instance methods, sets, frozensets, some file objects, generators, type objects, sockets, arrays, deques, regular expression pattern objects, and code objects.

Changed in version 3.2: Added support for thread.lock, threading.Lock, and code objects.

Several built-in types such as **`list`** and **`dict`** do not directly support weak references but can add support through subclassing:

```
class Dict(dict):
    pass

obj = Dict(red=1, green=2, blue=3)   # this object is we
```

CPython implementation detail: Other built-in types such as **`tuple`** and **`int`** do not support weak references even when subclassed.

Extension types can easily be made to support weak references; see

Weak Reference Support.

When `__slots__` are defined for a given type, weak reference support is disabled unless a `'__weakref__'` string is also present in the sequence of strings in the `__slots__` declaration. See _slots_ documentation for details.

class weakref.ref(*object*[, *callback*])

Return a weak reference to *object*. The original object can be retrieved by calling the reference object if the referent is still alive; if the referent is no longer alive, calling the reference object will cause **None** to be returned. If *callback* is provided and not **None**, and the returned weakref object is still alive, the callback will be called when the object is about to be finalized; the weak reference object will be passed as the only parameter to the callback; the referent will no longer be available.

It is allowable for many weak references to be constructed for the same object. Callbacks registered for each weak reference will be called from the most recently registered callback to the oldest registered callback.

Exceptions raised by the callback will be noted on the standard error output, but cannot be propagated; they are handled in exactly the same way as exceptions raised from an object's **__del__()** method.

Weak references are hashable if the *object* is hashable. They will maintain their hash value even after the *object* was deleted. If **hash()** is called the first time only after the *object* was deleted, the call will raise **TypeError**.

Weak references support tests for equality, but not ordering. If the referents are still alive, two references have the same equality relationship as their referents (regardless of the *callback*). If either referent has been deleted, the references are equal only if the reference objects are the same object.

This is a subclassable type rather than a factory function.

callback

This read-only attribute returns the callback currently associated to the weakref. If there is no callback or if the referent of the weakref is no longer alive then this attribute will have value `None`.

Changed in version 3.4: Added the **`__callback__`** attribute.

weakref.proxy(*object*[, *callback*])

Return a proxy to *object* which uses a weak reference. This supports use of the proxy in most contexts instead of requiring the explicit dereferencing used with weak reference objects. The returned object will have a type of either `ProxyType` or `CallableProxyType`, depending on whether *object* is callable. Proxy objects are not hashable regardless of the referent; this avoids a number of problems related to their fundamentally mutable nature, and prevents their use as dictionary keys. *callback* is the same as the parameter of the same name to the **`ref()`** function.

Accessing an attribute of the proxy object after the referent is garbage collected raises **`ReferenceError`**.

Changed in version 3.8: Extended the operator support on proxy objects to include the matrix multiplication operators `@` and `@=`.

weakref.getweakrefcount(*object*)

Return the number of weak references and proxies which refer to *object*.

weakref.getweakrefs(*object*)

Return a list of all weak reference and proxy objects which refer to *object*.

class weakref.WeakKeyDictionary([*dict*])

Mapping class that references keys weakly. Entries in the

dictionary will be discarded when there is no longer a strong reference to the key. This can be used to associate additional data with an object owned by other parts of an application without adding attributes to those objects. This can be especially useful with objects that override attribute accesses.

Changed in version 3.9: Added support for `|` and `|=` operators, specified in **PEP 584** [https://peps.python.org/pep-0584/].

`WeakKeyDictionary` objects have an additional method that exposes the internal references directly. The references are not guaranteed to be "live" at the time they are used, so the result of calling the references needs to be checked before being used. This can be used to avoid creating references that will cause the garbage collector to keep the keys around longer than needed.

WeakKeyDictionary.keyrefs()

Return an iterable of the weak references to the keys.

class weakref.WeakValueDictionary([*dict*])

Mapping class that references values weakly. Entries in the dictionary will be discarded when no strong reference to the value exists any more.

Changed in version 3.9: Added support for `|` and `|=` operators, as specified in **PEP 584** [https://peps.python.org/pep-0584/].

`WeakValueDictionary` objects have an additional method that has the same issues as the **`keyrefs()`** method of **`WeakKeyDictionary`** objects.

WeakValueDictionary.valuerefs()

Return an iterable of the weak references to the values.

class weakref.WeakSet([*elements*])

Set class that keeps weak references to its elements. An

element will be discarded when no strong reference to it exists any more.

class weakref.WeakMethod(*method*[, *callback*])

A custom **ref** subclass which simulates a weak reference to a bound method (i.e., a method defined on a class and looked up on an instance). Since a bound method is ephemeral, a standard weak reference cannot keep hold of it. **WeakMethod** has special code to recreate the bound method until either the object or the original function dies:

```
>>> class C:
...     def method(self):
...         print("method called!")
...
>>> c = C()
>>> r = weakref.ref(c.method)
>>> r()
>>> r = weakref.WeakMethod(c.method)
>>> r()
<bound method C.method of <__main__.C object at 0x7
>>> r()()
method called!
>>> del c
>>> gc.collect()
0
>>> r()
>>>
```

callback is the same as the parameter of the same name to the **ref()** function.

New in version 3.4.

class weakref.finalize(*obj*, *func*, */*, **args*, ***kwargs*)

Return a callable finalizer object which will be called when *obj* is garbage collected. Unlike an ordinary weak reference, a finalizer will always survive until the reference object is collected, greatly simplifying lifecycle management.

A finalizer is considered *alive* until it is called (either explicitly or at garbage collection), and after that it is *dead*. Calling a live finalizer returns the result of evaluating `func(*arg, **kwargs)`, whereas calling a dead finalizer returns **`None`**.

Exceptions raised by finalizer callbacks during garbage collection will be shown on the standard error output, but cannot be propagated. They are handled in the same way as exceptions raised from an object's **`__del__()`** method or a weak reference's callback.

When the program exits, each remaining live finalizer is called unless its **`atexit`** attribute has been set to false. They are called in reverse order of creation.

A finalizer will never invoke its callback during the later part of the interpreter shutdown when module globals are liable to have been replaced by **`None`**.

call()

> If *self* is alive then mark it as dead and return the result of calling `func(*args, **kwargs)`. If *self* is dead then return **`None`**.

detach()

> If *self* is alive then mark it as dead and return the tuple `(obj, func, args, kwargs)`. If *self* is dead then return **`None`**.

peek()

> If *self* is alive then return the tuple `(obj, func, args, kwargs)`. If *self* is dead then return **`None`**.

alive

> Property which is true if the finalizer is alive, false otherwise.

atexit

A writable boolean property which by default is true. When the program exits, it calls all remaining live finalizers for which `atexit` is true. They are called in reverse order of creation.

Note

It is important to ensure that *func*, *args* and *kwargs* do not own any references to *obj*, either directly or indirectly, since otherwise *obj* will never be garbage collected. In particular, *func* should not be a bound method of *obj*.

New in version 3.4.

weakref.ReferenceType
: The type object for weak references objects.

weakref.ProxyType
: The type object for proxies of objects which are not callable.

weakref.CallableProxyType
: The type object for proxies of callable objects.

weakref.ProxyTypes
: Sequence containing all the type objects for proxies. This can make it simpler to test if an object is a proxy without being dependent on naming both proxy types.

See also

PEP 205 **[https://peps.python.org/pep-0205/]** **- Weak References**
: The proposal and rationale for this feature, including links to earlier implementations and information about similar features in other languages.

Weak Reference Objects

Weak reference objects have no methods and no attributes besides **`ref.__callback__`**. A weak reference object allows the referent to be obtained, if it still exists, by calling it:

```
>>> import weakref
>>> class Object:
...     pass
...
>>> o = Object()
>>> r = weakref.ref(o)
>>> o2 = r()
>>> o is o2
True
```

If the referent no longer exists, calling the reference object returns **`None`**:

```
>>> del o, o2
>>> print(r())
None
```

Testing that a weak reference object is still live should be done using the expression `ref() is not None`. Normally, application code that needs to use a reference object should follow this pattern:

```
# r is a weak reference object
o = r()
if o is None:
    # referent has been garbage collected
    print("Object has been deallocated; can't frobnicate
else:
    print("Object is still live!")
    o.do_something_useful()
```

Using a separate test for “liveness” creates race conditions in threaded applications; another thread can cause a weak reference to become invalidated before the weak reference is called; the idiom shown above is safe in threaded applications as well as single-threaded applications.

Specialized versions of **ref** objects can be created through subclassing. This is used in the implementation of the **WeakValueDictionary** to reduce the memory overhead for each entry in the mapping. This may be most useful to associate additional information with a reference, but could also be used to insert additional processing on calls to retrieve the referent.

This example shows how a subclass of **ref** can be used to store additional information about an object and affect the value that's returned when the referent is accessed:

```
import weakref

class ExtendedRef(weakref.ref):
    def __init__(self, ob, callback=None, /, **annotatio
        super().__init__(ob, callback)
        self.__counter = 0
        for k, v in annotations.items():
            setattr(self, k, v)

    def __call__(self):
        """Return a pair containing the referent and the
        times the reference has been called.
        """
        ob = super().__call__()
        if ob is not None:
            self.__counter += 1
            ob = (ob, self.__counter)
        return ob
```

Example

This simple example shows how an application can use object IDs to retrieve objects that it has seen before. The IDs of the objects can then be used in other data structures without forcing the objects to remain alive, but the objects can still be retrieved by ID if they do.

```
import weakref
```

```
_id2obj_dict = weakref.WeakValueDictionary()

def remember(obj):
    oid = id(obj)
    _id2obj_dict[oid] = obj
    return oid

def id2obj(oid):
    return _id2obj_dict[oid]
```

Finalizer Objects

The main benefit of using **`finalize`** is that it makes it simple to register a callback without needing to preserve the returned finalizer object. For instance

```
>>> import weakref
>>> class Object:
...     pass
...
>>> kenny = Object()
>>> weakref.finalize(kenny, print, "You killed Kenny!")
<finalize object at ...; for 'Object' at ...>
>>> del kenny
You killed Kenny!
```

The finalizer can be called directly as well. However the finalizer will invoke the callback at most once.

```
>>> def callback(x, y, z):
...     print("CALLBACK")
...     return x + y + z
...
>>> obj = Object()
>>> f = weakref.finalize(obj, callback, 1, 2, z=3)
>>> assert f.alive
>>> assert f() == 6
CALLBACK
>>> assert not f.alive
```

```
>>> f()                          # callback not called becaus
>>> del obj                      # callback not called becaus
```

You can unregister a finalizer using its **`detach()`** method. This kills the finalizer and returns the arguments passed to the constructor when it was created.

```
>>> obj = Object()
>>> f = weakref.finalize(obj, callback, 1, 2, z=3)
>>> f.detach()
(<...Object object ...>, <function callback ...>, (1, 2)
>>> newobj, func, args, kwargs = _
>>> assert not f.alive
>>> assert newobj is obj
>>> assert func(*args, **kwargs) == 6
CALLBACK
```

Unless you set the **`atexit`** attribute to **`False`**, a finalizer will be called when the program exits if it is still alive. For instance

```
>>> obj = Object()
>>> weakref.finalize(obj, print, "obj dead or exiting")
<finalize object at ...; for 'Object' at ...>
>>> exit()
obj dead or exiting
```

Comparing finalizers with `__del__()` methods

Suppose we want to create a class whose instances represent temporary directories. The directories should be deleted with their contents when the first of the following events occurs:

- the object is garbage collected,
- the object's **`remove()`** method is called, or
- the program exits.

We might try to implement the class using a **`__del__()`** method as follows:

```
class TempDir:
    def __init__(self):
        self.name = tempfile.mkdtemp()

    def remove(self):
        if self.name is not None:
            shutil.rmtree(self.name)
            self.name = None

    @property
    def removed(self):
        return self.name is None

    def __del__(self):
        self.remove()
```

Starting with Python 3.4, **`__del__()`** methods no longer prevent reference cycles from being garbage collected, and module globals are no longer forced to **`None`** during interpreter shutdown. So this code should work without any issues on CPython.

However, handling of **`__del__()`** methods is notoriously implementation specific, since it depends on internal details of the interpreter's garbage collector implementation.

A more robust alternative can be to define a finalizer which only references the specific functions and objects that it needs, rather than having access to the full state of the object:

```
class TempDir:
    def __init__(self):
        self.name = tempfile.mkdtemp()
        self._finalizer = weakref.finalize(self, shutil.

    def remove(self):
        self._finalizer()

    @property
    def removed(self):
        return not self._finalizer.alive
```

Defined like this, our finalizer only receives a reference to the details it needs to clean up the directory appropriately. If the object never gets garbage collected the finalizer will still be called at exit.

The other advantage of weakref based finalizers is that they can be used to register finalizers for classes where the definition is controlled by a third party, such as running code when a module is unloaded:

```
import weakref, sys
def unloading_module():
    # implicit reference to the module globals from the
weakref.finalize(sys.modules[__name__], unloading_module
```

Note

If you create a finalizer object in a daemonic thread just as the program exits then there is the possibility that the finalizer does not get called at exit. However, in a daemonic thread `atexit.register()`, `try: ... finally: ...` and `with: ...` do not guarantee that cleanup occurs either.

`types` — Dynamic type creation and names for built-in types

Source code: Lib/types.py [https://github.com/python/cpython/tree/3.11/Lib/types.py]

This module defines utility functions to assist in dynamic creation of new types.

It also defines names for some object types that are used by the standard Python interpreter, but not exposed as builtins like `int` or `str` are.

Finally, it provides some additional type-related utility classes and functions that are not fundamental enough to be builtins.

Dynamic Type Creation

types.new_class(*name*, *bases*=*()*, *kwds*=*None*, *exec_body*=*None*)

Creates a class object dynamically using the appropriate metaclass.

The first three arguments are the components that make up a class definition header: the class name, the base classes (in order), the keyword arguments (such as `metaclass`).

The *exec_body* argument is a callback that is used to populate the freshly created class namespace. It should accept the class namespace as its sole argument and update the namespace directly with the class contents. If no callback is provided, it has the same effect as passing in `lambda ns: None`.

New in version 3.3.

types.prepare_class(*name*, *bases*=*()*, *kwds*=*None*)

Calculates the appropriate metaclass and creates the class namespace.

The arguments are the components that make up a class definition header: the class name, the base classes (in order) and the keyword arguments (such as `metaclass`).

The return value is a 3-tuple: `metaclass, namespace, kwds`

metaclass is the appropriate metaclass, *namespace* is the prepared class namespace and *kwds* is an updated copy of the passed in *kwds* argument with any `'metaclass'` entry removed. If no *kwds* argument is passed in, this will be an empty dict.

New in version 3.3.

Changed in version 3.6: The default value for the `namespace` element of the returned tuple has changed. Now an insertion-order-preserving mapping is used when the metaclass does not have a `__prepare__` method.

See also

Metaclasses

Full details of the class creation process supported by these functions

PEP 3115 **[https://peps.python.org/pep-3115/]** **- Metaclasses in Python 3000**

Introduced the `__prepare__` namespace hook

types.resolve_bases(*bases*)

Resolve MRO entries dynamically as specified by **PEP 560** [https://peps.python.org/pep-0560/].

This function looks for items in *bases* that are not instances of **type**, and returns a tuple where each such object that has an `__mro_entries__` method is replaced with an unpacked result of calling this method. If a *bases* item is an instance of **type**, or it doesn't have an `__mro_entries__` method, then it is included in the return tuple unchanged.

New in version 3.7.

PEP 560 [https://peps.python.org/pep-0560/] - Core support for typing module and generic types

Standard Interpreter Types

This module provides names for many of the types that are required to implement a Python interpreter. It deliberately avoids including some of the types that arise only incidentally during processing such as the `listiterator` type.

Typical use of these names is for **isinstance()** or **issubclass()** checks.

If you instantiate any of these types, note that signatures may vary between Python versions.

Standard names are defined for the following types:

types.NoneType
: The type of **None**.

  New in version 3.10.

types.FunctionType
types.LambdaType
: The type of user-defined functions and functions created by **lambda** expressions.

Raises an auditing event `function.__new__` with argument `code`.

The audit event only occurs for direct instantiation of function objects, and is not raised for normal compilation.

types.GeneratorType

The type of generator-iterator objects, created by generator functions.

types.CoroutineType

The type of coroutine objects, created by **`async def`** functions.

New in version 3.5.

types.AsyncGeneratorType

The type of asynchronous generator-iterator objects, created by asynchronous generator functions.

New in version 3.6.

class types.CodeType(***kwargs*)

The type for code objects such as returned by **`compile()`**.

Raises an auditing event `code.__new__` with arguments `code`, `filename`, `name`, `argcount`, `posonlyargcount`, `kwonlyargcount`, `nlocals`, `stacksize`, `flags`.

Note that the audited arguments may not match the names or positions required by the initializer. The audit event only occurs for direct instantiation of code objects, and is not raised for normal compilation.

replace(***kwargs*)

Return a copy of the code object with new values for the specified fields.

New in version 3.8.

types.CellType

The type for cell objects: such objects are used as containers for a function's free variables.

New in version 3.8.

types.MethodType

The type of methods of user-defined class instances.

types.BuiltinFunctionType
types.BuiltinMethodType

The type of built-in functions like `len()` or `sys.exit()`, and methods of built-in classes. (Here, the term "built-in" means "written in C".)

types.WrapperDescriptorType

The type of methods of some built-in data types and base classes such as `object.__init__()` or `object.__lt__()`.

New in version 3.7.

types.MethodWrapperType

The type of *bound* methods of some built-in data types and base classes. For example it is the type of `object().__str__`.

New in version 3.7.

types.NotImplementedType

The type of `NotImplemented`.

New in version 3.10.

types.MethodDescriptorType

The type of methods of some built-in data types such as `str.join()`.

New in version 3.7.

types.ClassMethodDescriptorType

The type of *unbound* class methods of some built-in data types such as `dict.__dict__['fromkeys']`.

New in version 3.7.

class types.ModuleType(*name*, *doc*=*None*)

The type of modules. The constructor takes the name of the module to be created and optionally its docstring.

Note

Use **`importlib.util.module_from_spec()`** to create a new module if you wish to set the various import-controlled attributes.

doc

The docstring of the module. Defaults to `None`.

loader

The loader which loaded the module. Defaults to `None`.

This attribute is to match **`importlib.machinery.ModuleSpec.loader`** as stored in the **`__spec__`** object.

Note

A future version of Python may stop setting this attribute by default. To guard against this potential change, preferably read from the **`__spec__`** attribute instead or use `getattr(module, "__loader__", None)` if you explicitly need to use this attribute.

Changed in version 3.4: Defaults to `None`. Previously the

attribute was optional.

name

The name of the module. Expected to match **importlib.machinery.ModuleSpec.name**.

package

Which package a module belongs to. If the module is top-level (i.e. not a part of any specific package) then the attribute should be set to `''`, else it should be set to the name of the package (which can be **__name__** if the module is a package itself). Defaults to `None`.

This attribute is to match **importlib.machinery.ModuleSpec.parent** as stored in the **__spec__** object.

Note

A future version of Python may stop setting this attribute by default. To guard against this potential change, preferably read from the **__spec__** attribute instead or use `getattr(module, "__package__", None)` if you explicitly need to use this attribute.

Changed in version 3.4: Defaults to `None`. Previously the attribute was optional.

spec

A record of the module's import-system-related state. Expected to be an instance of **importlib.machinery.ModuleSpec**.

New in version 3.4.

types.EllipsisType

The type of **Ellipsis**.

New in version 3.10.

class types.GenericAlias(*t_origin*, *t_args*)

The type of parameterized generics such as `list[int]`.

`t_origin` should be a non-parameterized generic class, such as `list`, `tuple` or `dict`. `t_args` should be a **`tuple`** (possibly of length 1) of types which parameterize `t_origin`:

```
>>> from types import GenericAlias

>>> list[int] == GenericAlias(list, (int,))
True
>>> dict[str, int] == GenericAlias(dict, (str, int))
True
```

New in version 3.9.

Changed in version 3.9.2: This type can now be subclassed.

class types.UnionType

The type of union type expressions.

New in version 3.10.

class types.TracebackType(*tb_next*, *tb_frame*, *tb_lasti*, *tb_lineno*)

The type of traceback objects such as found in `sys.exc_info()[2]`.

See the language reference for details of the available attributes and operations, and guidance on creating tracebacks dynamically.

types.FrameType

The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

See the language reference for details of the available

attributes and operations.

types.GetSetDescriptorType

The type of objects defined in extension modules with `PyGetSetDef`, such as `FrameType.f_locals` or `array.array.typecode`. This type is used as descriptor for object attributes; it has the same purpose as the **`property`** type, but for classes defined in extension modules.

types.MemberDescriptorType

The type of objects defined in extension modules with `PyMemberDef`, such as `datetime.timedelta.days`. This type is used as descriptor for simple C data members which use standard conversion functions; it has the same purpose as the **`property`** type, but for classes defined in extension modules.

CPython implementation detail: In other implementations of Python, this type may be identical to `GetSetDescriptorType`.

class types.MappingProxyType(*mapping*)

Read-only proxy of a mapping. It provides a dynamic view on the mapping's entries, which means that when the mapping changes, the view reflects these changes.

New in version 3.3.

Changed in version 3.9: Updated to support the new union (`|`) operator from **PEP 584** [https://peps.python.org/pep-0584/], which simply delegates to the underlying mapping.

key in proxy

Return `True` if the underlying mapping has a key *key*, else `False`.

proxy[key]

Return the item of the underlying mapping with key *key*. Raises a **`KeyError`** if *key* is not in the underlying

mapping.

iter(proxy)

Return an iterator over the keys of the underlying mapping. This is a shortcut for `iter(proxy.keys())`.

len(proxy)

Return the number of items in the underlying mapping.

copy()

Return a shallow copy of the underlying mapping.

get(*key*[, *default*])

Return the value for *key* if *key* is in the underlying mapping, else *default*. If *default* is not given, it defaults to `None`, so that this method never raises a **`KeyError`**.

items()

Return a new view of the underlying mapping's items (`(key, value)` pairs).

keys()

Return a new view of the underlying mapping's keys.

values()

Return a new view of the underlying mapping's values.

reversed(proxy)

Return a reverse iterator over the keys of the underlying mapping.

New in version 3.9.

Additional Utility Classes and Functions

class types.SimpleNamespace

A simple **object** subclass that provides attribute access to its namespace, as well as a meaningful repr.

Unlike **object**, with `SimpleNamespace` you can add and remove attributes. If a `SimpleNamespace` object is initialized with keyword arguments, those are directly added to the underlying namespace.

The type is roughly equivalent to the following code:

```
class SimpleNamespace:
    def __init__(self, /, **kwargs):
        self.__dict__.update(kwargs)

    def __repr__(self):
        items = (f"{k}={v!r}" for k, v in self.__di
        return "{}({})".format(type(self).__name__,

    def __eq__(self, other):
        if isinstance(self, SimpleNamespace) and is
           return self.__dict__ == other.__dict__
        return NotImplemented
```

`SimpleNamespace` may be useful as a replacement for `class NS: pass`. However, for a structured record type use **namedtuple()** instead.

New in version 3.3.

Changed in version 3.9: Attribute order in the repr changed from alphabetical to insertion (like `dict`).

types.DynamicClassAttribute(*fget=None*, *fset=None*, *fdel=None*, *doc=None*)

Route attribute access on a class to _getattr_.

This is a descriptor, used to define attributes that act differently when accessed through an instance and through a class. Instance access remains normal, but access to an attribute through a class will be routed to the class's _getattr_ method; this is done by raising AttributeError.

This allows one to have properties active on an instance, and have virtual attributes on the class with the same name (see **enum.Enum** for an example).

New in version 3.4.

Coroutine Utility Functions

types.coroutine(*gen_func*)

This function transforms a generator function into a coroutine function which returns a generator-based coroutine. The generator-based coroutine is still a generator iterator, but is also considered to be a coroutine object and is awaitable. However, it may not necessarily implement the **__await__()** method.

If *gen_func* is a generator function, it will be modified in-place.

If *gen_func* is not a generator function, it will be wrapped. If it returns an instance of **collections.abc.Generator**, the instance will be wrapped in an *awaitable* proxy object. All other types of objects will be returned as is.

New in version 3.5.

copy — Shallow and deep copy operations

Source code: Lib/copy.py [https://github.com/python/cpython/tree/3.11/Lib/copy.py]

Assignment statements in Python do not copy objects, they create bindings between a target and an object. For collections that are mutable or contain mutable items, a copy is sometimes needed so one can change one copy without changing the other. This module provides generic shallow and deep copy operations (explained below).

Interface summary:

copy.copy(*x*)

Return a shallow copy of *x*.

copy.deepcopy(*x*[, *memo*])

Return a deep copy of *x*.

exception copy.Error

Raised for module specific errors.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the

original.

Two problems often exist with deep copy operations that don't exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies everything it may copy too much, such as data which is intended to be shared between copies.

The **deepcopy()** function avoids these problems by:

- keeping a `memo` dictionary of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This module does not copy types like module, method, stack trace, stack frame, file, socket, window, or any similar types. It does "copy" functions and classes (shallow and deeply), by returning the original object unchanged; this is compatible with the way these are treated by the **pickle** module.

Shallow copies of dictionaries can be made using **dict.copy()**, and of lists by assigning a slice of the entire list, for example, `copied_list = original_list[:]`.

Classes can use the same interfaces to control copying that they use to control pickling. See the description of module **pickle** for information on these methods. In fact, the **copy** module uses the registered pickle functions from the **copyreg** module.

In order for a class to define its own copy implementation, it can define special methods **__copy__()** and **__deepcopy__()**. The former is called to implement the shallow copy operation; no additional arguments are passed. The latter is called to implement the deep copy operation; it is passed one argument, the `memo` dictionary. If the **__deepcopy__()** implementation needs to make a deep copy of a component, it should call the **deepcopy()** function with the component as first argument and the memo

dictionary as second argument. The memo dictionary should be treated as an opaque object.

: Discussion of the special methods used to support object state retrieval and restoration.

`pprint` — Data pretty printer

Source code: Lib/pprint.py [https://github.com/python/cpython/tree/3.11/Lib/pprint.py]

The `pprint` module provides a capability to "pretty-print" arbitrary Python data structures in a form which can be used as input to the interpreter. If the formatted structures include objects which are not fundamental Python types, the representation may not be loadable. This may be the case if objects such as files, sockets or classes are included, as well as many other objects which are not representable as Python literals.

The formatted representation keeps objects on a single line if it can, and breaks them onto multiple lines if they don't fit within the allowed width. Construct `PrettyPrinter` objects explicitly if you need to adjust the width constraint.

Dictionaries are sorted by key before the display is computed.

Changed in version 3.9: Added support for pretty-printing `types.SimpleNamespace`.

Changed in version 3.10: Added support for pretty-printing `dataclasses.dataclass`.

The `pprint` module defines one class:

class pprint.PrettyPrinter(*indent=1*, *width=80*, *depth=None*, *stream=None*, ***, *compact=False*, *sort_dicts=True*, *underscore_numbers=False*)

Construct a `PrettyPrinter` instance. This constructor understands several keyword parameters.

stream (default `sys.stdout`) is a file-like object to which the output will be written by calling its `write()` method. If

both *stream* and `sys.stdout` are `None`, then **`pprint()`** silently returns.

Other values configure the manner in which nesting of complex data structures is displayed.

indent (default 1) specifies the amount of indentation added for each nesting level.

depth controls the number of nesting levels which may be printed; if the data structure being printed is too deep, the next contained level is replaced by `...`. By default, there is no constraint on the depth of the objects being formatted.

width (default 80) specifies the desired maximum number of characters per line in the output. If a structure cannot be formatted within the width constraint, a best effort will be made.

compact impacts the way that long sequences (lists, tuples, sets, etc) are formatted. If *compact* is false (the default) then each item of a sequence will be formatted on a separate line. If *compact* is true, as many items as will fit within the *width* will be formatted on each output line.

If *sort_dicts* is true (the default), dictionaries will be formatted with their keys sorted, otherwise they will display in insertion order.

If *underscore_numbers* is true, integers will be formatted with the `_` character for a thousands separator, otherwise underscores are not displayed (the default).

Changed in version 3.4: Added the *compact* parameter.

Changed in version 3.8: Added the *sort_dicts* parameter.

Changed in version 3.10: Added the *underscore_numbers* parameter.

Changed in version 3.11: No longer attempts to write to `sys.stdout` if it is `None`.

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights
>>> stuff.insert(0, stuff[:])
>>> pp = pprint.PrettyPrinter(indent=4)
>>> pp.pprint(stuff)
[   ['spam', 'eggs', 'lumberjack', 'knights', 'ni']
    'spam',
    'eggs',
    'lumberjack',
    'knights',
    'ni']
>>> pp = pprint.PrettyPrinter(width=41, compact=Tru
>>> pp.pprint(stuff)
[['spam', 'eggs', 'lumberjack',
  'knights', 'ni'],
 'spam', 'eggs', 'lumberjack', 'knights',
 'ni']
>>> tup = ('spam', ('eggs', ('lumberjack', ('knight
... ('parrot', ('fresh fruit',))))))))
>>> pp = pprint.PrettyPrinter(depth=6)
>>> pp.pprint(tup)
('spam', ('eggs', ('lumberjack', ('knights', ('ni',
```

pprint.pformat(*object*, *indent*=*1*, *width*=*80*, *depth*=*None*, ***, *compact*=*False*, *sort_dicts*=*True*, *underscore_numbers*=*False*)

Return the formatted representation of *object* as a string. *indent*, *width*, *depth*, *compact*, *sort_dicts* and *underscore_numbers* are passed to the **`PrettyPrinter`** constructor as formatting parameters and their meanings are as described in its documentation above.

pprint.pp(*object*, **args*, *sort_dicts*=*False*, ***kwargs*)

Prints the formatted representation of *object* followed by a newline. If *sort_dicts* is false (the default), dictionaries will be displayed with their keys in insertion order, otherwise the dict keys will be sorted. *args* and *kwargs* will be passed to **`pprint()`** as formatting parameters.

New in version 3.8.

pprint.pprint(*object*, *stream*=*None*, *indent*=*1*, *width*=*80*, *depth*=*None*, ***, *compact*=*False*, *sort_dicts*=*True*, *underscore_numbers*=*False*)

Prints the formatted representation of *object* on *stream*, followed by a newline. If *stream* is `None`, `sys.stdout` is used. This may be used in the interactive interpreter instead of the **`print()`** function for inspecting values (you can even reassign `print = pprint.pprint` for use within a scope).

The configuration parameters *stream*, *indent*, *width*, *depth*, *compact*, *sort_dicts* and *underscore_numbers* are passed to the **`PrettyPrinter`** constructor and their meanings are as described in its documentation above.

```
>>> import pprint
>>> stuff = ['spam', 'eggs', 'lumberjack', 'knights
>>> stuff.insert(0, stuff)
>>> pprint.pprint(stuff)
[<Recursion on list with id=...>,
 'spam',
 'eggs',
 'lumberjack',
 'knights',
 'ni']
```

pprint.isreadable(*object*)

Determine if the formatted representation of *object* is "readable", or can be used to reconstruct the value using **`eval()`**. This always returns `False` for recursive objects.

```
>>> pprint.isreadable(stuff)
False
```

pprint.isrecursive(*object*)

Determine if *object* requires a recursive representation.

One more support function is also defined:

pprint.saferepr(*object*)

Return a string representation of *object*, protected against recursive data structures. If the representation of *object* exposes a recursive entry, the recursive reference will be represented as `<Recursion on typename with id=number>`. The representation is not otherwise formatted.

```
>>> pprint.saferepr(stuff)
"[<Recursion on list with id=...>, 'spam', 'eggs',
```

PrettyPrinter Objects

`PrettyPrinter` instances have the following methods:

PrettyPrinter.pformat(*object*)

Return the formatted representation of *object*. This takes into account the options passed to the **`PrettyPrinter`** constructor.

PrettyPrinter.pprint(*object*)

Print the formatted representation of *object* on the configured stream, followed by a newline.

The following methods provide the implementations for the corresponding functions of the same names. Using these methods on an instance is slightly more efficient since new **`PrettyPrinter`** objects don't need to be created.

PrettyPrinter.isreadable(*object*)

Determine if the formatted representation of the object is "readable," or can be used to reconstruct the value using **`eval()`**. Note that this returns `False` for recursive objects. If the *depth* parameter of the **`PrettyPrinter`** is set and the object is deeper than allowed, this returns `False`.

PrettyPrinter.isrecursive(*object*)

Determine if the object requires a recursive representation.

This method is provided as a hook to allow subclasses to modify the way objects are converted to strings. The default implementation uses the internals of the **`saferepr()`** implementation.

PrettyPrinter.format(*object*, *context*, *maxlevels*, *level*)

Returns three values: the formatted version of *object* as a string, a flag indicating whether the result is readable, and a flag indicating whether recursion was detected. The first argument is the object to be presented. The second is a dictionary which contains the **`id()`** of objects that are part of the current presentation context (direct and indirect containers for *object* that are affecting the presentation) as the keys; if an object needs to be presented which is already represented in *context*, the third return value should be `True`. Recursive calls to the **`format()`** method should add additional entries for containers to this dictionary. The third argument, *maxlevels*, gives the requested limit to recursion; this will be `0` if there is no requested limit. This argument should be passed unmodified to recursive calls. The fourth argument, *level*, gives the current level; recursive calls should be passed a value less than that of the current call.

Example

To demonstrate several uses of the **`pprint()`** function and its parameters, let's fetch information about a project from PyPI [https://pypi.org]:

```
>>> import json
>>> import pprint
>>> from urllib.request import urlopen
>>> with urlopen('https://pypi.org/pypi/sampleproject/js
...     project_info = json.load(resp)['info']
```

In its basic form, **`pprint()`** shows the whole object:

```
>>> pprint.pprint(project_info)
```

```

`reprlib` — Alternate `repr()` implementation

Source code: Lib/reprlib.py [https://github.com/python/cpython/tree/3.11/Lib/reprlib.py]

The `reprlib` module provides a means for producing object representations with limits on the size of the resulting strings. This is used in the Python debugger and may be useful in other contexts as well.

This module provides a class, an instance, and a function:

class reprlib.Repr

Class which provides formatting services useful in implementing functions similar to the built-in `repr()`; size limits for different object types are added to avoid the generation of representations which are excessively long.

reprlib.aRepr

This is an instance of `Repr` which is used to provide the `repr()` function described below. Changing the attributes of this object will affect the size limits used by `repr()` and the Python debugger.

reprlib.repr(*obj*)

This is the `repr()` method of `aRepr`. It returns a string similar to that returned by the built-in function of the same name, but with limits on most sizes.

In addition to size-limiting tools, the module also provides a decorator for detecting recursive calls to `__repr__()` and substituting a placeholder string instead.

@reprlib.recursive_repr(*fillvalue='...'*)

Decorator for **`__repr__()`** methods to detect recursive calls within the same thread. If a recursive call is made, the *fillvalue* is returned, otherwise, the usual **`__repr__()`** call is made. For example:

```
>>> from reprlib import recursive_repr
>>> class MyList(list):
...     @recursive_repr()
...     def __repr__(self):
...         return '<' + '|'.join(map(repr, self)) + '>'
...
>>> m = MyList('abc')
>>> m.append(m)
>>> m.append('x')
>>> print(m)
<'a'|'b'|'c'|...|'x'>
```

New in version 3.2.

Repr Objects

`Repr` instances provide several attributes which can be used to provide size limits for the representations of different object types, and methods which format specific object types.

Repr.fillvalue

This string is displayed for recursive references. It defaults to `...`.

New in version 3.11.

Repr.maxlevel

Depth limit on the creation of recursive representations. The default is `6`.

Repr.maxdict
Repr.maxlist

Repr.maxtuple
Repr.maxset
Repr.maxfrozenset
Repr.maxdeque
Repr.maxarray

Limits on the number of entries represented for the named object type. The default is `4` for **`maxdict`**, `5` for **`maxarray`**, and `6` for the others.

Repr.maxlong

Maximum number of characters in the representation for an integer. Digits are dropped from the middle. The default is `40`.

Repr.maxstring

Limit on the number of characters in the representation of the string. Note that the "normal" representation of the string is used as the character source: if escape sequences are needed in the representation, these may be mangled when the representation is shortened. The default is `30`.

Repr.maxother

This limit is used to control the size of object types for which no specific formatting method is available on the **`Repr`** object. It is applied in a similar manner as **`maxstring`**. The default is `20`.

Repr.repr(*obj*)

The equivalent to the built-in **`repr()`** that uses the formatting imposed by the instance.

Repr.repr1(*obj*, *level*)

Recursive implementation used by **`repr()`**. This uses the type of *obj* to determine which formatting method to call, passing it *obj* and *level*. The type-specific methods should call **`repr1()`** to perform recursive formatting, with `level - 1` for the value of *level* in the recursive call.

Repr.repr_TYPE(*obj*, *level*)

Formatting methods for specific types are implemented as methods with a name based on the type name. In the method name, **TYPE** is replaced by `'_'.join(type(obj).__name__.split())`. Dispatch to these methods is handled by **`repr1()`**. Type-specific methods which need to recursively format a value should call `self.repr1(subobj, level - 1)`.

Subclassing Repr Objects

The use of dynamic dispatching by **`Repr.repr1()`** allows subclasses of **`Repr`** to add support for additional built-in object types or to modify the handling of types already supported. This example shows how special support for file objects could be added:

```
import reprlib
import sys

class MyRepr(reprlib.Repr):

    def repr_TextIOWrapper(self, obj, level):
        if obj.name in {'<stdin>', '<stdout>', '<stderr>
            return obj.name
        return repr(obj)

aRepr = MyRepr()
print(aRepr.repr(sys.stdin))          # prints '<stdin>'
```

`enum` — Support for enumerations

New in version 3.4.

Source code: Lib/enum.py [https://github.com/python/cpython/tree/3.11/Lib/enum.py]

Important

This page contains the API reference information. For tutorial information and discussion of more advanced topics, see

- Basic Tutorial
- Advanced Tutorial
- Enum Cookbook

An enumeration:

- is a set of symbolic names (members) bound to unique values
- can be iterated over to return its canonical (i.e. non-alias) members in definition order
- uses *call* syntax to return members by value
- uses *index* syntax to return members by name

Enumerations are created either by using `class` syntax, or by using function-call syntax:

```
>>> from enum import Enum

>>> # class syntax
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

```
>>> # functional syntax
>>> Color = Enum('Color', ['RED', 'GREEN', 'BLUE'])
```

Even though we can use `class` syntax to create Enums, Enums are not normal Python classes. See How are Enums different? for more details.

Note

Nomenclature

- The class `Color` is an *enumeration* (or *enum*)
- The attributes `Color.RED`, `Color.GREEN`, etc., are *enumeration members* (or *members*) and are functionally constants.
- The enum members have *names* and *values* (the name of `Color.RED` is `RED`, the value of `Color.BLUE` is `3`, etc.)

Module Contents

`EnumType`

The `type` for Enum and its subclasses.

`Enum`

Base class for creating enumerated constants.

`IntEnum`

Base class for creating enumerated constants that are also subclasses of `int`. (Notes)

`StrEnum`

Base class for creating enumerated constants that are also subclasses of **`str`**. (Notes)

`Flag`

Base class for creating enumerated constants that can be combined using the bitwise operations without losing their **`Flag`** membership.

`IntFlag`

Base class for creating enumerated constants that can be combined using the bitwise operators without losing their **`IntFlag`** membership. **`IntFlag`** members are also subclasses of **`int`**. (Notes)

`ReprEnum`

Used by **`IntEnum`**, **`StrEnum`**, and **`IntFlag`** to keep the **`str()`** of the mixed-in type.

`EnumCheck`

An enumeration with the values `CONTINUOUS`, `NAMED_FLAGS`, and `UNIQUE`, for use with **`verify()`** to ensure various constraints are met by a given enumeration.

`FlagBoundary`

An enumeration with the values `STRICT`, `CONFORM`, `EJECT`, and `KEEP` which allows for more fine-grained control over how invalid values are dealt with in an

enumeration.

auto

Instances are replaced with an appropriate value for Enum members. **StrEnum** defaults to the lower-cased version of the member name, while other Enums default to 1 and increase from there.

property()

Allows **Enum** members to have attributes without conflicting with member names.

unique()

Enum class decorator that ensures only one name is bound to any one value.

verify()

Enum class decorator that checks user-selectable constraints on an enumeration.

member()

Make `obj` a member. Can be used as a decorator.

nonmember()

Do not make `obj` a member. Can be used as a decorator.

global_enum()

Modify the **str()** and **repr()** of

an enum to show its members as belonging to the module instead of its class. Should only be used if the enum members will be exported to the module global namespace.

show_flag_values()

Return a list of all power-of-two integers contained in a flag.

New in version 3.6: `Flag`, `IntFlag`, `auto`

New in version 3.11: `StrEnum`, `EnumCheck`, `ReprEnum`, `FlagBoundary`, `property`, `member`, `nonmember`, `global_enum`, `show_flag_values`

Data Types

class enum.EnumType

EnumType is the metaclass for *enum* enumerations. It is possible to subclass *EnumType* – see Subclassing EnumType for details.

EnumType is responsible for setting the correct **__repr__()**, **__str__()**, **__format__()**, and **__reduce__()** methods on the final *enum*, as well as creating the enum members, properly handling duplicates, providing iteration over the enum class, etc.

contains(*cls*, *member*)

Returns `True` if member belongs to the `cls`:

```
>>> some_var = Color.RED
>>> some_var in Color
True
```

Note

In Python 3.12 it will be possible to check for member values and not just members; until then, a `TypeError` will be raised if a non-Enum-member is used in a containment check.

dir(*cls*)

Returns `['__class__', '__doc__', '__members__', '__module__']` and the names of the members in *cls*:

```
>>> dir(Color)
['BLUE', 'GREEN', 'RED', '__class__', '__contai
```

getattr(*cls*, *name*)

Returns the Enum member in *cls* matching *name*, or raises an **AttributeError**:

```
>>> Color.GREEN
<Color.GREEN: 2>
```

getitem(*cls*, *name*)

Returns the Enum member in *cls* matching *name*, or raises a **KeyError**:

```
>>> Color['BLUE']
<Color.BLUE: 3>
```

iter(*cls*)

Returns each member in *cls* in definition order:

```
>>> list(Color)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE:
```

len(*cls*)

Returns the number of member in *cls*:

```
>>> len(Color)
3
```

reversed(*cls*)

Returns each member in *cls* in reverse definition order:

```
>>> list(reversed(Color))
[<Color.BLUE: 3>, <Color.GREEN: 2>, <Color.RED:
```

class enum.Enum

Enum is the base class for all *enum* enumerations.

name

The name used to define the `Enum` member:

```
>>> Color.BLUE.name
'BLUE'
```

value

The value given to the `Enum` member:

```
>>> Color.RED.value
1
```

Note

Enum member values

Member values can be anything: **`int`**, **`str`**, etc. If the exact value is unimportant you may use **`auto`** instances and an appropriate value will be chosen for you. See **`auto`** for the details.

ignore

`_ignore_` is only used during creation and is removed from the enumeration once creation is complete.

`_ignore_` is a list of names that will not become

members, and whose names will also be removed from the completed enumeration. See TimePeriod for an example.

call(*cls*, *value*, *names=None*, ***, *module=None*, *qualname=None*, *type=None*, *start=1*, *boundary=None*)

This method is called in two different ways:

- to look up an existing member:

  cls
  : The enum class being called.

  value
  : The value to lookup.

- to use the `cls` enum to create a new enum:

  cls
  : The enum class being called.

  value
  : The name of the new Enum to create.

  names
  : The names/values of the members for the new Enum.

  module
  : The name of the module the new Enum is

created in.

qualname

The actual location in the module where this Enum can be found.

type

A mix-in type for the new Enum.

start

The first integer value for the Enum (used by **`auto`**).

boundary

How to handle out-of-range values from bit operations (**`Flag`** only).

dir(*self*)

Returns `['__class__', '__doc__', '__module__', 'name', 'value']` and any public methods defined on *self._class_*:

```
>>> from datetime import date
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
```

```
...     SATURDAY = 6
...     SUNDAY = 7
...     @classmethod
...     def today(cls):
...         print('today is %s' % cls(date.toda
>>> dir(Weekday.SATURDAY)
['__class__', '__doc__', '__eq__', '__hash__',
```

_generate_next_value_(*name*, *start*, *count*, *last_values*)

name
: The name of the member being defined (e.g. 'RED').

start
: The start value for the Enum; the default is 1.

count
: The number of members currently defined, not including this one.

last_values
: A list of the previous values.

A *staticmethod* that is used to determine the next value returned by **auto**:

```
>>> from enum import auto
>>> class PowersOfThree(Enum):
...     @staticmethod
...     def _generate_next_value_(name, start,
...         return 3 ** (count + 1)
...     FIRST = auto()
...     SECOND = auto()
>>> PowersOfThree.SECOND.value
```

_init_subclass_(*cls*, ***kwds*)

A *classmethod* that is used to further configure subsequent subclasses. By default, does nothing.

missing(*cls*, *value*)

A *classmethod* for looking up values not found in *cls*. By default it does nothing, but can be overridden to implement custom search behavior:

```
>>> from enum import StrEnum
>>> class Build(StrEnum):
...     DEBUG = auto()
...     OPTIMIZED = auto()
...     @classmethod
...     def _missing_(cls, value):
...         value = value.lower()
...         for member in cls:
...             if member.value == value:
...                 return member
...         return None
>>> Build.DEBUG.value
'debug'
>>> Build('deBUG')
<Build.DEBUG: 'debug'>
```

repr(*self*)

Returns the string used for *repr()* calls. By default, returns the *Enum* name, member name, and value, but can be overridden:

```
>>> class OtherStyle(Enum):
...     ALTERNATE = auto()
...     OTHER = auto()
...     SOMETHING_ELSE = auto()
...     def __repr__(self):
...         cls_name = self.__class__.__name__
```

```
...         return f'{cls_name}.{self.name}'
>>> OtherStyle.ALTERNATE, str(OtherStyle.ALTERN
(OtherStyle.ALTERNATE, 'OtherStyle.ALTERNATE',
```

str(*self*)

Returns the string used for *str()* calls. By default, returns the *Enum* name and member name, but can be overridden:

```
>>> class OtherStyle(Enum):
...     ALTERNATE = auto()
...     OTHER = auto()
...     SOMETHING_ELSE = auto()
...     def __str__(self):
...         return f'{self.name}'
>>> OtherStyle.ALTERNATE, str(OtherStyle.ALTERN
(<OtherStyle.ALTERNATE: 1>, 'ALTERNATE', 'ALTER
```

format(*self*)

Returns the string used for *format()* and *f-string* calls. By default, returns **`__str__()`** return value, but can be overridden:

```
>>> class OtherStyle(Enum):
...     ALTERNATE = auto()
...     OTHER = auto()
...     SOMETHING_ELSE = auto()
...     def __format__(self, spec):
...         return f'{self.name}'
>>> OtherStyle.ALTERNATE, str(OtherStyle.ALTERN
(<OtherStyle.ALTERNATE: 1>, 'OtherStyle.ALTERNA
```

Note

Using **`auto`** with **`Enum`** results in integers of increasing value, starting with `1`.

class enum.IntEnum

IntEnum is the same as *Enum*, but its members are also integers and can be used anywhere that an integer can be used. If any integer operation is performed with an *IntEnum* member, the resulting value loses its enumeration status.

```
>>> from enum import IntEnum
>>> class Numbers(IntEnum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
>>> Numbers.THREE
<Numbers.THREE: 3>
>>> Numbers.ONE + Numbers.TWO
3
>>> Numbers.THREE + 5
8
>>> Numbers.THREE == 3
True
```

Note

Using `auto` with `IntEnum` results in integers of increasing value, starting with `1`.

Changed in version 3.11: **`__str__()`** is now **`int.__str__()`** to better support the *replacement of existing constants* use-case. **`__format__()`** was already **`int.__format__()`** for that same reason.

class enum.StrEnum

StrEnum is the same as *Enum*, but its members are also strings and can be used in most of the same places that a string can be used. The result of any string operation performed on or with a *StrEnum* member is not part of the enumeration.

Note

There are places in the stdlib that check for an exact `str`

instead of a **str** subclass (i.e. `type(unknown) == str` instead of `isinstance(unknown, str)`), and in those locations you will need to use `str(StrEnum.member)`.

Note

Using **auto** with **StrEnum** results in the lower-cased member name as the value.

Note

__str__() is **str.__str__()** to better support the *replacement of existing constants* use-case. **__format__()** is likewise **str.__format__()** for that same reason.

New in version 3.11.

class enum.Flag

Flag members support the bitwise operators `&` (*AND*), `|` (*OR*), `^` (*XOR*), and `~` (*INVERT*); the results of those operators are members of the enumeration.

contains(*self*, *value*)

Returns *True* if value is in self:

```
>>> from enum import Flag, auto
>>> class Color(Flag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> purple = Color.RED | Color.BLUE
>>> white = Color.RED | Color.GREEN | Color.BLU
>>> Color.GREEN in purple
False
>>> Color.GREEN in white
True
>>> purple in white
True
```

```
>>> white in purple
False
```

iter(self):

Returns all contained non-alias members:

```
>>> list(Color.RED)
[<Color.RED: 1>]
>>> list(purple)
[<Color.RED: 1>, <Color.BLUE: 4>]
```

Changed in version 3.11: Aliases are no longer returned during iteration.

len(self):

Returns number of members in flag:

```
>>> len(Color.GREEN)
1
>>> len(white)
3
```

bool(self):

Returns *True* if any members in flag, *False* otherwise:

```
>>> bool(Color.GREEN)
True
>>> bool(white)
True
>>> black = Color(0)
>>> bool(black)
False
```

_or_(*self*, *other*)

Returns current flag binary or'ed with other:

```
>>> Color.RED | Color.GREEN
<Color.RED|GREEN: 3>
```

and(*self*, *other*)

Returns current flag binary and'ed with other:

```
>>> purple & white
<Color.RED|BLUE: 5>
>>> purple & Color.GREEN
<Color: 0>
```

xor(*self*, *other*)

Returns current flag binary xor'ed with other:

```
>>> purple ^ white
<Color.GREEN: 2>
>>> purple ^ Color.GREEN
<Color.RED|GREEN|BLUE: 7>
```

invert(self):

Returns all the flags in *type(self)* that are not in self:

```
>>> ~white
<Color: 0>
>>> ~purple
<Color.GREEN: 2>
>>> ~Color.RED
<Color.GREEN|BLUE: 6>
```

_numeric_repr_()

Function used to format any remaining unnamed numeric values. Default is the value's repr; common choices are `hex()` and `oct()`.

Note

Using `auto` with `Flag` results in integers that are powers of two, starting with `1`.

Changed in version 3.11: The *repr()* of zero-valued flags has changed. It is now::

```
>>> Color(0)
<Color: 0>
```

class enum.IntFlag

IntFlag is the same as *Flag*, but its members are also integers and can be used anywhere that an integer can be used.

```
>>> from enum import IntFlag, auto
>>> class Color(IntFlag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> Color.RED & 2
<Color: 0>
>>> Color.RED | 2
<Color.RED|GREEN: 3>
```

If any integer operation is performed with an *IntFlag* member, the result is not an *IntFlag*:

```
>>> Color.RED + 2
3
```

If a *Flag* operation is performed with an *IntFlag* member and:

- the result is a valid *IntFlag*: an *IntFlag* is returned
- the result is not a valid *IntFlag*: the result depends on the *FlagBoundary* setting

The *repr()* of unnamed zero-valued flags has changed. It is now:

```
>>> Color(0)
<Color: 0>
```

Note

Using `auto` with `IntFlag` results in integers that are

powers of two, starting with `1`.

Changed in version 3.11: **`__str__()`** is now **`int.__str__()`** to better support the *replacement of existing constants* use-case. **`__format__()`** was already **`int.__format__()`** for that same reason.

Inversion of an **`IntFlag`** now returns a positive value that is the union of all flags not in the given flag, rather than a negative value. This matches the existing **`Flag`** behavior.

class enum.ReprEnum

`ReprEum` uses the **`repr()`** of **`Enum`**, but the **`str()`** of the mixed-in data type:

- **`int.__str__()`** for **`IntEnum`** and **`IntFlag`**
- **`str.__str__()`** for **`StrEnum`**

Inherit from **`ReprEnum`** to keep the **`str()`** / **`format()`** of the mixed-in data type instead of using the **`Enum`**-default **`str()`**.

New in version 3.11.

class enum.EnumCheck

EnumCheck contains the options used by the **`verify()`** decorator to ensure various constraints; failed constraints result in a **`ValueError`**.

UNIQUE

Ensure that each value has only one name:

```
>>> from enum import Enum, verify, UNIQUE
>>> @verify(UNIQUE)
... class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

```
...     CRIMSON = 1
Traceback (most recent call last):
...
ValueError: aliases found in <enum 'Color'>: CR
```

CONTINUOUS

Ensure that there are no missing values between the lowest-valued member and the highest-valued member:

```
>>> from enum import Enum, verify, CONTINUOUS
>>> @verify(CONTINUOUS)
... class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 5
Traceback (most recent call last):
...
ValueError: invalid enum 'Color': missing value
```

NAMED_FLAGS

Ensure that any flag groups/masks contain only named flags – useful when values are specified instead of being generated by `auto()`:

```
>>> from enum import Flag, verify, NAMED_FLAGS
>>> @verify(NAMED_FLAGS)
... class Color(Flag):
...     RED = 1
...     GREEN = 2
...     BLUE = 4
...     WHITE = 15
...     NEON = 31
Traceback (most recent call last):
...
ValueError: invalid Flag 'Color': aliases WHITE
```

Note

CONTINUOUS and NAMED_FLAGS are designed to work

with integer-valued members.

New in version 3.11.

class enum.FlagBoundary

FlagBoundary controls how out-of-range values are handled in *Flag* and its subclasses.

STRICT

Out-of-range values cause a **ValueError** to be raised. This is the default for **Flag**:

```
>>> from enum import Flag, STRICT
>>> class StrictFlag(Flag, boundary=STRICT):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> StrictFlag(2**2 + 2**4)
Traceback (most recent call last):
...
ValueError: <flag 'StrictFlag'> invalid value 2
    given 0b0 10100
  allowed 0b0 00111
```

CONFORM

Out-of-range values have invalid values removed, leaving a valid *Flag* value:

```
>>> from enum import Flag, CONFORM
>>> class ConformFlag(Flag, boundary=CONFORM):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> ConformFlag(2**2 + 2**4)
<ConformFlag.BLUE: 4>
```

EJECT

Out-of-range values lose their *Flag* membership and

revert to **int**. This is the default for **IntFlag**:

```
>>> from enum import Flag, EJECT
>>> class EjectFlag(Flag, boundary=EJECT):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> EjectFlag(2**2 + 2**4)
20
```

KEEP

Out-of-range values are kept, and the *Flag* membership is kept. This is used for some stdlib flags:

```
>>> from enum import Flag, KEEP
>>> class KeepFlag(Flag, boundary=KEEP):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
>>> KeepFlag(2**2 + 2**4)
<KeepFlag.BLUE|16: 20>
```

New in version 3.11.

Supported **__dunder__** names

__members__ is a read-only ordered mapping of `member_name:member` items. It is only available on the class.

__new__(), if specified, must create and return the enum members; it is also a very good idea to set the member's **_value_** appropriately. Once all the members are created it is no longer used.

Supported **_sunder_** names

- `_name_` – name of the member

- `_value_` – value of the member; can be set / modified in `__new__`
- `_missing_` – a lookup function used when a value is not found; may be overridden
- `_ignore_` – a list of names, either as a **`list`** or a **`str`**, that will not be transformed into members, and will be removed from the final class
- `_order_` – used in Python 2/3 code to ensure member order is consistent (class attribute, removed during class creation)
- `_generate_next_value_` – used to get an appropriate value for an enum member; may be overridden

> **Note**
>
> For standard **`Enum`** classes the next value chosen is the last value seen incremented by one.
>
> For **`Flag`** classes the next value chosen will be the next highest power-of-two, regardless of the last value seen.

New in version 3.6: `_missing_`, `_order_`, `_generate_next_value_`

New in version 3.7: `_ignore_`

Utilities and Decorators

class enum.auto

> *auto* can be used in place of a value. If used, the *Enum* machinery will call an *Enum*'s **`_generate_next_value_()`** to get an appropriate value. For *Enum* and *IntEnum* that

appropriate value will be the last value plus one; for *Flag* and *IntFlag* it will be the first power-of-two greater than the last value; for *StrEnum* it will be the lower-cased version of the member's name. Care must be taken if mixing *auto()* with manually specified values.

auto instances are only resolved when at the top level of an assignment:

- `FIRST = auto()` will work (auto() is replaced with `1`);
- `SECOND = auto(), -2` will work (auto is replaced with `2`, so `2, -2` is used to create the `SECOND` enum member;
- `THREE = [auto(), -3]` will *not* work (`<auto instance>, -3` is used to create the `THREE` enum member)

Changed in version 3.11.1: In prior versions, `auto()` had to be the only thing on the assignment line to work properly.

`_generate_next_value_` can be overridden to customize the values used by *auto*.

Note

in 3.13 the default `"generate_next_value_` will always return the highest member value incremented by 1, and will fail if any member is an incompatible type.

@enum.property

A decorator similar to the built-in *property*, but specifically for enumerations. It allows member attributes to have the same names as members themselves.

Note

the *property* and the member must be defined in separate classes; for example, the *value* and *name* attributes are defined in the *Enum* class, and *Enum* subclasses can define members with the names `value` and `name`.

New in version 3.11.

@enum.unique

A **`class`** decorator specifically for enumerations. It searches an enumeration's **`__members__`**, gathering any aliases it finds; if any are found **`ValueError`** is raised with the details:

```
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
...     FOUR = 3
...
Traceback (most recent call last):
...
ValueError: duplicate values found in <enum 'Mistak
```

@enum.verify

A **`class`** decorator specifically for enumerations. Members from **`EnumCheck`** are used to specify which constraints should be checked on the decorated enumeration.

New in version 3.11.

@enum.member

A decorator for use in enums: its target will become a member.

New in version 3.11.

@enum.nonmember

A decorator for use in enums: its target will not become a member.

New in version 3.11.

@enum.global_enum

A decorator to change the **str()** and **repr()** of an enum to show its members as belonging to the module instead of its class. Should only be used when the enum members are exported to the module global namespace (see **re.RegexFlag** for an example).

New in version 3.11.

enum.show_flag_values(*value*)

Return a list of all power-of-two integers contained in a flag *value*.

New in version 3.11.

Notes

IntEnum, **StrEnum**, and **IntFlag**

These three enum types are designed to be drop-in replacements for existing integer- and string-based values; as such, they have extra limitations:

- `__str__` uses the value and not the name of the enum member
- `__format__`, because it uses `__str__`, will also use the value of the enum member instead of its name

If you do not need/want those limitations, you can either create your own base class by mixing in the `int` or `str` type yourself:

```
>>> from enum import Enum
>>> class MyIntEnum(int, Enum):
...     pass
```

or you can reassign the appropriate **`str()`**, etc., in your enum:

```
>>> from enum import IntEnum
>>> class MyIntEnum(IntEnum):
...     __str__ = IntEnum.__str__
```

`graphlib` — Functionality to operate with graph-like structures

Source code: Lib/graphlib.py [https://github.com/python/cpython/tree/3.11/Lib/graphlib.py]

---

class graphlib.TopologicalSorter(*graph=None*)

Provides functionality to topologically sort a graph of hashable nodes.

A topological order is a linear ordering of the vertices in a graph such that for every directed edge u -> v from vertex u to vertex v, vertex u comes before vertex v in the ordering. For instance, the vertices of the graph may represent tasks to be performed, and the edges may represent constraints that one task must be performed before another; in this example, a topological ordering is just a valid sequence for the tasks. A complete topological ordering is possible if and only if the graph has no directed cycles, that is, if it is a directed acyclic graph.

If the optional *graph* argument is provided it must be a dictionary representing a directed acyclic graph where the keys are nodes and the values are iterables of all predecessors of that node in the graph (the nodes that have edges that point to the value in the key). Additional nodes can be added to the graph using the `add()` method.

In the general case, the steps required to perform the sorting of a given graph are as follows:

- Create an instance of the `TopologicalSorter` with an

optional initial graph.
- Add additional nodes to the graph.
- Call **`prepare()`** on the graph.
- While **`is_active()`** is `True`, iterate over the nodes returned by **`get_ready()`** and process them. Call **`done()`** on each node as it finishes processing.

In case just an immediate sorting of the nodes in the graph is required and no parallelism is involved, the convenience method **`TopologicalSorter.static_order()`** can be used directly:

```
>>> graph = {"D": {"B", "C"}, "C": {"A"}, "B": {"A"
>>> ts = TopologicalSorter(graph)
>>> tuple(ts.static_order())
('A', 'C', 'B', 'D')
```

The class is designed to easily support parallel processing of the nodes as they become ready. For instance:

```
topological_sorter = TopologicalSorter()

# Add nodes to 'topological_sorter'...

topological_sorter.prepare()
while topological_sorter.is_active():
    for node in topological_sorter.get_ready():
        # Worker threads or processes take nodes to
        # 'task_queue' queue.
        task_queue.put(node)

    # When the work for a node is done, workers put
    # 'finalized_tasks_queue' so we can get more no
    # The definition of 'is_active()' guarantees th
    # least one node has been placed on 'task_queue
    # been passed to 'done()', so this blocking 'ge
    # succeed.  After calling 'done()', we loop bac
    # again, so put newly freed nodes on 'task_queu
```

```
    # logically possible.
    node = finalized_tasks_queue.get()
    topological_sorter.done(node)
```

add(*node*, **predecessors*)

Add a new node and its predecessors to the graph. Both the *node* and all elements in *predecessors* must be hashable.

If called multiple times with the same node argument, the set of dependencies will be the union of all dependencies passed in.

It is possible to add a node with no dependencies (*predecessors* is not provided) or to provide a dependency twice. If a node that has not been provided before is included among *predecessors* it will be automatically added to the graph with no predecessors of its own.

Raises **`ValueError`** if called after **`prepare()`**.

prepare()

Mark the graph as finished and check for cycles in the graph. If any cycle is detected, **`CycleError`** will be raised, but **`get_ready()`** can still be used to obtain as many nodes as possible until cycles block more progress. After a call to this function, the graph cannot be modified, and therefore no more nodes can be added using **`add()`**.

is_active()

Returns `True` if more progress can be made and `False` otherwise. Progress can be made if cycles do not block the resolution and either there are still nodes ready that haven't yet been returned by **`TopologicalSorter.get_ready()`** or the number of nodes marked **`TopologicalSorter.done()`** is less than the number that have been returned by

TopologicalSorter.get_ready().

The **__bool__()** method of this class defers to this function, so instead of:

```
if ts.is_active():
    ...
```

it is possible to simply do:

```
if ts:
    ...
```

Raises **ValueError** if called without calling **prepare()** previously.

done(**nodes*)

Marks a set of nodes returned by **TopologicalSorter.get_ready()** as processed, unblocking any successor of each node in *nodes* for being returned in the future by a call to **TopologicalSorter.get_ready()**.

Raises **ValueError** if any node in *nodes* has already been marked as processed by a previous call to this method or if a node was not added to the graph by using **TopologicalSorter.add()**, if called without calling **prepare()** or if node has not yet been returned by **get_ready()**.

get_ready()

Returns a `tuple` with all the nodes that are ready. Initially it returns all nodes with no predecessors, and once those are marked as processed by calling **TopologicalSorter.done()**, further calls will return all new nodes that have all their predecessors already processed. Once no more progress can be made, empty tuples are returned.

Raises **ValueError** if called without calling

prepare() previously.

static_order()

Returns an iterator object which will iterate over nodes in a topological order. When using this method, **prepare()** and **done()** should not be called. This method is equivalent to:

```
def static_order(self):
    self.prepare()
    while self.is_active():
        node_group = self.get_ready()
        yield from node_group
        self.done(*node_group)
```

The particular order that is returned may depend on the specific order in which the items were inserted in the graph. For example:

```
>>> ts = TopologicalSorter()
>>> ts.add(3, 2, 1)
>>> ts.add(1, 0)
>>> print([*ts.static_order()])
[2, 0, 1, 3]

>>> ts2 = TopologicalSorter()
>>> ts2.add(1, 0)
>>> ts2.add(3, 2, 1)
>>> print([*ts2.static_order()])
[0, 2, 1, 3]
```

This is due to the fact that “0” and “2” are in the same level in the graph (they would have been returned in the same call to **get_ready()**) and the order between them is determined by the order of insertion.

If any cycle is detected, **CycleError** will be raised.

New in version 3.9.

Exceptions

The `graphlib` module defines the following exception classes:

exception graphlib.CycleError

Subclass of `ValueError` raised by `TopologicalSorter.prepare()` if cycles exist in the working graph. If multiple cycles exist, only one undefined choice among them will be reported and included in the exception.

The detected cycle can be accessed via the second element in the `args` attribute of the exception instance and consists in a list of nodes, such that each node is, in the graph, an immediate predecessor of the next node in the list. In the reported list, the first and the last node will be the same, to make it clear that it is cyclic.

Numeric and Mathematical Modules

The modules described in this chapter provide numeric and math-related functions and data types. The **numbers** module defines an abstract hierarchy of numeric types. The **math** and **cmath** modules contain various mathematical functions for floating-point and complex numbers. The **decimal** module supports exact representations of decimal numbers, using arbitrary precision arithmetic.

The following modules are documented in this chapter:

- **numbers** — Numeric abstract base classes
  - The numeric tower
  - Notes for type implementors
    - Adding More Numeric ABCs
    - Implementing the arithmetic operations
- **math** — Mathematical functions
  - Number-theoretic and representation functions
  - Power and logarithmic functions
  - Trigonometric functions
  - Angular conversion
  - Hyperbolic functions
  - Special functions
  - Constants
- **cmath** — Mathematical functions for complex numbers
  - Conversions to and from polar coordinates
  - Power and logarithmic functions
  - Trigonometric functions

- Hyperbolic functions
- Classification functions
- Constants

- **`decimal`** — Decimal fixed point and floating point arithmetic
  - Quick-start Tutorial
  - Decimal objects
    - Logical operands
  - Context objects
  - Constants
  - Rounding modes
  - Signals
  - Floating Point Notes
    - Mitigating round-off error with increased precision
    - Special values
  - Working with threads
  - Recipes
  - Decimal FAQ
- **`fractions`** — Rational numbers
- **`random`** — Generate pseudo-random numbers
  - Bookkeeping functions
  - Functions for bytes
  - Functions for integers
  - Functions for sequences
  - Real-valued distributions
  - Alternative Generator
  - Notes on Reproducibility
  - Examples
  - Recipes
- **`statistics`** — Mathematical statistics functions
  - Averages and measures of central location
  - Measures of spread

- Statistics for relations between two inputs
- Function details
- Exceptions
- `NormalDist` objects
  - `NormalDist` Examples and Recipes

`numbers` — Numeric abstract base classes

Source code: Lib/numbers.py [https://github.com/python/cpython/tree/3.11/Lib/numbers.py]

The `numbers` module (**PEP 3141** [https://peps.python.org/pep-3141/]) defines a hierarchy of numeric abstract base classes which progressively define more operations. None of the types defined in this module are intended to be instantiated.

class numbers.Number

The root of the numeric hierarchy. If you just want to check if an argument *x* is a number, without caring what kind, use `isinstance(x, Number)`.

The numeric tower

class numbers.Complex

Subclasses of this type describe complex numbers and include the operations that work on the built-in `complex` type. These are: conversions to `complex` and `bool`, `real`, `imag`, `+`, `-`, `*`, `/`, `**`, `abs()`, `conjugate()`, `==`, and `!=`. All except `-` and `!=` are abstract.

real

Abstract. Retrieves the real component of this number.

imag

Abstract. Retrieves the imaginary component of this number.

abstractmethod conjugate()

Abstract. Returns the complex conjugate. For example, `(1+3j).conjugate() == (1-3j)`.

class numbers.Real

To **`Complex`**, **`Real`** adds the operations that work on real numbers.

In short, those are: a conversion to **`float`**, **`math.trunc()`**, **`round()`**, **`math.floor()`**, **`math.ceil()`**, **`divmod()`**, `//`, `%`, `<`, `<=`, `>`, and `>=`.

Real also provides defaults for **`complex()`**, **`real`**, **`imag`**, and **`conjugate()`**.

class numbers.Rational

Subtypes **`Real`** and adds **`numerator`** and **`denominator`** properties. It also provides a default for **`float()`**.

The **`numerator`** and **`denominator`** values should be instances of **`Integral`** and should be in lowest terms with **`denominator`** positive.

numerator

Abstract.

denominator

Abstract.

class numbers.Integral

Subtypes **`Rational`** and adds a conversion to **`int`**. Provides defaults for **`float()`**, **`numerator`**, and **`denominator`**. Adds abstract methods for **`pow()`** with modulus and bit-string operations: `<<`, `>>`, `&`, `^`, `|`, `~`.

Notes for type implementors

Implementors should be careful to make equal numbers equal and hash them to the same values. This may be subtle if there are two

different extensions of the real numbers. For example, **`fractions.Fraction`** implements **`hash()`** as follows:

```
def __hash__(self):
    if self.denominator == 1:
        # Get integers right.
        return hash(self.numerator)
    # Expensive check, but definitely correct.
    if self == float(self):
        return hash(float(self))
    else:
        # Use tuple's hash to avoid a high collision rat
        # simple fractions.
        return hash((self.numerator, self.denominator))
```

Adding More Numeric ABCs

There are, of course, more possible ABCs for numbers, and this would be a poor hierarchy if it precluded the possibility of adding those. You can add `MyFoo` between **`Complex`** and **`Real`** with:

```
class MyFoo(Complex): ...
MyFoo.register(Real)
```

Implementing the arithmetic operations

We want to implement the arithmetic operations so that mixed-mode operations either call an implementation whose author knew about the types of both arguments, or convert both to the nearest built in type and do the operation there. For subtypes of **`Integral`**, this means that **`__add__()`** and **`__radd__()`** should be defined as:

```
class MyIntegral(Integral):

    def __add__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(self, other)
        elif isinstance(other, OtherTypeIKnowAbout):
```

```
            return do_my_other_adding_stuff(self, other)
        else:
            return NotImplemented

    def __radd__(self, other):
        if isinstance(other, MyIntegral):
            return do_my_adding_stuff(other, self)
        elif isinstance(other, OtherTypeIKnowAbout):
            return do_my_other_adding_stuff(other, self)
        elif isinstance(other, Integral):
            return int(other) + int(self)
        elif isinstance(other, Real):
            return float(other) + float(self)
        elif isinstance(other, Complex):
            return complex(other) + complex(self)
        else:
            return NotImplemented
```

There are 5 different cases for a mixed-type operation on subclasses of **`Complex`**. I'll refer to all of the above code that doesn't refer to `MyIntegral` and `OtherTypeIKnowAbout` as "boilerplate". `a` will be an instance of `A`, which is a subtype of **`Complex`** (`a : A <: Complex`), and `b : B <: Complex`. I'll consider `a + b`:

1. If `A` defines an **`__add__()`** which accepts `b`, all is well.
2. If `A` falls back to the boilerplate code, and it were to return a value from **`__add__()`**, we'd miss the possibility that `B` defines a more intelligent **`__radd__()`**, so the boilerplate should return **`NotImplemented`** from **`__add__()`**. (Or `A` may not implement **`__add__()`** at all.)
3. Then `B`'s **`__radd__()`** gets a chance. If it accepts `a`, all is well.
4. If it falls back to the boilerplate, there are no more possible methods to try, so this is where the default implementation should live.
5. If `B <: A`, Python tries `B.__radd__` before `A.__add__`. This is ok, because it

was implemented with knowledge of `A`, so it can handle those instances before delegating to **`Complex`**.

If `A <: Complex` and `B <: Real` without sharing any other knowledge, then the appropriate shared operation is the one involving the built in **`complex`**, and both **`__radd__()`** s land there, so `a+b == b+a`.

Because most of the operations on any given type will be very similar, it can be useful to define a helper function which generates the forward and reverse instances of any given operator. For example, **`fractions.Fraction`** uses:

```
def _operator_fallbacks(monomorphic_operator, fallback_o
    def forward(a, b):
        if isinstance(b, (int, Fraction)):
            return monomorphic_operator(a, b)
        elif isinstance(b, float):
            return fallback_operator(float(a), b)
        elif isinstance(b, complex):
            return fallback_operator(complex(a), b)
        else:
            return NotImplemented
    forward.__name__ = '__' + fallback_operator.__name__
    forward.__doc__ = monomorphic_operator.__doc__

    def reverse(b, a):
        if isinstance(a, Rational):
            # Includes ints.
            return monomorphic_operator(a, b)
        elif isinstance(a, Real):
            return fallback_operator(float(a), float(b))
        elif isinstance(a, Complex):
            return fallback_operator(complex(a), complex
        else:
            return NotImplemented
    reverse.__name__ = '__r' + fallback_operator.__name_
    reverse.__doc__ = monomorphic_operator.__doc__
```

```
    return forward, reverse

def _add(a, b):
    """a + b"""
    return Fraction(a.numerator * b.denominator +
                    b.numerator * a.denominator,
                    a.denominator * b.denominator)

__add__, __radd__ = _operator_fallbacks(_add, operator.a

# ...
```

`math` — Mathematical functions

This module provides access to the mathematical functions defined by the C standard.

These functions cannot be used with complex numbers; use the functions of the same name from the `cmath` module if you require support for complex numbers. The distinction between functions which support complex numbers and those which don't is made since most users do not want to learn quite as much mathematics as required to understand complex numbers. Receiving an exception instead of a complex result allows earlier detection of the unexpected complex number used as a parameter, so that the programmer can determine how and why it was generated in the first place.

The following functions are provided by this module. Except when explicitly noted otherwise, all return values are floats.

Number-theoretic and representation functions

math.ceil(*x*)

Return the ceiling of *x*, the smallest integer greater than or equal to *x*. If *x* is not a float, delegates to `x.__ceil__`, which should return an `Integral` value.

math.comb(*n*, *k*)

Return the number of ways to choose *k* items from *n* items without repetition and without order.

Evaluates to `n! / (k! * (n - k)!)` when `k <= n` and evaluates to zero when `k > n`.

Also called the binomial coefficient because it is equivalent to the coefficient of k-th term in polynomial expansion of `(1 + x)^n`.

Raises **`TypeError`** if either of the arguments are not integers. Raises **`ValueError`** if either of the arguments are negative.

New in version 3.8.

math.copysign(*x*, *y*)

Return a float with the magnitude (absolute value) of *x* but the sign of *y*. On platforms that support signed zeros, `copysign(1.0, -0.0)` returns *-1.0*.

math.fabs(*x*)

Return the absolute value of *x*.

math.factorial(*n*)

Return *n* factorial as an integer. Raises **`ValueError`** if *n* is not integral or is negative.

Deprecated since version 3.9: Accepting floats with integral values (like `5.0`) is deprecated.

math.floor(*x*)

Return the floor of *x*, the largest integer less than or equal to *x*. If *x* is not a float, delegates to **`x.__floor__`**, which should return an **`Integral`** value.

math.fmod(*x*, *y*)

Return `fmod(x, y)`, as defined by the platform C library. Note that the Python expression `x % y` may not return the same result. The intent of the C standard is that `fmod(x, y)` be exactly (mathematically; to infinite precision) equal to

`x - n*y` for some integer *n* such that the result has the same sign as *x* and magnitude less than `abs(y)`. Python's `x % y` returns a result with the sign of *y* instead, and may not be exactly computable for float arguments. For example, `fmod(-1e-100, 1e100)` is `-1e-100`, but the result of Python's `-1e-100 % 1e100` is `1e100-1e-100`, which cannot be represented exactly as a float, and rounds to the surprising `1e100`. For this reason, function **`fmod()`** is generally preferred when working with floats, while Python's `x % y` is preferred when working with integers.

math.frexp(*x*)

Return the mantissa and exponent of *x* as the pair `(m, e)`. *m* is a float and *e* is an integer such that `x == m * 2**e` exactly. If *x* is zero, returns `(0.0, 0)`, otherwise `0.5 <= abs(m) < 1`. This is used to "pick apart" the internal representation of a float in a portable way.

math.fsum(*iterable*)

Return an accurate floating point sum of values in the iterable. Avoids loss of precision by tracking multiple intermediate partial sums:

```
>>> sum([.1, .1, .1, .1, .1, .1, .1, .1, .1, .1])
0.9999999999999999
>>> fsum([.1, .1, .1, .1, .1, .1, .1, .1, .1, .1])
1.0
```

The algorithm's accuracy depends on IEEE-754 arithmetic guarantees and the typical case where the rounding mode is half-even. On some non-Windows builds, the underlying C library uses extended precision addition and may occasionally double-round an intermediate sum causing it to be off in its least significant bit.

For further discussion and two alternative approaches, see the ASPN cookbook recipes for accurate floating point summation [https://code.activestate.com/recipes/393090/].

math.gcd(**integers*)

Return the greatest common divisor of the specified integer arguments. If any of the arguments is nonzero, then the returned value is the largest positive integer that is a divisor of all arguments. If all arguments are zero, then the returned value is `0`. `gcd()` without arguments returns `0`.

New in version 3.5.

Changed in version 3.9: Added support for an arbitrary number of arguments. Formerly, only two arguments were supported.

math.isclose(*a*, *b*, ***, *rel_tol=1e-09*, *abs_tol=0.0*)

Return `True` if the values *a* and *b* are close to each other and `False` otherwise.

Whether or not two values are considered close is determined according to given absolute and relative tolerances.

rel_tol is the relative tolerance – it is the maximum allowed difference between *a* and *b*, relative to the larger absolute value of *a* or *b*. For example, to set a tolerance of 5%, pass `rel_tol=0.05`. The default tolerance is `1e-09`, which assures that the two values are the same within about 9 decimal digits. *rel_tol* must be greater than zero.

abs_tol is the minimum absolute tolerance – useful for comparisons near zero. *abs_tol* must be at least zero.

If no errors occur, the result will be: `abs(a-b) <= max(rel_tol * max(abs(a), abs(b)), abs_tol)`.

The IEEE 754 special values of `NaN`, `inf`, and `-inf` will be handled according to IEEE rules. Specifically, `NaN` is not considered close to any other value, including `NaN`. `inf` and `-inf` are only considered close to themselves.

New in version 3.5.

See also

PEP 485 [https://peps.python.org/pep-0485/] – A function for testing approximate equality

math.isfinite(*x*)

Return `True` if *x* is neither an infinity nor a NaN, and `False` otherwise. (Note that `0.0` *is* considered finite.)

New in version 3.2.

math.isinf(*x*)

Return `True` if *x* is a positive or negative infinity, and `False` otherwise.

math.isnan(*x*)

Return `True` if *x* is a NaN (not a number), and `False` otherwise.

math.isqrt(*n*)

Return the integer square root of the nonnegative integer *n*. This is the floor of the exact square root of *n*, or equivalently the greatest integer *a* such that $a^2 \le n$.

For some applications, it may be more convenient to have the least integer *a* such that $n \le a^2$, or in other words the ceiling of the exact square root of *n*. For positive *n*, this can be computed using `a = 1 + isqrt(n - 1)`.

New in version 3.8.

math.lcm(**integers*)

Return the least common multiple of the specified integer arguments. If all arguments are nonzero, then the returned value is the smallest positive integer that is a multiple of all arguments. If any of the arguments is zero, then the returned value is `0`. `lcm()` without arguments returns `1`.

New in version 3.9.

math.ldexp(*x*, *i*)

Return `x * (2**i)`. This is essentially the inverse of function **`frexp()`**.

math.modf(*x*)

Return the fractional and integer parts of *x*. Both results carry the sign of *x* and are floats.

math.nextafter(*x*, *y*)

Return the next floating-point value after *x* towards *y*.

If *x* is equal to *y*, return *y*.

Examples:

- `math.nextafter(x, math.inf)` goes up: towards positive infinity.
- `math.nextafter(x, -math.inf)` goes down: towards minus infinity.
- `math.nextafter(x, 0.0)` goes towards zero.
- `math.nextafter(x, math.copysign(math.inf, x))` goes away from zero.

See also **`math.ulp()`**.

New in version 3.9.

math.perm(*n*, *k*=*None*)

Return the number of ways to choose *k* items from *n* items without repetition and with order.

Evaluates to `n! / (n - k)!` when `k <= n` and evaluates to zero when `k > n`.

If *k* is not specified or is None, then *k* defaults to *n* and the function returns `n!`.

Raises **TypeError** if either of the arguments are not integers. Raises **ValueError** if either of the arguments are negative.

New in version 3.8.

math.prod(*iterable*, *, *start=1*)

Calculate the product of all the elements in the input *iterable*. The default *start* value for the product is `1`.

When the iterable is empty, return the start value. This function is intended specifically for use with numeric values and may reject non-numeric types.

New in version 3.8.

math.remainder(*x*, *y*)

Return the IEEE 754-style remainder of *x* with respect to *y*. For finite *x* and finite nonzero *y*, this is the difference `x - n*y`, where `n` is the closest integer to the exact value of the quotient `x / y`. If `x / y` is exactly halfway between two consecutive integers, the nearest *even* integer is used for `n`. The remainder `r = remainder(x, y)` thus always satisfies `abs(r) <= 0.5 * abs(y)`.

Special cases follow IEEE 754: in particular, `remainder(x, math.inf)` is *x* for any finite *x*, and `remainder(x, 0)` and `remainder(math.inf, x)` raise **ValueError** for any non-NaN *x*. If the result of the remainder operation is zero, that zero will have the same sign as *x*.

On platforms using IEEE 754 binary floating-point, the result of this operation is always exactly representable: no rounding error is introduced.

New in version 3.7.

math.trunc(*x*)

Return *x* with the fractional part removed, leaving the integer

part. This rounds toward 0: `trunc()` is equivalent to **`floor()`** for positive *x*, and equivalent to **`ceil()`** for negative *x*. If *x* is not a float, delegates to **`x.__trunc__`**, which should return an **`Integral`** value.

math.ulp(*x*)

Return the value of the least significant bit of the float *x*:

- If *x* is a NaN (not a number), return *x*.
- If *x* is negative, return `ulp(-x)`.
- If *x* is a positive infinity, return *x*.
- If *x* is equal to zero, return the smallest positive *denormalized* representable float (smaller than the minimum positive *normalized* float, **`sys.float_info.min`**).
- If *x* is equal to the largest positive representable float, return the value of the least significant bit of *x*, such that the first float smaller than *x* is `x - ulp(x)`.
- Otherwise (*x* is a positive finite number), return the value of the least significant bit of *x*, such that the first float bigger than *x* is `x + ulp(x)`.

ULP stands for “Unit in the Last Place”.

See also **`math.nextafter()`** and **`sys.float_info.epsilon`**.

New in version 3.9.

Note that **`frexp()`** and **`modf()`** have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an ‘output parameter’ (there is no such thing in Python).

For the **`ceil()`**, **`floor()`**, and **`modf()`** functions, note that *all* floating-point numbers of sufficiently large magnitude are exact integers. Python floats typically carry no more than 53 bits of precision (the same as the platform C double type), in which case any float *x* with `abs(x) >= 2**52` necessarily has no fractional

bits.

Power and logarithmic functions

math.cbrt(*x*)

Return the cube root of *x*.

New in version 3.11.

math.exp(*x*)

Return *e* raised to the power *x*, where *e* = 2.718281… is the base of natural logarithms. This is usually more accurate than `math.e ** x` or `pow(math.e, x)`.

math.exp2(*x*)

Return *2* raised to the power *x*.

New in version 3.11.

math.expm1(*x*)

Return *e* raised to the power *x*, minus 1. Here *e* is the base of natural logarithms. For small floats *x*, the subtraction in `exp(x) - 1` can result in a significant loss of precision [https://en.wikipedia.org/wiki/Loss_of_significance]; the **`expm1()`** function provides a way to compute this quantity to full precision:

```
>>> from math import exp, expm1
>>> exp(1e-5) - 1  # gives result accurate to 11 pl
1.0000050000069649e-05
>>> expm1(1e-5)    # result accurate to full precis
1.0000050000166668e-05
```

New in version 3.2.

math.log(*x*[, *base*])

With one argument, return the natural logarithm of *x* (to base

e).

With two arguments, return the logarithm of *x* to the given *base*, calculated as `log(x)/log(base)`.

math.log1p(*x*)

Return the natural logarithm of *1+x* (base *e*). The result is calculated in a way which is accurate for *x* near zero.

math.log2(*x*)

Return the base-2 logarithm of *x*. This is usually more accurate than `log(x, 2)`.

New in version 3.3.

See also

`int.bit_length()` returns the number of bits necessary to represent an integer in binary, excluding the sign and leading zeros.

math.log10(*x*)

Return the base-10 logarithm of *x*. This is usually more accurate than `log(x, 10)`.

math.pow(*x*, *y*)

Return `x` raised to the power `y`. Exceptional cases follow the IEEE 754 standard as far as possible. In particular, `pow(1.0, x)` and `pow(x, 0.0)` always return `1.0`, even when `x` is a zero or a NaN. If both `x` and `y` are finite, `x` is negative, and `y` is not an integer then `pow(x, y)` is undefined, and raises **`ValueError`**.

Unlike the built-in `**` operator, **`math.pow()`** converts both its arguments to type **`float`**. Use `**` or the built-in **`pow()`** function for computing exact integer powers.

Changed in version 3.11: The special cases `pow(0.0, -inf)` and `pow(-0.0, -inf)` were changed to return `inf` instead of raising **`ValueError`**, for consistency with IEEE 754.

math.sqrt(*x*)

Return the square root of *x*.

Trigonometric functions

math.acos(*x*)

Return the arc cosine of *x*, in radians. The result is between `0` and `pi`.

math.asin(*x*)

Return the arc sine of *x*, in radians. The result is between `-pi/2` and `pi/2`.

math.atan(*x*)

Return the arc tangent of *x*, in radians. The result is between `-pi/2` and `pi/2`.

math.atan2(*y*, *x*)

Return `atan(y / x)`, in radians. The result is between `-pi` and `pi`. The vector in the plane from the origin to point `(x, y)` makes this angle with the positive X axis. The point of **`atan2()`** is that the signs of both inputs are known to it, so it can compute the correct quadrant for the angle. For example, `atan(1)` and `atan2(1, 1)` are both `pi/4`, but `atan2(-1, -1)` is `-3*pi/4`.

math.cos(*x*)

Return the cosine of *x* radians.

math.dist(*p*, *q*)

Return the Euclidean distance between two points *p* and *q*, each given as a sequence (or iterable) of coordinates. The two points must have the same dimension.

Roughly equivalent to:

```
sqrt(sum((px - qx) ** 2.0 for px, qx in zip(p, q)))
```

New in version 3.8.

math.hypot(**coordinates*)

Return the Euclidean norm, `sqrt(sum(x**2 for x in coordinates))`. This is the length of the vector from the origin to the point given by the coordinates.

For a two dimensional point `(x, y)`, this is equivalent to computing the hypotenuse of a right triangle using the Pythagorean theorem, `sqrt(x*x + y*y)`.

Changed in version 3.8: Added support for n-dimensional points. Formerly, only the two dimensional case was supported.

Changed in version 3.10: Improved the algorithm's accuracy so that the maximum error is under 1 ulp (unit in the last place). More typically, the result is almost always correctly rounded to within 1/2 ulp.

math.sin(*x*)

Return the sine of *x* radians.

math.tan(*x*)

Return the tangent of *x* radians.

Angular conversion

math.degrees(*x*)

Convert angle *x* from radians to degrees.

math.radians(*x*)

Convert angle *x* from degrees to radians.

Hyperbolic functions

Hyperbolic functions [https://en.wikipedia.org/wiki/Hyperbolic_function] are analogs of trigonometric functions that are based on hyperbolas instead of circles.

math.acosh(*x*)

Return the inverse hyperbolic cosine of *x*.

math.asinh(*x*)

Return the inverse hyperbolic sine of *x*.

math.atanh(*x*)

Return the inverse hyperbolic tangent of *x*.

math.cosh(*x*)

Return the hyperbolic cosine of *x*.

math.sinh(*x*)

Return the hyperbolic sine of *x*.

math.tanh(*x*)

Return the hyperbolic tangent of *x*.

Special functions

math.erf(*x*)

Return the error function [https://en.wikipedia.org/wiki/Error_function] at *x*.

The **`erf()`** function can be used to compute traditional statistical functions such as the cumulative standard normal

distribution [https://en.wikipedia.org/wiki/Normal_distribution#Cumulative_distribution_functions]:

```
def phi(x):
    'Cumulative distribution function for the stand
    return (1.0 + erf(x / sqrt(2.0))) / 2.0
```

New in version 3.2.

math.erfc(*x*)

Return the complementary error function at *x*. The complementary error function [https://en.wikipedia.org/wiki/Error_function] is defined as `1.0 - erf(x)`. It is used for large values of *x* where a subtraction from one would cause a loss of significance [https://en.wikipedia.org/wiki/Loss_of_significance].

New in version 3.2.

math.gamma(*x*)

Return the Gamma function [https://en.wikipedia.org/wiki/Gamma_function] at *x*.

New in version 3.2.

math.lgamma(*x*)

Return the natural logarithm of the absolute value of the Gamma function at *x*.

New in version 3.2.

Constants

math.pi

The mathematical constant $\pi = 3.141592\ldots$, to available precision.

math.e

The mathematical constant $e = 2.718281\ldots$, to available

precision.

math.tau

The mathematical constant τ = 6.283185…, to available precision. Tau is a circle constant equal to 2π, the ratio of a circle's circumference to its radius. To learn more about Tau, check out Vi Hart's video Pi is (still) Wrong [https://www.youtube.com/watch?v=jG7vhMMXagQ], and start celebrating Tau day [https://tauday.com/] by eating twice as much pie!

New in version 3.6.

math.inf

A floating-point positive infinity. (For negative infinity, use `-math.inf`.) Equivalent to the output of `float('inf')`.

New in version 3.5.

math.nan

A floating-point "not a number" (NaN) value. Equivalent to the output of `float('nan')`. Due to the requirements of the IEEE-754 standard [https://en.wikipedia.org/wiki/IEEE_754], `math.nan` and `float('nan')` are not considered to equal to any other numeric value, including themselves. To check whether a number is a NaN, use the **`isnan()`** function to test for NaNs instead of `is` or `==`. Example:

```
>>> import math
>>> math.nan == math.nan
False
>>> float('nan') == float('nan')
False
>>> math.isnan(math.nan)
True
>>> math.isnan(float('nan'))
True
```

Changed in version 3.11: It is now always available.

New in version 3.5.

CPython implementation detail: The `math` module consists mostly of thin wrappers around the platform C math library functions. Behavior in exceptional cases follows Annex F of the C99 standard where appropriate. The current implementation will raise `ValueError` for invalid operations like `sqrt(-1.0)` or `log(0.0)` (where C99 Annex F recommends signaling invalid operation or divide-by-zero), and `OverflowError` for results that overflow (for example, `exp(1000.0)`). A NaN will not be returned from any of the functions above unless one or more of the input arguments was a NaN; in that case, most functions will return a NaN, but (again following C99 Annex F) there are some exceptions to this rule, for example `pow(float('nan'), 0.0)` or `hypot(float('nan'), float('inf'))`.

Note that Python makes no effort to distinguish signaling NaNs from quiet NaNs, and behavior for signaling NaNs remains unspecified. Typical behavior is to treat all NaNs as though they were quiet.

See also

Module `cmath`
Complex number versions of many of these functions.

`cmath` — Mathematical functions for complex numbers

This module provides access to mathematical functions for complex numbers. The functions in this module accept integers, floating-point numbers or complex numbers as arguments. They will also accept any Python object that has either a **`__complex__()`** or a **`__float__()`** method: these methods are used to convert the object to a complex or floating-point number, respectively, and the function is then applied to the result of the conversion.

Note

On platforms with hardware and system-level support for signed zeros, functions involving branch cuts are continuous on *both* sides of the branch cut: the sign of the zero distinguishes one side of the branch cut from the other. On platforms that do not support signed zeros the continuity is as specified below.

Conversions to and from polar coordinates

A Python complex number `z` is stored internally using *rectangular* or *Cartesian* coordinates. It is completely determined by its *real part* `z.real` and its *imaginary part* `z.imag`. In other words:

```
z == z.real + z.imag*1j
```

Polar coordinates give an alternative way to represent a complex number. In polar coordinates, a complex number *z* is defined by the modulus *r* and the phase angle *phi*. The modulus *r* is the distance from *z* to the origin, while the phase *phi* is the counterclockwise

angle, measured in radians, from the positive x-axis to the line segment that joins the origin to *z*.

The following functions can be used to convert from the native rectangular coordinates to polar coordinates and back.

cmath.phase(*x*)

Return the phase of *x* (also known as the *argument* of *x*), as a float. `phase(x)` is equivalent to `math.atan2(x.imag, x.real)`. The result lies in the range [-π, π], and the branch cut for this operation lies along the negative real axis, continuous from above. On systems with support for signed zeros (which includes most systems in current use), this means that the sign of the result is the same as the sign of `x.imag`, even when `x.imag` is zero:

```
>>> phase(complex(-1.0, 0.0))
3.141592653589793
>>> phase(complex(-1.0, -0.0))
-3.141592653589793
```

Note

The modulus (absolute value) of a complex number *x* can be computed using the built-in **`abs()`** function. There is no separate **`cmath`** module function for this operation.

cmath.polar(*x*)

Return the representation of *x* in polar coordinates. Returns a pair `(r, phi)` where *r* is the modulus of *x* and phi is the phase of *x*. `polar(x)` is equivalent to `(abs(x), phase(x))`.

cmath.rect(*r*, *phi*)

Return the complex number *x* with polar coordinates *r* and *phi*. Equivalent to `r * (math.cos(phi) + math.sin(phi)*1j)`.

Power and logarithmic functions

cmath.exp(*x*)

Return *e* raised to the power *x*, where *e* is the base of natural logarithms.

cmath.log(*x*[, *base*])

Returns the logarithm of *x* to the given *base*. If the *base* is not specified, returns the natural logarithm of *x*. There is one branch cut, from 0 along the negative real axis to -∞, continuous from above.

cmath.log10(*x*)

Return the base-10 logarithm of *x*. This has the same branch cut as **`log()`**.

cmath.sqrt(*x*)

Return the square root of *x*. This has the same branch cut as **`log()`**.

Trigonometric functions

cmath.acos(*x*)

Return the arc cosine of *x*. There are two branch cuts: One extends right from 1 along the real axis to ∞, continuous from below. The other extends left from -1 along the real axis to -∞, continuous from above.

cmath.asin(*x*)

Return the arc sine of *x*. This has the same branch cuts as **`acos()`**.

cmath.atan(*x*)

Return the arc tangent of *x*. There are two branch cuts: One extends from `1j` along the imaginary axis to `∞j`, continuous

from the right. The other extends from `-1j` along the imaginary axis to `-∞j`, continuous from the left.

cmath.cos(*x*)

Return the cosine of *x*.

cmath.sin(*x*)

Return the sine of *x*.

cmath.tan(*x*)

Return the tangent of *x*.

Hyperbolic functions

cmath.acosh(*x*)

Return the inverse hyperbolic cosine of *x*. There is one branch cut, extending left from 1 along the real axis to -∞, continuous from above.

cmath.asinh(*x*)

Return the inverse hyperbolic sine of *x*. There are two branch cuts: One extends from `1j` along the imaginary axis to `∞j`, continuous from the right. The other extends from `-1j` along the imaginary axis to `-∞j`, continuous from the left.

cmath.atanh(*x*)

Return the inverse hyperbolic tangent of *x*. There are two branch cuts: One extends from `1` along the real axis to `∞`, continuous from below. The other extends from `-1` along the real axis to `-∞`, continuous from above.

cmath.cosh(*x*)

Return the hyperbolic cosine of *x*.

cmath.sinh(*x*)

Return the hyperbolic sine of *x*.

cmath.tanh(*x*)

Return the hyperbolic tangent of *x*.

Classification functions

cmath.isfinite(*x*)

Return `True` if both the real and imaginary parts of *x* are finite, and `False` otherwise.

New in version 3.2.

cmath.isinf(*x*)

Return `True` if either the real or the imaginary part of *x* is an infinity, and `False` otherwise.

cmath.isnan(*x*)

Return `True` if either the real or the imaginary part of *x* is a NaN, and `False` otherwise.

cmath.isclose(*a*, *b*, ***, *rel_tol=1e-09*, *abs_tol=0.0*)

Return `True` if the values *a* and *b* are close to each other and `False` otherwise.

Whether or not two values are considered close is determined according to given absolute and relative tolerances.

rel_tol is the relative tolerance – it is the maximum allowed difference between *a* and *b*, relative to the larger absolute value of *a* or *b*. For example, to set a tolerance of 5%, pass `rel_tol=0.05`. The default tolerance is `1e-09`, which assures that the two values are the same within about 9 decimal digits. *rel_tol* must be greater than zero.

abs_tol is the minimum absolute tolerance – useful for comparisons near zero. *abs_tol* must be at least zero.

If no errors occur, the result will be: `abs(a-b) <= max(rel_tol * max(abs(a), abs(b)), abs_tol)`.

The IEEE 754 special values of `NaN`, `inf`, and `-inf` will be handled according to IEEE rules. Specifically, `NaN` is not considered close to any other value, including `NaN`. `inf` and `-inf` are only considered close to themselves.

New in version 3.5.

See also

PEP 485 [https://peps.python.org/pep-0485/] – A function for testing approximate equality

Constants

cmath.pi

The mathematical constant π, as a float.

cmath.e

The mathematical constant *e*, as a float.

cmath.tau

The mathematical constant τ, as a float.

New in version 3.6.

cmath.inf

Floating-point positive infinity. Equivalent to `float('inf')`.

New in version 3.6.

cmath.infj

Complex number with zero real part and positive infinity imaginary part. Equivalent to `complex(0.0,`

`float('inf')`.

New in version 3.6.

cmath.nan

A floating-point “not a number” (NaN) value. Equivalent to `float('nan')`.

New in version 3.6.

cmath.nanj

Complex number with zero real part and NaN imaginary part. Equivalent to `complex(0.0, float('nan'))`.

New in version 3.6.

Note that the selection of functions is similar, but not identical, to that in module **math**. The reason for having two modules is that some users aren’t interested in complex numbers, and perhaps don’t even know what they are. They would rather have `math.sqrt(-1)` raise an exception than return a complex number. Also note that the functions defined in **cmath** always return a complex number, even if the answer can be expressed as a real number (in which case the complex number has an imaginary part of zero).

A note on branch cuts: They are curves along which the given function fails to be continuous. They are a necessary feature of many complex functions. It is assumed that if you need to compute with complex functions, you will understand about branch cuts. Consult almost any (not too elementary) book on complex variables for enlightenment. For information of the proper choice of branch cuts for numerical purposes, a good reference should be the following:

(1987) pp165–211.

`decimal` — Decimal fixed point and floating point arithmetic

Source code: Lib/decimal.py [https://github.com/python/cpython/tree/3.11/Lib/decimal.py]

The `decimal` module provides support for fast correctly rounded decimal floating point arithmetic. It offers several advantages over the `float` datatype:

- Decimal "is based on a floating-point model which was designed with people in mind, and necessarily has a paramount guiding principle – computers must provide an arithmetic that works in the same way as the arithmetic that people learn at school." – excerpt from the decimal arithmetic specification.

- Decimal numbers can be represented exactly. In contrast, numbers like `1.1` and `2.2` do not have exact representations in binary floating point. End users typically would not expect `1.1 + 2.2` to display as `3.3000000000000003` as it does with binary floating point.

- The exactness carries over into arithmetic. In decimal floating point, `0.1 + 0.1 + 0.1 - 0.3` is exactly equal to zero. In binary floating point, the result is `5.5511151231257827e-017`. While near to zero, the differences prevent reliable equality testing and differences can accumulate. For this reason, decimal is preferred in accounting applications which have strict equality invariants.

- The decimal module incorporates a notion of significant places so that `1.30 + 1.20` is `2.50`. The trailing zero is kept to indicate significance. This is the customary presentation for monetary applications. For multiplication,

the “schoolbook” approach uses all the figures in the multiplicands. For instance, `1.3 * 1.2` gives **`1.56`** while `1.30 * 1.20` gives **`1.5600`**.

- Unlike hardware based binary floating point, the decimal module has a user alterable precision (defaulting to 28 places) which can be as large as needed for a given problem:

```
>>> from decimal import *
>>> getcontext().prec = 6
>>> Decimal(1) / Decimal(7)
Decimal('0.142857')
>>> getcontext().prec = 28
>>> Decimal(1) / Decimal(7)
Decimal('0.1428571428571428571428571429')
```

- Both binary and decimal floating point are implemented in terms of published standards. While the built-in float type exposes only a modest portion of its capabilities, the decimal module exposes all required parts of the standard. When needed, the programmer has full control over rounding and signal handling. This includes an option to enforce exact arithmetic by using exceptions to block any inexact operations.

- The decimal module was designed to support “without prejudice, both exact unrounded decimal arithmetic (sometimes called fixed-point arithmetic) and rounded floating-point arithmetic.” – excerpt from the decimal arithmetic specification.

The module design is centered around three concepts: the decimal number, the context for arithmetic, and signals.

A decimal number is immutable. It has a sign, coefficient digits, and an exponent. To preserve significance, the coefficient digits do not truncate trailing zeros. Decimals also include special values such as **`Infinity`**, **`-Infinity`**, and **`NaN`**. The standard also differentiates **`-0`** from **`+0`**.

The context for arithmetic is an environment specifying precision,

rounding rules, limits on exponents, flags indicating the results of operations, and trap enablers which determine whether signals are treated as exceptions. Rounding options include **`ROUND_CEILING`**, **`ROUND_DOWN`**, **`ROUND_FLOOR`**, **`ROUND_HALF_DOWN`**, **`ROUND_HALF_EVEN`**, **`ROUND_HALF_UP`**, **`ROUND_UP`**, and **`ROUND_05UP`**.

Signals are groups of exceptional conditions arising during the course of computation. Depending on the needs of the application, signals may be ignored, considered as informational, or treated as exceptions. The signals in the decimal module are: **`Clamped`**, **`InvalidOperation`**, **`DivisionByZero`**, **`Inexact`**, **`Rounded`**, **`Subnormal`**, **`Overflow`**, **`Underflow`** and **`FloatOperation`**.

For each signal there is a flag and a trap enabler. When a signal is encountered, its flag is set to one, then, if the trap enabler is set to one, an exception is raised. Flags are sticky, so the user needs to reset them before monitoring a calculation.

- IBM's General Decimal Arithmetic Specification, The General Decimal Arithmetic Specification [https://speleotrove.com/decimal/decarith.html].

Quick-start Tutorial

The usual start to using decimals is importing the module, viewing the current context with **`getcontext()`** and, if necessary, setting new values for precision, rounding, or enabled traps:

```
>>> from decimal import *
>>> getcontext()
Context(prec=28, rounding=ROUND_HALF_EVEN, Emin=-999999,
        capitals=1, clamp=0, flags=[], traps=[Overflow,
        InvalidOperation])

>>> getcontext().prec = 7       # Set a new precision
```

Decimal instances can be constructed from integers, strings, floats, or tuples. Construction from an integer or a float performs an exact conversion of the value of that integer or float. Decimal numbers include special values such as **`NaN`** which stands for “Not a number”, positive and negative **`Infinity`**, and **`-0`**:

```
>>> getcontext().prec = 28
>>> Decimal(10)
Decimal('10')
>>> Decimal('3.14')
Decimal('3.14')
>>> Decimal(3.14)
Decimal('3.140000000000000124344978758017532527446746826
>>> Decimal((0, (3, 1, 4), -2))
Decimal('3.14')
>>> Decimal(str(2.0 ** 0.5))
Decimal('1.4142135623730951')
>>> Decimal(2) ** Decimal('0.5')
Decimal('1.4142135623730950488016887242')
>>> Decimal('NaN')
Decimal('NaN')
>>> Decimal('-Infinity')
Decimal('-Infinity')
```

If the **`FloatOperation`** signal is trapped, accidental mixing of decimals and floats in constructors or ordering comparisons raises an exception:

```
>>> c = getcontext()
>>> c.traps[FloatOperation] = True
>>> Decimal(3.14)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'
>>> Decimal('3.5') < 3.7
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.FloatOperation: [<class 'decimal.FloatOperation'
>>> Decimal('3.5') == 3.5
```

```
True
```

New in version 3.3.

The significance of a new Decimal is determined solely by the number of digits input. Context precision and rounding only come into play during arithmetic operations.

```
>>> getcontext().prec = 6
>>> Decimal('3.0')
Decimal('3.0')
>>> Decimal('3.1415926535')
Decimal('3.1415926535')
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85987')
>>> getcontext().rounding = ROUND_UP
>>> Decimal('3.1415926535') + Decimal('2.7182818285')
Decimal('5.85988')
```

If the internal limits of the C version are exceeded, constructing a decimal raises **InvalidOperation**:

```
>>> Decimal("1e9999999999999999999")
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
decimal.InvalidOperation: [<class 'decimal.InvalidOperat
```

Changed in version 3.3.

Decimals interact well with much of the rest of Python. Here is a small decimal floating point flying circus:

```
>>> data = list(map(Decimal, '1.34 1.87 3.45 2.35 1.00 0
>>> max(data)
Decimal('9.25')
>>> min(data)
Decimal('0.03')
>>> sorted(data)
[Decimal('0.03'), Decimal('1.00'), Decimal('1.34'), Deci
 Decimal('2.35'), Decimal('3.45'), Decimal('9.25')]
```

```
>>> sum(data)
Decimal('19.29')
>>> a,b,c = data[:3]
>>> str(a)
'1.34'
>>> float(a)
1.34
>>> round(a, 1)
Decimal('1.3')
>>> int(a)
1
>>> a * 5
Decimal('6.70')
>>> a * b
Decimal('2.5058')
>>> c % a
Decimal('0.77')
```

And some mathematical functions are also available to Decimal:

```
>>> getcontext().prec = 28
>>> Decimal(2).sqrt()
Decimal('1.4142135623730950488016887242')
>>> Decimal(1).exp()
Decimal('2.7182818284590452353602874713')
>>> Decimal('10').ln()
Decimal('2.3025850929940456840179914547')
>>> Decimal('10').log10()
Decimal('1')
```

The **`quantize()`** method rounds a number to a fixed exponent. This method is useful for monetary applications that often round results to a fixed number of places:

```
>>> Decimal('7.325').quantize(Decimal('.01'), rounding=R
Decimal('7.32')
>>> Decimal('7.325').quantize(Decimal('1.'), rounding=RO
Decimal('8')
```

As shown above, the **`getcontext()`** function accesses the current

context and allows the settings to be changed. This approach meets the needs of most applications.

For more advanced work, it may be useful to create alternate contexts using the Context() constructor. To make an alternate active, use the **`setcontext()`** function.

In accordance with the standard, the **`decimal`** module provides two ready to use standard contexts, **`BasicContext`** and **`ExtendedContext`**. The former is especially useful for debugging because many of the traps are enabled:

```
>>> myothercontext = Context(prec=60, rounding=ROUND_HAI
>>> setcontext(myothercontext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857142857142857142857142857142857142857142

>>> ExtendedContext
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999,
        capitals=1, clamp=0, flags=[], traps=[])
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(7)
Decimal('0.142857143')
>>> Decimal(42) / Decimal(0)
Decimal('Infinity')

>>> setcontext(BasicContext)
>>> Decimal(42) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#143>", line 1, in -toplevel-
    Decimal(42) / Decimal(0)
DivisionByZero: x / 0
```

Contexts also have signal flags for monitoring exceptional conditions encountered during computations. The flags remain set until explicitly cleared, so it is best to clear the flags before each set of monitored computations by using the **`clear_flags()`** method.

```
>>> setcontext(ExtendedContext)
>>> getcontext().clear_flags()
```

```
>>> Decimal(355) / Decimal(113)
Decimal('3.14159292')
>>> getcontext()
Context(prec=9, rounding=ROUND_HALF_EVEN, Emin=-999999,
        capitals=1, clamp=0, flags=[Inexact, Rounded], t
```

The *flags* entry shows that the rational approximation to **`Pi`** was rounded (digits beyond the context precision were thrown away) and that the result is inexact (some of the discarded digits were non-zero).

Individual traps are set using the dictionary in the **`traps`** field of a context:

```
>>> setcontext(ExtendedContext)
>>> Decimal(1) / Decimal(0)
Decimal('Infinity')
>>> getcontext().traps[DivisionByZero] = 1
>>> Decimal(1) / Decimal(0)
Traceback (most recent call last):
  File "<pyshell#112>", line 1, in -toplevel-
    Decimal(1) / Decimal(0)
DivisionByZero: x / 0
```

Most programs adjust the current context only once, at the beginning of the program. And, in many applications, data is converted to **`Decimal`** with a single cast inside a loop. With context set and decimals created, the bulk of the program manipulates the data no differently than with other Python numeric types.

Decimal objects

class decimal.Decimal(*value='0'*, *context=None*)

Construct a new **`Decimal`** object based from *value*.

value can be an integer, string, tuple, **`float`**, or another **`Decimal`** object. If no *value* is given, returns `Decimal('0')`. If *value* is a string, it should conform to the

decimal numeric string syntax after leading and trailing whitespace characters, as well as underscores throughout, are removed:

```
sign           ::=  '+' | '-'
digit          ::=  '0' | '1' | '2' | '3' | '4' | '
indicator      ::=  'e' | 'E'
digits         ::=  digit [digit]...
decimal-part   ::=  digits '.' [digits] | ['.'] dig
exponent-part  ::=  indicator [sign] digits
infinity       ::=  'Infinity' | 'Inf'
nan            ::=  'NaN' [digits] | 'sNaN' [digits
numeric-value  ::=  decimal-part [exponent-part] |
numeric-string ::=  [sign] numeric-value | [sign] n
```

Other Unicode decimal digits are also permitted where `digit` appears above. These include decimal digits from various other alphabets (for example, Arabic-Indic and Devanāgarī digits) along with the fullwidth digits `'\uff10'` through `'\uff19'`.

If *value* is a **`tuple`**, it should have three components, a sign (**`0`** for positive or **`1`** for negative), a **`tuple`** of digits, and an integer exponent. For example, `Decimal((0, (1, 4, 1, 4), -3))` returns `Decimal('1.414')`.

If *value* is a **`float`**, the binary floating point value is losslessly converted to its exact decimal equivalent. This conversion can often require 53 or more digits of precision. For example, `Decimal(float('1.1'))` converts to `Decimal('1.100000000000000088817841970012523233890`

The *context* precision does not affect how many digits are stored. That is determined exclusively by the number of digits in *value*. For example, `Decimal('3.00000')` records all five zeros even if the context precision is only three.

The purpose of the *context* argument is determining what to do if *value* is a malformed string. If the context traps **`InvalidOperation`**, an exception is raised; otherwise, the constructor returns a new Decimal with the value of **`NaN`**.

Once constructed, **`Decimal`** objects are immutable.

Changed in version 3.2: The argument to the constructor is now permitted to be a **`float`** instance.

Changed in version 3.3: **`float`** arguments raise an exception if the **`FloatOperation`** trap is set. By default the trap is off.

Changed in version 3.6: Underscores are allowed for grouping, as with integral and floating-point literals in code.

Decimal floating point objects share many properties with the other built-in numeric types such as **`float`** and **`int`**. All of the usual math operations and special methods apply. Likewise, decimal objects can be copied, pickled, printed, used as dictionary keys, used as set elements, compared, sorted, and coerced to another type (such as **`float`** or **`int`**).

There are some small differences between arithmetic on Decimal objects and arithmetic on integers and floats. When the remainder operator `%` is applied to Decimal objects, the sign of the result is the sign of the *dividend* rather than the sign of the divisor:

```
>>> (-7) % 4
1
>>> Decimal(-7) % Decimal(4)
Decimal('-3')
```

The integer division operator `//` behaves analogously, returning the integer part of the true quotient (truncating towards zero) rather than its floor, so as to preserve the usual identity `x == (x // y) * y + x % y`:

```
>>> -7 // 4
-2
>>> Decimal(-7) // Decimal(4)
Decimal('-1')
```

The `%` and `//` operators implement the `remainder` and `divide-integer` operations (respectively) as described in

the specification.

Decimal objects cannot generally be combined with floats or instances of **fractions.Fraction** in arithmetic operations: an attempt to add a **Decimal** to a **float**, for example, will raise a **TypeError**. However, it is possible to use Python's comparison operators to compare a **Decimal** instance `x` with another number `y`. This avoids confusing results when doing equality comparisons between numbers of different types.

Changed in version 3.2: Mixed-type comparisons between **Decimal** instances and other numeric types are now fully supported.

In addition to the standard numeric properties, decimal floating point objects also have a number of specialized methods:

adjusted()

Return the adjusted exponent after shifting out the coefficient's rightmost digits until only the lead digit remains: `Decimal('321e+5').adjusted()` returns seven. Used for determining the position of the most significant digit with respect to the decimal point.

as_integer_ratio()

Return a pair `(n, d)` of integers that represent the given **Decimal** instance as a fraction, in lowest terms and with a positive denominator:

```
>>> Decimal('-3.14').as_integer_ratio()
(-157, 50)
```

The conversion is exact. Raise OverflowError on infinities and ValueError on NaNs.

New in version 3.6.

as_tuple()

Return a named tuple representation of the number: `DecimalTuple(sign, digits, exponent)`.

canonical()

Return the canonical encoding of the argument. Currently, the encoding of a **`Decimal`** instance is always canonical, so this operation returns its argument unchanged.

compare(*other*, *context*=*None*)

Compare the values of two Decimal instances. **`compare()`** returns a Decimal instance, and if either operand is a NaN then the result is a NaN:

```
a or b is a NaN  ==> Decimal('NaN')
a < b            ==> Decimal('-1')
a == b           ==> Decimal('0')
a > b            ==> Decimal('1')
```

compare_signal(*other*, *context*=*None*)

This operation is identical to the **`compare()`** method, except that all NaNs signal. That is, if neither operand is a signaling NaN then any quiet NaN operand is treated as though it were a signaling NaN.

compare_total(*other*, *context*=*None*)

Compare two operands using their abstract representation rather than their numerical value. Similar to the **`compare()`** method, but the result gives a total ordering on **`Decimal`** instances. Two **`Decimal`** instances with the same numeric value but different representations compare unequal in this ordering:

```
>>> Decimal('12.0').compare_total(Decimal('12')
Decimal('-1')
```

Quiet and signaling NaNs are also included in the total ordering. The result of this function is `Decimal('0')`

if both operands have the same representation, `Decimal('-1')` if the first operand is lower in the total order than the second, and `Decimal('1')` if the first operand is higher in the total order than the second operand. See the specification for details of the total order.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

compare_total_mag(*other*, *context=None*)

Compare two operands using their abstract representation rather than their value as in **`compare_total()`**, but ignoring the sign of each operand. `x.compare_total_mag(y)` is equivalent to `x.copy_abs().compare_total(y.copy_abs())`.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

conjugate()

Just returns self, this method is only to comply with the Decimal Specification.

copy_abs()

Return the absolute value of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

copy_negate()

Return the negation of the argument. This operation is unaffected by the context and is quiet: no flags are changed and no rounding is performed.

copy_sign(*other*, *context*=*None*)

Return a copy of the first operand with the sign set to be the same as the sign of the second operand. For example:

```
>>> Decimal('2.3').copy_sign(Decimal('-1.5'))
Decimal('-2.3')
```

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

exp(*context*=*None*)

Return the value of the (natural) exponential function `e**x` at the given number. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

```
>>> Decimal(1).exp()
Decimal('2.718281828459045235360287471')
>>> Decimal(321).exp()
Decimal('2.561702493119680037517373933E+139')
```

classmethod from_float(*f*)

Alternative constructor that only accepts instances of **float** or **int**.

Note `Decimal.from_float(0.1)` is not the same as `Decimal('0.1')`. Since 0.1 is not exactly representable in binary floating point, the value is stored as the nearest representable value which is `0x1.999999999999ap-4`. That equivalent value in decimal is `0.1000000000000000055511151231257827021181583404`

Note

From Python 3.2 onwards, a **Decimal** instance can

also be constructed directly from a **float**.

```
>>> Decimal.from_float(0.1)
Decimal('0.1000000000000000055511151231257827021
>>> Decimal.from_float(float('nan'))
Decimal('NaN')
>>> Decimal.from_float(float('inf'))
Decimal('Infinity')
>>> Decimal.from_float(float('-inf'))
Decimal('-Infinity')
```

New in version 3.1.

fma(*other*, *third*, *context=None*)

Fused multiply-add. Return self*other + third with no rounding of the intermediate product self*other.

```
>>> Decimal(2).fma(3, 5)
Decimal('11')
```

is_canonical()

Return **True** if the argument is canonical and **False** otherwise. Currently, a **Decimal** instance is always canonical, so this operation always returns **True**.

is_finite()

Return **True** if the argument is a finite number, and **False** if the argument is an infinity or a NaN.

is_infinite()

Return **True** if the argument is either positive or negative infinity and **False** otherwise.

is_nan()

Return **True** if the argument is a (quiet or signaling) NaN and **False** otherwise.

is_normal(*context=None*)

Return **True** if the argument is a *normal* finite number. Return **False** if the argument is zero, subnormal, infinite or a NaN.

is_qnan()

Return **True** if the argument is a quiet NaN, and **False** otherwise.

is_signed()

Return **True** if the argument has a negative sign and **False** otherwise. Note that zeros and NaNs can both carry signs.

is_snan()

Return **True** if the argument is a signaling NaN and **False** otherwise.

is_subnormal(*context=None*)

Return **True** if the argument is subnormal, and **False** otherwise.

is_zero()

Return **True** if the argument is a (positive or negative) zero and **False** otherwise.

ln(*context=None*)

Return the natural (base e) logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

log10(*context=None*)

Return the base ten logarithm of the operand. The result is correctly rounded using the **ROUND_HALF_EVEN** rounding mode.

logb(*context*=*None*)

For a nonzero number, return the adjusted exponent of its operand as a **`Decimal`** instance. If the operand is a zero then `Decimal('-Infinity')` is returned and the **`DivisionByZero`** flag is raised. If the operand is an infinity then `Decimal('Infinity')` is returned.

logical_and(*other*, *context*=*None*)

`logical_and()` is a logical operation which takes two *logical operands* (see Logical operands). The result is the digit-wise `and` of the two operands.

logical_invert(*context*=*None*)

`logical_invert()` is a logical operation. The result is the digit-wise inversion of the operand.

logical_or(*other*, *context*=*None*)

`logical_or()` is a logical operation which takes two *logical operands* (see Logical operands). The result is the digit-wise `or` of the two operands.

logical_xor(*other*, *context*=*None*)

`logical_xor()` is a logical operation which takes two *logical operands* (see Logical operands). The result is the digit-wise exclusive or of the two operands.

max(*other*, *context*=*None*)

Like `max(self, other)` except that the context rounding rule is applied before returning and that **`NaN`** values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

max_mag(*other*, *context*=*None*)

Similar to the **`max()`** method, but the comparison is done using the absolute values of the operands.

min(*other*, *context*=*None*)

Like `min(self, other)` except that the context rounding rule is applied before returning and that **`NaN`** values are either signaled or ignored (depending on the context and whether they are signaling or quiet).

min_mag(*other*, *context*=*None*)

Similar to the **`min()`** method, but the comparison is done using the absolute values of the operands.

next_minus(*context*=*None*)

Return the largest number representable in the given context (or in the current thread's context if no context is given) that is smaller than the given operand.

next_plus(*context*=*None*)

Return the smallest number representable in the given context (or in the current thread's context if no context is given) that is larger than the given operand.

next_toward(*other*, *context*=*None*)

If the two operands are unequal, return the number closest to the first operand in the direction of the second operand. If both operands are numerically equal, return a copy of the first operand with the sign set to be the same as the sign of the second operand.

normalize(*context*=*None*)

Normalize the number by stripping the rightmost trailing zeros and converting any result equal to **`Decimal('0')`** to **`Decimal('0e0')`**. Used for producing canonical values for attributes of an equivalence class. For example, `Decimal('32.100')` and `Decimal('0.321000e+2')` both normalize to the equivalent value `Decimal('32.1')`.

number_class(*context=None*)

Return a string describing the *class* of the operand. The returned value is one of the following ten strings.

- `"-Infinity"`, indicating that the operand is negative infinity.
- `"-Normal"`, indicating that the operand is a negative normal number.
- `"-Subnormal"`, indicating that the operand is negative and subnormal.
- `"-Zero"`, indicating that the operand is a negative zero.
- `"+Zero"`, indicating that the operand is a positive zero.
- `"+Subnormal"`, indicating that the operand is positive and subnormal.
- `"+Normal"`, indicating that the operand is a positive normal number.
- `"+Infinity"`, indicating that the operand is positive infinity.
- `"NaN"`, indicating that the operand is a quiet NaN (Not a Number).
- `"sNaN"`, indicating that the operand is a signaling NaN.

quantize(*exp*, *rounding=None*, *context=None*)

Return a value equal to the first operand after rounding and having the exponent of the second operand.

```
>>> Decimal('1.41421356').quantize(Decimal('1.0
Decimal('1.414')
```

Unlike other operations, if the length of the coefficient after the quantize operation would be greater than precision, then an **`InvalidOperation`** is signaled. This guarantees that, unless there is an error condition, the quantized exponent is always equal to that of the right-hand operand.

Also unlike other operations, quantize never signals

Underflow, even if the result is subnormal and inexact.

If the exponent of the second operand is larger than that of the first then rounding may be necessary. In this case, the rounding mode is determined by the `rounding` argument if given, else by the given `context` argument; if neither argument is given the rounding mode of the current thread's context is used.

An error is returned whenever the resulting exponent is greater than **`Emax`** or less than **`Etiny`**.

radix()

Return `Decimal(10)`, the radix (base) in which the **`Decimal`** class does all its arithmetic. Included for compatibility with the specification.

remainder_near(*other*, *context*=*None*)

Return the remainder from dividing *self* by *other*. This differs from `self % other` in that the sign of the remainder is chosen so as to minimize its absolute value. More precisely, the return value is `self - n * other` where `n` is the integer nearest to the exact value of `self / other`, and if two integers are equally near then the even one is chosen.

If the result is zero then its sign will be the sign of *self*.

```
>>> Decimal(18).remainder_near(Decimal(10))
Decimal('-2')
>>> Decimal(25).remainder_near(Decimal(10))
Decimal('5')
>>> Decimal(35).remainder_near(Decimal(10))
Decimal('-5')
```

rotate(*other*, *context*=*None*)

Return the result of rotating the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -

precision through precision. The absolute value of the second operand gives the number of places to rotate. If the second operand is positive then rotation is to the left; otherwise rotation is to the right. The coefficient of the first operand is padded on the left with zeros to length precision if necessary. The sign and exponent of the first operand are unchanged.

same_quantum(*other*, *context*=*None*)

Test whether self and other have the same exponent or whether both are **`NaN`**.

This operation is unaffected by context and is quiet: no flags are changed and no rounding is performed. As an exception, the C version may raise InvalidOperation if the second operand cannot be converted exactly.

scaleb(*other*, *context*=*None*)

Return the first operand with exponent adjusted by the second. Equivalently, return the first operand multiplied by `10**other`. The second operand must be an integer.

shift(*other*, *context*=*None*)

Return the result of shifting the digits of the first operand by an amount specified by the second operand. The second operand must be an integer in the range -precision through precision. The absolute value of the second operand gives the number of places to shift. If the second operand is positive then the shift is to the left; otherwise the shift is to the right. Digits shifted into the coefficient are zeros. The sign and exponent of the first operand are unchanged.

sqrt(*context*=*None*)

Return the square root of the argument to full precision.

to_eng_string(*context*=*None*)

Convert to a string, using engineering notation if an exponent is needed.

Engineering notation has an exponent which is a multiple of 3. This can leave up to 3 digits to the left of the decimal place and may require the addition of either one or two trailing zeros.

For example, this converts `Decimal('123E+1')` to `Decimal('1.23E+3')`.

to_integral(*rounding*=*None*, *context*=*None*)

Identical to the **`to_integral_value()`** method. The `to_integral` name has been kept for compatibility with older versions.

to_integral_exact(*rounding*=*None*, *context*=*None*)

Round to the nearest integer, signaling **`Inexact`** or **`Rounded`** as appropriate if rounding occurs. The rounding mode is determined by the `rounding` parameter if given, else by the given `context`. If neither parameter is given then the rounding mode of the current context is used.

to_integral_value(*rounding*=*None*, *context*=*None*)

Round to the nearest integer without signaling **`Inexact`** or **`Rounded`**. If given, applies *rounding*; otherwise, uses the rounding method in either the supplied *context* or the current context.

Logical operands

The **`logical_and()`**, **`logical_invert()`**, **`logical_or()`**, and **`logical_xor()`** methods expect their arguments to be *logical operands*. A *logical operand* is a **`Decimal`** instance whose exponent and sign are both zero, and whose digits are all either **`0`** or **`1`**.

Context objects

Contexts are environments for arithmetic operations. They govern precision, set rules for rounding, determine which signals are treated as exceptions, and limit the range for exponents.

Each thread has its own current context which is accessed or changed using the **`getcontext()`** and **`setcontext()`** functions:

decimal.getcontext()

Return the current context for the active thread.

decimal.setcontext(*c*)

Set the current context for the active thread to *c*.

You can also use the **`with`** statement and the **`localcontext()`** function to temporarily change the active context.

decimal.localcontext(*ctx=None*, ***kwargs*)

Return a context manager that will set the current context for the active thread to a copy of *ctx* on entry to the with-statement and restore the previous context when exiting the with-statement. If no context is specified, a copy of the current context is used. The *kwargs* argument is used to set the attributes of the new context.

For example, the following code sets the current decimal precision to 42 places, performs a calculation, and then automatically restores the previous context:

```
from decimal import localcontext

with localcontext() as ctx:
    ctx.prec = 42   # Perform a high precision calc
    s = calculate_something()
s = +s  # Round the final result back to the defaul
```

Using keyword arguments, the code would be the following:

```
from decimal import localcontext

with localcontext(prec=42) as ctx:
    s = calculate_something()
s = +s
```

Raises **TypeError** if *kwargs* supplies an attribute that **Context** doesn't support. Raises either **TypeError** or **ValueError** if *kwargs* supplies an invalid value for an attribute.

Changed in version 3.11: **localcontext()** now supports setting context attributes through the use of keyword arguments.

New contexts can also be created using the **Context** constructor described below. In addition, the module provides three pre-made contexts:

class decimal.BasicContext

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to **ROUND_HALF_UP**. All flags are cleared. All traps are enabled (treated as exceptions) except **Inexact**, **Rounded**, and **Subnormal**.

Because many of the traps are enabled, this context is useful for debugging.

class decimal.ExtendedContext

This is a standard context defined by the General Decimal Arithmetic Specification. Precision is set to nine. Rounding is set to **ROUND_HALF_EVEN**. All flags are cleared. No traps are enabled (so that exceptions are not raised during computations).

Because the traps are disabled, this context is useful for applications that prefer to have result value of **NaN** or **Infinity** instead of raising exceptions. This allows an application to complete a run in the presence of conditions

that would otherwise halt the program.

class decimal.DefaultContext

This context is used by the **Context** constructor as a prototype for new contexts. Changing a field (such a precision) has the effect of changing the default for new contexts created by the **Context** constructor.

This context is most useful in multi-threaded environments. Changing one of the fields before threads are started has the effect of setting system-wide defaults. Changing the fields after threads have started is not recommended as it would require thread synchronization to prevent race conditions.

In single threaded environments, it is preferable to not use this context at all. Instead, simply create contexts explicitly as described below.

The default values are **prec**=**28**, **rounding**=**ROUND_HALF_EVEN**, and enabled traps for **Overflow**, **InvalidOperation**, and **DivisionByZero**.

In addition to the three supplied contexts, new contexts can be created with the **Context** constructor.

class decimal.Context(*prec*=*None*, *rounding*=*None*, *Emin*=*None*, *Emax*=*None*, *capitals*=*None*, *clamp*=*None*, *flags*=*None*, *traps*=*None*)

Creates a new context. If a field is not specified or is **None**, the default values are copied from the **DefaultContext**. If the *flags* field is not specified or is **None**, all flags are cleared.

prec is an integer in the range [**1**, **MAX_PREC**] that sets the precision for arithmetic operations in the context.

The *rounding* option is one of the constants listed in the section Rounding Modes.

The *traps* and *flags* fields list any signals to be set. Generally, new contexts should only set traps and leave the flags clear.

The *Emin* and *Emax* fields are integers specifying the outer limits allowable for exponents. *Emin* must be in the range [**MIN_EMIN**, **0**], *Emax* in the range [**0**, **MAX_EMAX**].

The *capitals* field is either **0** or **1** (the default). If set to **1**, exponents are printed with a capital **E**; otherwise, a lowercase **e** is used: **Decimal('6.02e+23')**.

The *clamp* field is either **0** (the default) or **1**. If set to **1**, the exponent `e` of a **Decimal** instance representable in this context is strictly limited to the range `Emin - prec + 1 <= e <= Emax - prec + 1`. If *clamp* is **0** then a weaker condition holds: the adjusted exponent of the **Decimal** instance is at most `Emax`. When *clamp* is **1**, a large normal number will, where possible, have its exponent reduced and a corresponding number of zeros added to its coefficient, in order to fit the exponent constraints; this preserves the value of the number but loses information about significant trailing zeros. For example:

```
>>> Context(prec=6, Emax=999, clamp=1).create_decim
Decimal('1.23000E+999')
```

A *clamp* value of **1** allows compatibility with the fixed-width decimal interchange formats specified in IEEE 754.

The **Context** class defines several general purpose methods as well as a large number of methods for doing arithmetic directly in a given context. In addition, for each of the **Decimal** methods described above (with the exception of the **adjusted()** and **as_tuple()** methods) there is a corresponding **Context** method. For example, for a **Context** instance `C` and **Decimal** instance `x`, `C.exp(x)` is equivalent to `x.exp(context=C)`. Each **Context** method accepts a Python integer (an instance of **int**) anywhere that a Decimal instance is accepted.

clear_flags()

Resets all of the flags to **0**.

clear_traps()

Resets all of the traps to `0`.

New in version 3.3.

copy()

Return a duplicate of the context.

copy_decimal(*num*)

Return a copy of the Decimal instance num.

create_decimal(*num*)

Creates a new Decimal instance from *num* but using *self* as context. Unlike the `Decimal` constructor, the context precision, rounding method, flags, and traps are applied to the conversion.

This is useful because constants are often given to a greater precision than is needed by the application. Another benefit is that rounding immediately eliminates unintended effects from digits beyond the current precision. In the following example, using unrounded inputs means that adding zero to a sum can change the result:

```
>>> getcontext().prec = 3
>>> Decimal('3.4445') + Decimal('1.0023')
Decimal('4.45')
>>> Decimal('3.4445') + Decimal(0) + Decimal('1
Decimal('4.44')
```

This method implements the to-number operation of the IBM specification. If the argument is a string, no leading or trailing whitespace or underscores are permitted.

create_decimal_from_float(*f*)

Creates a new Decimal instance from a float *f* but

rounding using *self* as the context. Unlike the **`Decimal.from_float()`** class method, the context precision, rounding method, flags, and traps are applied to the conversion.

```
>>> context = Context(prec=5, rounding=ROUND_DO
>>> context.create_decimal_from_float(math.pi)
Decimal('3.1415')
>>> context = Context(prec=5, traps=[Inexact])
>>> context.create_decimal_from_float(math.pi)
Traceback (most recent call last):
    ...
decimal.Inexact: None
```

New in version 3.1.

Etiny()

Returns a value equal to `Emin - prec + 1` which is the minimum exponent value for subnormal results. When underflow occurs, the exponent is set to **`Etiny`**.

Etop()

Returns a value equal to `Emax - prec + 1`.

The usual approach to working with decimals is to create **`Decimal`** instances and then apply arithmetic operations which take place within the current context for the active thread. An alternative approach is to use context methods for calculating within a specific context. The methods are similar to those for the **`Decimal`** class and are only briefly recounted here.

abs(*x*)

Returns the absolute value of *x*.

add(*x*, *y*)

Return the sum of *x* and *y*.

canonical(*x*)

Returns the same Decimal object *x*.

compare(*x*, *y*)

Compares *x* and *y* numerically.

compare_signal(*x*, *y*)

Compares the values of the two operands numerically.

compare_total(*x*, *y*)

Compares two operands using their abstract representation.

compare_total_mag(*x*, *y*)

Compares two operands using their abstract representation, ignoring sign.

copy_abs(*x*)

Returns a copy of *x* with the sign set to 0.

copy_negate(*x*)

Returns a copy of *x* with the sign inverted.

copy_sign(*x*, *y*)

Copies the sign from *y* to *x*.

divide(*x*, *y*)

Return *x* divided by *y*.

divide_int(*x*, *y*)

Return *x* divided by *y*, truncated to an integer.

divmod(*x*, *y*)

Divides two numbers and returns the integer part of the

result.

exp(*x*)
: Returns `e ** x`.

fma(*x*, *y*, *z*)
: Returns *x* multiplied by *y*, plus *z*.

is_canonical(*x*)
: Returns `True` if *x* is canonical; otherwise returns `False`.

is_finite(*x*)
: Returns `True` if *x* is finite; otherwise returns `False`.

is_infinite(*x*)
: Returns `True` if *x* is infinite; otherwise returns `False`.

is_nan(*x*)
: Returns `True` if *x* is a qNaN or sNaN; otherwise returns `False`.

is_normal(*x*)
: Returns `True` if *x* is a normal number; otherwise returns `False`.

is_qnan(*x*)
: Returns `True` if *x* is a quiet NaN; otherwise returns `False`.

is_signed(*x*)
: Returns `True` if *x* is negative; otherwise returns `False`.

is_snan(*x*)

Returns `True` if *x* is a signaling NaN; otherwise returns `False`.

is_subnormal(*x*)

Returns `True` if *x* is subnormal; otherwise returns `False`.

is_zero(*x*)

Returns `True` if *x* is a zero; otherwise returns `False`.

ln(*x*)

Returns the natural (base e) logarithm of *x*.

log10(*x*)

Returns the base 10 logarithm of *x*.

logb(*x*)

Returns the exponent of the magnitude of the operand's MSD.

logical_and(*x*, *y*)

Applies the logical operation *and* between each operand's digits.

logical_invert(*x*)

Invert all the digits in *x*.

logical_or(*x*, *y*)

Applies the logical operation *or* between each operand's digits.

logical_xor(*x*, *y*)

Applies the logical operation *xor* between each operand's digits.

max(*x*, *y*)

Compares two values numerically and returns the maximum.

max_mag(*x*, *y*)

Compares the values numerically with their sign ignored.

min(*x*, *y*)

Compares two values numerically and returns the minimum.

min_mag(*x*, *y*)

Compares the values numerically with their sign ignored.

minus(*x*)

Minus corresponds to the unary prefix minus operator in Python.

multiply(*x*, *y*)

Return the product of *x* and *y*.

next_minus(*x*)

Returns the largest representable number smaller than *x*.

next_plus(*x*)

Returns the smallest representable number larger than *x*.

next_toward(*x*, *y*)

Returns the number closest to *x*, in direction towards *y*.

normalize(*x*)

Reduces *x* to its simplest form.

number_class(*x*)

Returns an indication of the class of *x*.

plus(*x*)

Plus corresponds to the unary prefix plus operator in Python. This operation applies the context precision and rounding, so it is *not* an identity operation.

power(*x*, *y*, *modulo*=*None*)

Return `x` to the power of `y`, reduced modulo `modulo` if given.

With two arguments, compute `x**y`. If `x` is negative then `y` must be integral. The result will be inexact unless `y` is integral and the result is finite and can be expressed exactly in 'precision' digits. The rounding mode of the context is used. Results are always correctly rounded in the Python version.

`Decimal(0) ** Decimal(0)` results in `InvalidOperation`, and if `InvalidOperation` is not trapped, then results in `Decimal('NaN')`.

Changed in version 3.3: The C module computes **`power()`** in terms of the correctly rounded **`exp()`** and **`ln()`** functions. The result is well-defined but only "almost always correctly rounded".

With three arguments, compute `(x**y) % modulo`. For the three argument form, the following restrictions on the arguments hold:

- all three arguments must be integral
- `y` must be nonnegative
- at least one of `x` or `y` must be nonzero

- `modulo` must be nonzero and have at most 'precision' digits

The value resulting from `Context.power(x, y, modulo)` is equal to the value that would be obtained by computing `(x**y) % modulo` with unbounded precision, but is computed more efficiently. The exponent of the result is zero, regardless of the exponents of `x`, `y` and `modulo`. The result is always exact.

quantize(*x*, *y*)

Returns a value equal to *x* (rounded), having the exponent of *y*.

radix()

Just returns 10, as this is Decimal, :)

remainder(*x*, *y*)

Returns the remainder from integer division.

The sign of the result, if non-zero, is the same as that of the original dividend.

remainder_near(*x*, *y*)

Returns `x - y * n`, where *n* is the integer nearest the exact value of `x / y` (if the result is 0 then its sign will be the sign of *x*).

rotate(*x*, *y*)

Returns a rotated copy of *x*, *y* times.

same_quantum(*x*, *y*)

Returns `True` if the two operands have the same exponent.

scaleb(*x*, *y*)

Returns the first operand after adding the second value its exp.

shift(*x*, *y*)

Returns a shifted copy of *x*, *y* times.

sqrt(*x*)

Square root of a non-negative number to context precision.

subtract(*x*, *y*)

Return the difference between *x* and *y*.

to_eng_string(*x*)

Convert to a string, using engineering notation if an exponent is needed.

Engineering notation has an exponent which is a multiple of 3. This can leave up to 3 digits to the left of the decimal place and may require the addition of either one or two trailing zeros.

to_integral_exact(*x*)

Rounds to an integer.

to_sci_string(*x*)

Converts a number to a string using scientific notation.

Constants

The constants in this section are only relevant for the C module. They are also included in the pure Python version for compatibility.

32-bit	64-bit
425000000	425000000
999999999	999999999
1999999997	2999999997
2147483647	9223372036854775807
-2147483647	-9223372036854775807
-2147483648	-9223372036854775808

decimal.HAVE_THREADS

The value is `True`. Deprecated, because Python now always has threads.

Deprecated since version 3.9.

decimal.HAVE_CONTEXTVAR

The default value is `True`. If Python is **configured using the --without-decimal-contextvar option**, the C version uses a thread-local rather than a coroutine-local context and the value is `False`. This is slightly faster in some nested context scenarios.

New in version 3.9: backported to 3.7 and 3.8.

Rounding modes

decimal.ROUND_CEILING

Round towards **`Infinity`**.

decimal.ROUND_DOWN

Round towards zero.

decimal.ROUND_FLOOR

Round towards **`-Infinity`**.

decimal.ROUND_HALF_DOWN

Round to nearest with ties going towards zero.

decimal.ROUND_HALF_EVEN

Round to nearest with ties going to nearest even integer.

decimal.ROUND_HALF_UP

Round to nearest with ties going away from zero.

decimal.ROUND_UP

Round away from zero.

decimal.ROUND_05UP

Round away from zero if last digit after rounding towards zero would have been 0 or 5; otherwise round towards zero.

Signals

Signals represent conditions that arise during computation. Each corresponds to one context flag and one context trap enabler.

The context flag is set whenever the condition is encountered. After the computation, flags may be checked for informational purposes (for instance, to determine whether a computation was exact). After checking the flags, be sure to clear all flags before starting the next computation.

If the context's trap enabler is set for the signal, then the condition causes a Python exception to be raised. For example, if the **DivisionByZero** trap is set, then a **DivisionByZero** exception is raised upon encountering the condition.

class decimal.Clamped

Altered an exponent to fit representation constraints.

Typically, clamping occurs when an exponent falls outside the context's **Emin** and **Emax** limits. If possible, the exponent is reduced to fit by adding zeros to the coefficient.

class decimal.DecimalException

Base class for other signals and a subclass of **ArithmeticError**.

class decimal.DivisionByZero

Signals the division of a non-infinite number by zero.

Can occur with division, modulo division, or when raising a number to a negative power. If this signal is not trapped,

returns **`Infinity`** or **`-Infinity`** with the sign determined by the inputs to the calculation.

class decimal.Inexact

Indicates that rounding occurred and the result is not exact.

Signals when non-zero digits were discarded during rounding. The rounded result is returned. The signal flag or trap is used to detect when results are inexact.

class decimal.InvalidOperation

An invalid operation was performed.

Indicates that an operation was requested that does not make sense. If not trapped, returns **`NaN`**. Possible causes include:

```
Infinity - Infinity
0 * Infinity
Infinity / Infinity
x % 0
Infinity % x
sqrt(-x) and x > 0
0 ** 0
x ** (non-integer)
x ** Infinity
```

class decimal.Overflow

Numerical overflow.

Indicates the exponent is larger than **`Emax`** after rounding has occurred. If not trapped, the result depends on the rounding mode, either pulling inward to the largest representable finite number or rounding outward to **`Infinity`**. In either case, **`Inexact`** and **`Rounded`** are also signaled.

class decimal.Rounded

Rounding occurred though possibly no information was lost.

Signaled whenever rounding discards digits; even if those digits are zero (such as rounding `5.00` to `5.0`). If not trapped, returns the result unchanged. This signal is used to detect loss of significant digits.

class decimal.Subnormal

Exponent was lower than **`Emin`** prior to rounding.

Occurs when an operation result is subnormal (the exponent is too small). If not trapped, returns the result unchanged.

class decimal.Underflow

Numerical underflow with result rounded to zero.

Occurs when a subnormal result is pushed to zero by rounding. **`Inexact`** and **`Subnormal`** are also signaled.

class decimal.FloatOperation

Enable stricter semantics for mixing floats and Decimals.

If the signal is not trapped (default), mixing floats and Decimals is permitted in the **`Decimal`** constructor, **`create_decimal()`** and all comparison operators. Both conversion and comparisons are exact. Any occurrence of a mixed operation is silently recorded by setting **`FloatOperation`** in the context flags. Explicit conversions with **`from_float()`** or **`create_decimal_from_float()`** do not set the flag.

Otherwise (the signal is trapped), only equality comparisons and explicit conversions are silent. All other mixed operations raise **`FloatOperation`**.

The following table summarizes the hierarchy of signals:

```
exceptions.ArithmeticError(exceptions.Exception)
    DecimalException
        Clamped
        DivisionByZero(DecimalException, exceptions.Zero
```

```
        Inexact
            Overflow(Inexact, Rounded)
            Underflow(Inexact, Rounded, Subnormal)
        InvalidOperation
        Rounded
        Subnormal
        FloatOperation(DecimalException, exceptions.Type
```

Floating Point Notes

Mitigating round-off error with increased precision

The use of decimal floating point eliminates decimal representation error (making it possible to represent `0.1` exactly); however, some operations can still incur round-off error when non-zero digits exceed the fixed precision.

The effects of round-off error can be amplified by the addition or subtraction of nearly offsetting quantities resulting in loss of significance. Knuth provides two instructive examples where rounded floating point arithmetic with insufficient precision causes the breakdown of the associative and distributive properties of addition:

```
# Examples from Seminumerical Algorithms, Section 4.2.2.
>>> from decimal import Decimal, getcontext
>>> getcontext().prec = 8

>>> u, v, w = Decimal(11111113), Decimal(-11111111), Dec
>>> (u + v) + w
Decimal('9.5111111')
>>> u + (v + w)
Decimal('10')

>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.00
>>> (u*v) + (u*w)
Decimal('0.01')
>>> u * (v+w)
Decimal('0.0060000')
```

The **decimal** module makes it possible to restore the identities by expanding the precision sufficiently to avoid loss of significance:

```
>>> getcontext().prec = 20
>>> u, v, w = Decimal(11111113), Decimal(-11111111), Dec
>>> (u + v) + w
Decimal('9.51111111')
>>> u + (v + w)
Decimal('9.51111111')
>>>
>>> u, v, w = Decimal(20000), Decimal(-6), Decimal('6.00
>>> (u*v) + (u*w)
Decimal('0.0060000')
>>> u * (v+w)
Decimal('0.0060000')
```

Special values

The number system for the **decimal** module provides special values including **NaN**, **sNaN**, **-Infinity**, **Infinity**, and two zeros, **+0** and **-0**.

Infinities can be constructed directly with: `Decimal('Infinity')`. Also, they can arise from dividing by zero when the **DivisionByZero** signal is not trapped. Likewise, when the **Overflow** signal is not trapped, infinity can result from rounding beyond the limits of the largest representable number.

The infinities are signed (affine) and can be used in arithmetic operations where they get treated as very large, indeterminate numbers. For instance, adding a constant to infinity gives another infinite result.

Some operations are indeterminate and return **NaN**, or if the **InvalidOperation** signal is trapped, raise an exception. For example, `0/0` returns **NaN** which means “not a number”. This variety of **NaN** is quiet and, once created, will flow through other computations always resulting in another **NaN**. This behavior can be useful for a series of computations that occasionally have missing inputs — it allows the calculation to proceed while flagging specific

results as invalid.

A variant is **sNaN** which signals rather than remaining quiet after every operation. This is a useful return value when an invalid result needs to interrupt a calculation for special handling.

The behavior of Python's comparison operators can be a little surprising where a **NaN** is involved. A test for equality where one of the operands is a quiet or signaling **NaN** always returns **False** (even when doing `Decimal('NaN')==Decimal('NaN')`), while a test for inequality always returns **True**. An attempt to compare two Decimals using any of the `<`, `<=`, `>` or `>=` operators will raise the **InvalidOperation** signal if either operand is a **NaN**, and return **False** if this signal is not trapped. Note that the General Decimal Arithmetic specification does not specify the behavior of direct comparisons; these rules for comparisons involving a **NaN** were taken from the IEEE 854 standard (see Table 3 in section 5.7). To ensure strict standards-compliance, use the **compare()** and **compare-signal()** methods instead.

The signed zeros can result from calculations that underflow. They keep the sign that would have resulted if the calculation had been carried out to greater precision. Since their magnitude is zero, both positive and negative zeros are treated as equal and their sign is informational.

In addition to the two signed zeros which are distinct yet equal, there are various representations of zero with differing precisions yet equivalent in value. This takes a bit of getting used to. For an eye accustomed to normalized floating point representations, it is not immediately obvious that the following calculation returns a value equal to zero:

```
>>> 1 / Decimal('Infinity')
Decimal('0E-1000026')
```

Working with threads

The **getcontext()** function accesses a different **Context** object for each thread. Having separate thread contexts means that threads

may make changes (such as `getcontext().prec=10`) without interfering with other threads.

Likewise, the **`setcontext()`** function automatically assigns its target to the current thread.

If **`setcontext()`** has not been called before **`getcontext()`**, then **`getcontext()`** will automatically create a new context for use in the current thread.

The new context is copied from a prototype context called *DefaultContext*. To control the defaults so that each thread will use the same values throughout the application, directly modify the *DefaultContext* object. This should be done *before* any threads are started so that there won't be a race condition between threads calling **`getcontext()`**. For example:

```
# Set applicationwide defaults for all threads about to
DefaultContext.prec = 12
DefaultContext.rounding = ROUND_DOWN
DefaultContext.traps = ExtendedContext.traps.copy()
DefaultContext.traps[InvalidOperation] = 1
setcontext(DefaultContext)

# Afterwards, the threads can be started
t1.start()
t2.start()
t3.start()
 . . .
```

Recipes

Here are a few recipes that serve as utility functions and that demonstrate ways to work with the **`Decimal`** class:

```
def moneyfmt(value, places=2, curr='', sep=',', dp='.',
             pos='', neg='-', trailneg=''):
    """Convert Decimal to a money formatted string.

    places:  required number of places after the decimal
```

```
curr:    optional currency symbol before the sign (m
sep:     optional grouping separator (comma, period,
dp:      decimal point indicator (comma or period)
         only specify as blank when places is zero
pos:     optional sign for positive numbers: '+', sp
neg:     optional sign for negative numbers: '-', '(
trailneg:optional trailing minus indicator:  '-', ')

>>> d = Decimal('-1234567.8901')
>>> moneyfmt(d, curr='$')
'-$1,234,567.89'
>>> moneyfmt(d, places=0, sep='.', dp='', neg='', tr
'1.234.568-'
>>> moneyfmt(d, curr='$', neg='(', trailneg=')')
'($1,234,567.89)'
>>> moneyfmt(Decimal(123456789), sep=' ')
'123 456 789.00'
>>> moneyfmt(Decimal('-0.02'), neg='<', trailneg='>'
'<0.02>'

"""
q = Decimal(10) ** -places      # 2 places --> '0.01
sign, digits, exp = value.quantize(q).as_tuple()
result = []
digits = list(map(str, digits))
build, next = result.append, digits.pop
if sign:
    build(trailneg)
for i in range(places):
    build(next() if digits else '0')
if places:
    build(dp)
if not digits:
    build('0')
i = 0
while digits:
    build(next())
    i += 1
```

```
        if i == 3 and digits:
            i = 0
            build(sep)
    build(curr)
    build(neg if sign else pos)
    return ''.join(reversed(result))

def pi():
    """Compute Pi to the current precision.

    >>> print(pi())
    3.141592653589793238462643383

    """
    getcontext().prec += 2  # extra digits for intermedi
    three = Decimal(3)      # substitute "three=3.0" for
    lasts, t, s, n, na, d, da = 0, three, 3, 1, 0, 0, 24
    while s != lasts:
        lasts = s
        n, na = n+na, na+8
        d, da = d+da, da+32
        t = (t * n) / d
        s += t
    getcontext().prec -= 2
    return +s               # unary plus applies the new

def exp(x):
    """Return e raised to the power of x.  Result type m

    >>> print(exp(Decimal(1)))
    2.718281828459045235360287471
    >>> print(exp(Decimal(2)))
    7.389056098930650227230427461
    >>> print(exp(2.0))

        fact *= i * (i-1)
        num *= x * x
        sign *= -1
        s += num / fact * sign
    getcontext().prec -= 2
    return +s
```

Decimal FAQ

Q. It is cumbersome to type `decimal.Decimal('1234.5')`. Is there a way to minimize typing when using the interactive interpreter?

A. Some users abbreviate the constructor to just a single letter:

```
>>> D = decimal.Decimal
>>> D('1.23') + D('3.45')
Decimal('4.68')
```

Q. In a fixed-point application with two decimal places, some inputs

have many places and need to be rounded. Others are not supposed to have excess digits and need to be validated. What methods should be used?

A. The **`quantize()`** method rounds to a fixed number of decimal places. If the **`Inexact`** trap is set, it is also useful for validation:

```
>>> TWOPLACES = Decimal(10) ** -2       # same as Decima

>>> # Round to two places
>>> Decimal('3.214').quantize(TWOPLACES)
Decimal('3.21')

>>> # Validate that a number does not exceed two places
>>> Decimal('3.21').quantize(TWOPLACES, context=Context(
Decimal('3.21')

>>> Decimal('3.214').quantize(TWOPLACES, context=Context
Traceback (most recent call last):
   ...
Inexact: None
```

Q. Once I have valid two place inputs, how do I maintain that invariant throughout an application?

A. Some operations like addition, subtraction, and multiplication by an integer will automatically preserve fixed point. Others operations, like division and non-integer multiplication, will change the number of decimal places and need to be followed-up with a **`quantize()`** step:

```
>>> a = Decimal('102.72')           # Initial fixed-poir
>>> b = Decimal('3.17')
>>> a + b                           # Addition preserves
Decimal('105.89')
>>> a - b
Decimal('99.55')
>>> a * 42                          # So does integer mu
Decimal('4314.24')
>>> (a * b).quantize(TWOPLACES)     # Must quantize non-
```

```
Decimal('325.62')
>>> (b / a).quantize(TWOPLACES)      # And quantize divis
Decimal('0.03')
```

In developing fixed-point applications, it is convenient to define functions to handle the **`quantize()`** step:

```
>>> def mul(x, y, fp=TWOPLACES):
...     return (x * y).quantize(fp)
>>> def div(x, y, fp=TWOPLACES):
...     return (x / y).quantize(fp)

>>> mul(a, b)                        # Automatically pres
Decimal('325.62')
>>> div(b, a)
Decimal('0.03')
```

Q. There are many ways to express the same value. The numbers **`200`**, **`200.000`**, **`2E2`**, and **`02E+4`** all have the same value at various precisions. Is there a way to transform them to a single recognizable canonical value?

A. The **`normalize()`** method maps all equivalent values to a single representative:

```
>>> values = map(Decimal, '200 200.000 2E2 .02E+4'.split
>>> [v.normalize() for v in values]
[Decimal('2E+2'), Decimal('2E+2'), Decimal('2E+2'), Deci
```

Q. Some decimal values always print with exponential notation. Is there a way to get a non-exponential representation?

A. For some values, exponential notation is the only way to express the number of significant places in the coefficient. For example, expressing **`5.0E+3`** as **`5000`** keeps the value constant but cannot show the original's two-place significance.

If an application does not care about tracking significance, it is easy to remove the exponent and trailing zeroes, losing significance, but keeping the value unchanged:

```
>>> def remove_exponent(d):
...     return d.quantize(Decimal(1)) if d == d.to_integ

>>> remove_exponent(Decimal('5E+3'))
Decimal('5000')
```

Q. Is there a way to convert a regular float to a **`Decimal`**?

A. Yes, any binary floating point number can be exactly expressed as a Decimal though an exact conversion may take more precision than intuition would suggest:

```
>>> Decimal(math.pi)
Decimal('3.141592653589793115997963468544185161590576171
```

Q. Within a complex calculation, how can I make sure that I haven't gotten a spurious result because of insufficient precision or rounding anomalies.

A. The decimal module makes it easy to test results. A best practice is to re-run calculations using greater precision and with various rounding modes. Widely differing results indicate insufficient precision, rounding mode issues, ill-conditioned inputs, or a numerically unstable algorithm.

Q. I noticed that context precision is applied to the results of operations but not to the inputs. Is there anything to watch out for when mixing values of different precisions?

A. Yes. The principle is that all values are considered to be exact and so is the arithmetic on those values. Only the results are rounded. The advantage for inputs is that "what you type is what you get". A disadvantage is that the results can look odd if you forget that the inputs haven't been rounded:

```
>>> getcontext().prec = 3
>>> Decimal('3.104') + Decimal('2.104')
Decimal('5.21')
>>> Decimal('3.104') + Decimal('0.000') + Decimal('2.104
Decimal('5.20')
```

The solution is either to increase precision or to force rounding of inputs using the unary plus operation:

```
>>> getcontext().prec = 3
>>> +Decimal('1.23456789')      # unary plus triggers ro
Decimal('1.23')
```

Alternatively, inputs can be rounded upon creation using the **`Context.create_decimal()`** method:

```
>>> Context(prec=5, rounding=ROUND_DOWN).create_decimal(
Decimal('1.2345')
```

Q. Is the CPython implementation fast for large numbers?

A. Yes. In the CPython and PyPy3 implementations, the C/CFFI versions of the decimal module integrate the high speed libmpdec [https://www.bytereef.org/mpdecimal/doc/libmpdec/index.html] library for arbitrary precision correctly rounded decimal floating point arithmetic 1. `libmpdec` uses Karatsuba multiplication [https://en.wikipedia.org/wiki/Karatsuba_algorithm] for medium-sized numbers and the Number Theoretic Transform [https://en.wikipedia.org/wiki/Discrete_Fourier_transform_(general)#Number-theoretic_transform] for very large numbers.

The context must be adapted for exact arbitrary precision arithmetic. **`Emin`** and **`Emax`** should always be set to the maximum values, **`clamp`** should always be 0 (the default). Setting **`prec`** requires some care.

The easiest approach for trying out bignum arithmetic is to use the maximum value for **`prec`** as well 2:

```
>>> setcontext(Context(prec=MAX_PREC, Emax=MAX_EMAX, Emi
>>> x = Decimal(2) ** 256
>>> x / 128
Decimal('904625697166532776746648320380374280103671755200
```

For inexact results, **`MAX_PREC`** is far too large on 64-bit platforms and the available memory will be insufficient:

```
>>> Decimal(1) / 3
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
MemoryError
```

On systems with overallocation (e.g. Linux), a more sophisticated approach is to adjust **`prec`** to the amount of available RAM. Suppose that you have 8GB of RAM and expect 10 simultaneous operands using a maximum of 500MB each:

```
>>> import sys
>>>
>>> # Maximum number of digits for a single operand usin
>>> # with 19 digits per word (4-byte and 9 digits for t
>>> maxdigits = 19 * ((500 * 1024**2) // 8)
>>>
>>> # Check that this works:
>>> c = Context(prec=maxdigits, Emax=MAX_EMAX, Emin=MIN_
>>> c.traps[Inexact] = True
>>> setcontext(c)
>>>
>>> # Fill the available precision with nines:
>>> x = Decimal(0).logical_invert() * 9
>>> sys.getsizeof(x)
524288112
>>> x + 2
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  decimal.Inexact: [<class 'decimal.Inexact'>]
```

In general (and especially on systems without overallocation), it is recommended to estimate even tighter bounds and set the **`Inexact`** trap if all calculations are expected to be exact.

1

New in version 3.3.

2

Changed in version 3.9: This approach now works for all exact

results except for non-integer powers.

`fractions` — Rational numbers

Source code: Lib/fractions.py [https://github.com/python/cpython/tree/3.11/Lib/fractions.py]

The `fractions` module provides support for rational number arithmetic.

A Fraction instance can be constructed from a pair of integers, from another rational number, or from a string.

class fractions.Fraction(*numerator=0*, *denominator=1*)

class fractions.Fraction(*other_fraction*)

class fractions.Fraction(*float*)

class fractions.Fraction(*decimal*)

class fractions.Fraction(*string*)

The first version requires that *numerator* and *denominator* are instances of `numbers.Rational` and returns a new `Fraction` instance with value `numerator/denominator`. If *denominator* is `0`, it raises a `ZeroDivisionError`. The second version requires that *other_fraction* is an instance of `numbers.Rational` and returns a `Fraction` instance with the same value. The next two versions accept either a `float` or a `decimal.Decimal` instance, and return a `Fraction` instance with exactly the same value. Note that due to the usual issues with binary floating-point (see Floating Point Arithmetic: Issues and Limitations), the argument to `Fraction(1.1)` is not exactly equal to 11/10, and so `Fraction(1.1)` does *not* return `Fraction(11, 10)` as one might expect. (But see the documentation for the `limit_denominator()` method below.) The last version of the constructor expects a string or unicode instance. The

usual form for this instance is:

```
[sign] numerator ['/' denominator]
```

where the optional `sign` may be either '+' or '-' and `numerator` and `denominator` (if present) are strings of decimal digits (underscores may be used to delimit digits as with integral literals in code). In addition, any string that represents a finite value and is accepted by the **`float`** constructor is also accepted by the **`Fraction`** constructor. In either form the input string may also have leading and/or trailing whitespace. Here are some examples:

```
>>> from fractions import Fraction
>>> Fraction(16, -10)
Fraction(-8, 5)
>>> Fraction(123)
Fraction(123, 1)
>>> Fraction()
Fraction(0, 1)
>>> Fraction('3/7')
Fraction(3, 7)
>>> Fraction(' -3/7 ')
Fraction(-3, 7)
>>> Fraction('1.414213 \t\n')
Fraction(1414213, 1000000)
>>> Fraction('-.125')
Fraction(-1, 8)
>>> Fraction('7e-6')
Fraction(7, 1000000)
>>> Fraction(2.25)
Fraction(9, 4)
>>> Fraction(1.1)
Fraction(2476979795053773, 2251799813685248)
>>> from decimal import Decimal
>>> Fraction(Decimal('1.1'))
Fraction(11, 10)
```

The **`Fraction`** class inherits from the abstract base class **`numbers.Rational`**, and implements all of the methods and

operations from that class. **Fraction** instances are hashable, and should be treated as immutable. In addition, **Fraction** has the following properties and methods:

Changed in version 3.2: The **Fraction** constructor now accepts **float** and **decimal.Decimal** instances.

Changed in version 3.9: The **math.gcd()** function is now used to normalize the *numerator* and *denominator*. **math.gcd()** always return a **int** type. Previously, the GCD type depended on *numerator* and *denominator*.

Changed in version 3.11: Underscores are now permitted when creating a **Fraction** instance from a string, following **PEP 515** [https://peps.python.org/pep-0515/] rules.

Changed in version 3.11: **Fraction** implements `__int__` now to satisfy `typing.SupportsInt` instance checks.

numerator

Numerator of the Fraction in lowest term.

denominator

Denominator of the Fraction in lowest term.

as_integer_ratio()

Return a tuple of two integers, whose ratio is equal to the Fraction and with a positive denominator.

New in version 3.8.

classmethod from_float(*flt*)

Alternative constructor which only accepts instances of **float** or **numbers.Integral**. Beware that `Fraction.from_float(0.3)` is not the same value as `Fraction(3, 10)`.

Note

From Python 3.2 onwards, you can also construct a **`Fraction`** instance directly from a **`float`**.

classmethod from_decimal(*dec*)

Alternative constructor which only accepts instances of **`decimal.Decimal`** or **`numbers.Integral`**.

Note

From Python 3.2 onwards, you can also construct a **`Fraction`** instance directly from a **`decimal.Decimal`** instance.

limit_denominator(*max_denominator = 1000000*)

Finds and returns the closest **`Fraction`** to `self` that has denominator at most max_denominator. This method is useful for finding rational approximations to a given floating-point number:

```
>>> from fractions import Fraction
>>> Fraction('3.1415926535897932').limit_denomi
Fraction(355, 113)
```

or for recovering a rational number that's represented as a float:

```
>>> from math import pi, cos
>>> Fraction(cos(pi/3))
Fraction(4503599627370497, 9007199254740992)
>>> Fraction(cos(pi/3)).limit_denominator()
Fraction(1, 2)
>>> Fraction(1.1).limit_denominator()
Fraction(11, 10)
```

floor()

Returns the greatest **`int`** `<= self`. This method can

also be accessed through the **`math.floor()`** function:

```
>>> from math import floor
>>> floor(Fraction(355, 113))
3
```

ceil()

Returns the least **`int`** `>= self`. This method can also be accessed through the **`math.ceil()`** function.

round()

round(*ndigits*)

The first version returns the nearest **`int`** to `self`, rounding half to even. The second version rounds `self` to the nearest multiple of `Fraction(1, 10**ndigits)` (logically, if `ndigits` is negative), again rounding half toward even. This method can also be accessed through the **`round()`** function.

Module `numbers`

The abstract base classes making up the numeric tower.

`random` — Generate pseudo-random numbers

Source code: Lib/random.py [https://github.com/python/cpython/tree/3.11/Lib/random.py]

This module implements pseudo-random number generators for various distributions.

For integers, there is uniform selection from a range. For sequences, there is uniform selection of a random element, a function to generate a random permutation of a list in-place, and a function for random sampling without replacement.

On the real line, there are functions to compute uniform, normal (Gaussian), lognormal, negative exponential, gamma, and beta distributions. For generating distributions of angles, the von Mises distribution is available.

Almost all module functions depend on the basic function `random()`, which generates a random float uniformly in the semi-open range [0.0, 1.0). Python uses the Mersenne Twister as the core generator. It produces 53-bit precision floats and has a period of 2**19937-1. The underlying implementation in C is both fast and threadsafe. The Mersenne Twister is one of the most extensively tested random number generators in existence. However, being completely deterministic, it is not suitable for all purposes, and is completely unsuitable for cryptographic purposes.

The functions supplied by this module are actually bound methods of a hidden instance of the `random.Random` class. You can instantiate your own instances of `Random` to get generators that don't share state.

Class `Random` can also be subclassed if you want to use a different

basic generator of your own devising: in that case, override the **`random()`**, **`seed()`**, **`getstate()`**, and **`setstate()`** methods. Optionally, a new generator can supply a **`getrandbits()`** method — this allows **`randrange()`** to produce selections over an arbitrarily large range.

The **`random`** module also provides the **`SystemRandom`** class which uses the system function **`os.urandom()`** to generate random numbers from sources provided by the operating system.

Warning

The pseudo-random generators of this module should not be used for security purposes. For security or cryptographic uses, see the **`secrets`** module.

M. Matsumoto and T. Nishimura, “Mersenne Twister: A 623-dimensionally equidistributed uniform pseudorandom number generator”, ACM Transactions on Modeling and Computer Simulation Vol. 8, No. 1, January pp.3–30 1998.

Complementary-Multiply-with-Carry recipe [https://code.activestate.com/recipes/576707/] for a compatible alternative random number generator with a long period and comparatively simple update operations.

Bookkeeping functions

random.seed(*a*=*None*, *version*=*2*)

Initialize the random number generator.

If *a* is omitted or `None`, the current system time is used. If randomness sources are provided by the operating system, they are used instead of the system time (see the **`os.urandom()`** function for details on availability).

If *a* is an int, it is used directly.

With version 2 (the default), a **str**, **bytes**, or **bytearray** object gets converted to an **int** and all of its bits are used.

With version 1 (provided for reproducing random sequences from older versions of Python), the algorithm for **str** and **bytes** generates a narrower range of seeds.

Changed in version 3.2: Moved to the version 2 scheme which uses all of the bits in a string seed.

Changed in version 3.11: The *seed* must be one of the following types: *NoneType*, **int**, **float**, **str**, **bytes**, or **bytearray**.

random.getstate()

Return an object capturing the current internal state of the generator. This object can be passed to **setstate()** to restore the state.

random.setstate(*state*)

state should have been obtained from a previous call to **getstate()**, and **setstate()** restores the internal state of the generator to what it was at the time **getstate()** was called.

Functions for bytes

random.randbytes(*n*)

Generate *n* random bytes.

This method should not be used for generating security tokens. Use **secrets.token_bytes()** instead.

New in version 3.9.

Functions for integers

random.randrange(*stop*)

random.randrange(*start*, *stop*[, *step*])

Return a randomly selected element from `range(start, stop, step)`. This is equivalent to `choice(range(start, stop, step))`, but doesn't actually build a range object.

The positional argument pattern matches that of **`range()`**. Keyword arguments should not be used because the function may use them in unexpected ways.

Changed in version 3.2: **`randrange()`** is more sophisticated about producing equally distributed values. Formerly it used a style like `int(random()*n)` which could produce slightly uneven distributions.

Deprecated since version 3.10: The automatic conversion of non-integer types to equivalent integers is deprecated. Currently `randrange(10.0)` is losslessly converted to `randrange(10)`. In the future, this will raise a **`TypeError`**.

Deprecated since version 3.10: The exception raised for non-integral values such as `randrange(10.5)` or `randrange('10')` will be changed from **`ValueError`** to **`TypeError`**.

random.randint(*a*, *b*)

Return a random integer *N* such that `a <= N <= b`. Alias for `randrange(a, b+1)`.

random.getrandbits(*k*)

Returns a non-negative Python integer with *k* random bits. This method is supplied with the MersenneTwister generator and some other generators may also provide it as an optional part of the API. When available, **`getrandbits()`** enables **`randrange()`** to handle arbitrarily large ranges.

Changed in version 3.9: This method now accepts zero for *k*.

Functions for sequences

random.choice(*seq*)

Return a random element from the non-empty sequence *seq*. If *seq* is empty, raises **IndexError**.

random.choices(*population*, *weights*=*None*, ***, *cum_weights*=*None*, *k*=*1*)

Return a *k* sized list of elements chosen from the *population* with replacement. If the *population* is empty, raises **IndexError**.

If a *weights* sequence is specified, selections are made according to the relative weights. Alternatively, if a *cum_weights* sequence is given, the selections are made according to the cumulative weights (perhaps computed using **itertools.accumulate()**). For example, the relative weights `[10, 5, 30, 5]` are equivalent to the cumulative weights `[10, 15, 45, 50]`. Internally, the relative weights are converted to cumulative weights before making selections, so supplying the cumulative weights saves work.

If neither *weights* nor *cum_weights* are specified, selections are made with equal probability. If a weights sequence is supplied, it must be the same length as the *population* sequence. It is a **TypeError** to specify both *weights* and *cum_weights*.

The *weights* or *cum_weights* can use any numeric type that interoperates with the **float** values returned by **random()** (that includes integers, floats, and fractions but excludes decimals). Weights are assumed to be non-negative and finite. A **ValueError** is raised if all weights are zero.

For a given seed, the **choices()** function with equal weighting typically produces a different sequence than repeated calls to **choice()**. The algorithm used by **choices()** uses floating point arithmetic for internal consistency and speed. The algorithm used by **choice()**

defaults to integer arithmetic with repeated selections to avoid small biases from round-off error.

New in version 3.6.

Changed in version 3.9: Raises a **`ValueError`** if all weights are zero.

random.shuffle(*x*)

Shuffle the sequence *x* in place.

To shuffle an immutable sequence and return a new shuffled list, use `sample(x, k=len(x))` instead.

Note that even for small `len(x)`, the total number of permutations of *x* can quickly grow larger than the period of most random number generators. This implies that most permutations of a long sequence can never be generated. For example, a sequence of length 2080 is the largest that can fit within the period of the Mersenne Twister random number generator.

Deprecated since version 3.9, removed in version 3.11: The optional parameter *random*.

random.sample(*population*, *k*, ***, *counts=None*)

Return a *k* length list of unique elements chosen from the population sequence. Used for random sampling without replacement.

Returns a new list containing elements from the population while leaving the original population unchanged. The resulting list is in selection order so that all sub-slices will also be valid random samples. This allows raffle winners (the sample) to be partitioned into grand prize and second place winners (the subslices).

Members of the population need not be hashable or unique. If the population contains repeats, then each occurrence is a possible selection in the sample.

Repeated elements can be specified one at a time or with the optional keyword-only *counts* parameter. For example, `sample(['red', 'blue'], counts=[4, 2], k=5)` is equivalent to `sample(['red', 'red', 'red', 'red', 'blue', 'blue'], k=5)`.

To choose a sample from a range of integers, use a **`range()`** object as an argument. This is especially fast and space efficient for sampling from a large population: `sample(range(10000000), k=60)`.

If the sample size is larger than the population size, a **`ValueError`** is raised.

Changed in version 3.9: Added the *counts* parameter.

Changed in version 3.11: The *population* must be a sequence. Automatic conversion of sets to lists is no longer supported.

Real-valued distributions

The following functions generate specific real-valued distributions. Function parameters are named after the corresponding variables in the distribution's equation, as used in common mathematical practice; most of these equations can be found in any statistics text.

random.random()

Return the next random floating point number in the range [0.0, 1.0).

random.uniform(*a*, *b*)

Return a random floating point number *N* such that `a <= N <= b` for `a <= b` and `b <= N <= a` for `b < a`.

The end-point value `b` may or may not be included in the range depending on floating-point rounding in the equation `a + (b-a) * random()`.

random.triangular(*low*, *high*, *mode*)

Return a random floating point number *N* such that `low <= N <= high` and with the specified *mode* between those bounds. The *low* and *high* bounds default to zero and one. The *mode* argument defaults to the midpoint between the bounds, giving a symmetric distribution.

random.betavariate(*alpha*, *beta*)

Beta distribution. Conditions on the parameters are `alpha > 0` and `beta > 0`. Returned values range between 0 and 1.

random.expovariate(*lambd*)

Exponential distribution. *lambd* is 1.0 divided by the desired mean. It should be nonzero. (The parameter would be called "lambda", but that is a reserved word in Python.) Returned values range from 0 to positive infinity if *lambd* is positive, and from negative infinity to 0 if *lambd* is negative.

random.gammavariate(*alpha*, *beta*)

Gamma distribution. (*Not* the gamma function!) Conditions on the parameters are `alpha > 0` and `beta > 0`.

The probability distribution function is:

```
                x ** (alpha - 1) * math.exp(-x / beta)
pdf(x) =  --------------------------------------
            math.gamma(alpha) * beta ** alpha
```

random.gauss(*mu* = *0.0*, *sigma* = *1.0*)

Normal distribution, also called the Gaussian distribution. *mu* is the mean, and *sigma* is the standard deviation. This is slightly faster than the **`normalvariate()`** function defined below.

Multithreading note: When two threads call this function simultaneously, it is possible that they will receive the same return value. This can be avoided in three ways. 1) Have each thread use a different instance of the random number generator. 2) Put locks around all calls. 3) Use the slower, but

thread-safe `normalvariate()` function instead.

Changed in version 3.11: *mu* and *sigma* now have default arguments.

random.lognormvariate(*mu*, *sigma*)

Log normal distribution. If you take the natural logarithm of this distribution, you'll get a normal distribution with mean *mu* and standard deviation *sigma*. *mu* can have any value, and *sigma* must be greater than zero.

random.normalvariate(*mu* = *0.0*, *sigma* = *1.0*)

Normal distribution. *mu* is the mean, and *sigma* is the standard deviation.

Changed in version 3.11: *mu* and *sigma* now have default arguments.

random.vonmisesvariate(*mu*, *kappa*)

mu is the mean angle, expressed in radians between 0 and 2*pi, and *kappa* is the concentration parameter, which must be greater than or equal to zero. If *kappa* is equal to zero, this distribution reduces to a uniform random angle over the range 0 to 2*pi.

random.paretovariate(*alpha*)

Pareto distribution. *alpha* is the shape parameter.

random.weibullvariate(*alpha*, *beta*)

Weibull distribution. *alpha* is the scale parameter and *beta* is the shape parameter.

Alternative Generator

class random.Random([*seed*])

Class that implements the default pseudo-random number

generator used by the **random** module.

Deprecated since version 3.9: In the future, the *seed* must be one of the following types: **NoneType**, **int**, **float**, **str**, **bytes**, or **bytearray**.

class random.SystemRandom([*seed*])

Class that uses the **os.urandom()** function for generating random numbers from sources provided by the operating system. Not available on all systems. Does not rely on software state, and sequences are not reproducible. Accordingly, the **seed()** method has no effect and is ignored. The **getstate()** and **setstate()** methods raise **NotImplementedError** if called.

Notes on Reproducibility

Sometimes it is useful to be able to reproduce the sequences given by a pseudo-random number generator. By re-using a seed value, the same sequence should be reproducible from run to run as long as multiple threads are not running.

Most of the random module's algorithms and seeding functions are subject to change across Python versions, but two aspects are guaranteed not to change:

- If a new seeding method is added, then a backward compatible seeder will be offered.
- The generator's **random()** method will continue to produce the same sequence when the compatible seeder is given the same seed.

Examples

Basic examples:

```
>>> random()                                  # Random float:
0.37444887175646646
```

```
>>> uniform(2.5, 10.0)                     # Random float:
3.1800146073117523

>>> expovariate(1 / 5)                     # Interval betw
5.148957571865031

>>> randrange(10)                          # Integer from
7

>>> randrange(0, 101, 2)                   # Even integer
26

>>> choice(['win', 'lose', 'draw'])        # Single random
'draw'

>>> deck = 'ace two three four'.split()
>>> shuffle(deck)                          # Shuffle a lis
>>> deck
['four', 'two', 'ace', 'three']

>>> sample([10, 20, 30, 40, 50], k=4)      # Four samples
[40, 10, 50, 30]
```

Simulations:

```
>>> # Six roulette wheel spins (weighted sampling with r
>>> choices(['red', 'black', 'green'], [18, 18, 2], k=6)
['red', 'green', 'black', 'black', 'red', 'black']

>>> # Deal 20 cards without replacement from a deck
>>> # of 52 playing cards, and determine the proportion
>>> # with a ten-value:  ten, jack, queen, or king.
>>> dealt = sample(['tens', 'low cards'], counts=[16, 36
>>> dealt.count('tens') / 20
0.15

>>> # Estimate the probability of getting 5 or more head
>>> # of a biased coin that settles on heads 60% of the
>>> def trial():
```

```
...     return choices('HT', cum_weights=(0.60, 1.00), k
...
>>> sum(trial() for i in range(10_000)) / 10_000
0.4169

>>> # Probability of the median of 5 samples being in mi
>>> def trial():
...     return 2_500 <= sorted(choices(range(10_000), k=
...
>>> sum(trial() for i in range(10_000)) / 10_000
0.7958
```

Example of statistical bootstrapping [https://en.wikipedia.org/wiki/Bootstrapping_(statistics)] using resampling with replacement to estimate a confidence interval for the mean of a sample:

```
# https://www.thoughtco.com/example-of-bootstrapping-312
from statistics import fmean as mean
from random import choices

data = [41, 50, 29, 37, 81, 30, 73, 63, 20, 35, 68, 22,
means = sorted(mean(choices(data, k=len(data))) for i in
print(f'The sample mean of {mean(data):.1f} has a 90% co
      f'interval from {means[5]:.1f} to {means[94]:.1f}'
```

Example of a resampling permutation test [https://en.wikipedia.org/wiki/Resampling_(statistics)#Permutation_tests] to determine the statistical significance or p-value [https://en.wikipedia.org/wiki/P-value] of an observed difference between the effects of a drug versus a placebo:

```
# Example from "Statistics is Easy" by Dennis Shasha and
from statistics import fmean as mean
from random import shuffle

drug = [54, 73, 53, 70, 73, 68, 52, 65, 65]
placebo = [54, 51, 58, 44, 55, 52, 42, 47, 58, 46]
observed_diff = mean(drug) - mean(placebo)

n = 10_000
```

```
count = 0
combined = drug + placebo
for i in range(n):
    shuffle(combined)
    new_diff = mean(combined[:len(drug)]) - mean(combine
    count += (new_diff >= observed_diff)

print(f'{n} label reshufflings produced only {count} ins
print(f'at least as extreme as the observed difference o
print(f'The one-sided p-value of {count / n:.4f} leads u
print(f'hypothesis that there is no difference between t
```

Simulation of arrival times and service deliveries for a multiserver queue:

```
from heapq import heapify, heapreplace
from random import expovariate, gauss
from statistics import mean, quantiles

average_arrival_interval = 5.6
average_service_time = 15.0
stdev_service_time = 3.5
num_servers = 3

waits = []
arrival_time = 0.0
servers = [0.0] * num_servers  # time when each server b
heapify(servers)
for i in range(1_000_000):
    arrival_time += expovariate(1.0 / average_arrival_in
    next_server_available = servers[0]
    wait = max(0.0, next_server_available - arrival_time
    waits.append(wait)
    service_duration = max(0.0, gauss(average_service_ti
    service_completed = arrival_time + wait + service_du
    heapreplace(servers, service_completed)

print(f'Mean wait: {mean(waits):.1f}   Max wait: {max(wa
print('Quartiles:', [round(q, 1) for q in quantiles(wait
```

A Concrete Introduction to Probability (using Python) [https://nbviewer.jupyter.org/url/norvig.com/ipython/Probability.ipynb] a tutorial by Peter Norvig [https://norvig.com/bio.html] covering the basics of probability theory, how to write simulations, and how to perform data analysis using Python.

Recipes

These recipes show how to efficiently make random selections from the combinatoric iterators in the **`itertools`** module:

```
def random_product(*args, repeat=1):
    "Random selection from itertools.product(*args, **kw
    pools = [tuple(pool) for pool in args] * repeat
    return tuple(map(random.choice, pools))

def random_permutation(iterable, r=None):
    "Random selection from itertools.permutations(iterab
    pool = tuple(iterable)
    r = len(pool) if r is None else r
    return tuple(random.sample(pool, r))

def random_combination(iterable, r):
    "Random selection from itertools.combinations(iterab
```

```
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.sample(range(n), r))
    return tuple(pool[i] for i in indices)

def random_combination_with_replacement(iterable, r):
    "Random selection from itertools.combinations_with_r
    pool = tuple(iterable)
    n = len(pool)
    indices = sorted(random.choices(range(n), k=r))
    return tuple(pool[i] for i in indices)
```

The default **`random()`** returns multiples of 2^{-53} in the range $0.0 \le x < 1.0$. All such numbers are evenly spaced and are exactly representable as Python floats. However, many other representable floats in that interval are not possible selections. For example, `0.05954861408025609` isn't an integer multiple of 2^{-53}.

The following recipe takes a different approach. All floats in the interval are possible selections. The mantissa comes from a uniform distribution of integers in the range $2^{52} \le mantissa < 2^{53}$. The exponent comes from a geometric distribution where exponents smaller than *-53* occur half as often as the next larger exponent.

```
from random import Random
from math import ldexp

class FullRandom(Random):

    def random(self):
        mantissa = 0x10_0000_0000_0000 | self.getrandbit
        exponent = -53
        x = 0
        while not x:
            x = self.getrandbits(32)
            exponent += x.bit_length() - 32
        return ldexp(mantissa, exponent)
```

All real valued distributions in the class will use the new method:

```
>>> fr = FullRandom()
>>> fr.random()
0.05954861408025609
>>> fr.expovariate(0.25)
8.87925541791544
```

The recipe is conceptually equivalent to an algorithm that chooses from all the multiples of 2^{-1074} in the range $0.0 \le x < 1.0$. All such numbers are evenly spaced, but most have to be rounded down to the nearest representable Python float. (The value 2^{-1074} is the smallest positive unnormalized float and is equal to `math.ulp(0.0)`.)

`statistics` — Mathematical statistics functions

New in version 3.4.

Source code: Lib/statistics.py [https://github.com/python/cpython/tree/3.11/Lib/statistics.py]

This module provides functions for calculating mathematical statistics of numeric (`Real`-valued) data.

The module is not intended to be a competitor to third-party libraries such as NumPy [https://numpy.org], SciPy [https://www.scipy.org/], or proprietary full-featured statistics packages aimed at professional statisticians such as Minitab, SAS and Matlab. It is aimed at the level of graphing and scientific calculators.

Unless explicitly noted, these functions support `int`, `float`, `Decimal` and `Fraction`. Behaviour with other types (whether in the numeric tower or not) is currently unsupported. Collections with a mix of types are also undefined and implementation-dependent. If your input data consists of mixed types, you may be able to use `map()` to ensure a consistent result, for example: `map(float, input_data)`.

Some datasets use `NaN` (not a number) values to represent missing data. Since NaNs have unusual comparison semantics, they cause surprising or undefined behaviors in the statistics functions that sort data or that count occurrences. The functions affected are `median()`, `median_low()`, `median_high()`, `median_grouped()`, `mode()`, `multimode()`, and `quantiles()`. The `NaN` values should be stripped before calling these functions:

```
>>> from statistics import median
```

```
>>> from math import isnan
>>> from itertools import filterfalse

>>> data = [20.7, float('NaN'),19.2, 18.3, float('NaN'),
>>> sorted(data)  # This has surprising behavior
[20.7, nan, 14.4, 18.3, 19.2, nan]
>>> median(data)  # This result is unexpected
16.35

>>> sum(map(isnan, data))    # Number of missing values
2
>>> clean = list(filterfalse(isnan, data))  # Strip NaN
>>> clean
[20.7, 19.2, 18.3, 14.4]
>>> sorted(clean)  # Sorting now works as expected
[14.4, 18.3, 19.2, 20.7]
>>> median(clean)       # This result is now well define
18.75
```

Averages and measures of central location

These functions calculate an average or typical value from a population or sample.

mean()	Arithmetic mean ("average") of data.
fmean()	Fast, floating point arithmetic mean, with optional weighting.
geometric_mean()	Geometric mean of data.
harmonic_mean()	Harmonic mean of data.
median()	Median (middle value) of data.
median_low()	Low median of data.
median_high()	High median of data.
median_grouped()	Median, or 50th percentile, of grouped data.
mode()	Single mode (most common value) of discrete or nominal data.
multimode()	List of modes (most common values) of discrete or nominal data.
quantiles()	Divide data into intervals with equal probability.

Measures of spread

These functions calculate a measure of how much the population or sample tends to deviate from the typical or average values.

pstdev()	Population standard deviation of data.
pvariance()	Population variance of data.
stdev()	Sample standard deviation of data.
variance()	Sample variance of data.

Statistics for relations between two inputs

These functions calculate statistics regarding relations between two inputs.

covariance()	Sample covariance for two variables.
correlation()	Pearson's correlation coefficient for two variables.
linear_regression()	Slope and intercept for simple linear regression.

Function details

Note: The functions do not require the data given to them to be sorted. However, for reading convenience, most of the examples show sorted sequences.

statistics.mean(*data*)

Return the sample arithmetic mean of *data* which can be a sequence or iterable.

The arithmetic mean is the sum of the data divided by the number of data points. It is commonly called “the average”, although it is only one of many different mathematical averages. It is a measure of the central location of the data.

If *data* is empty, **StatisticsError** will be raised.

Some examples of use:

```
>>> mean([1, 2, 3, 4, 4])
2.8
>>> mean([-1.0, 2.5, 3.25, 5.75])
```

```
2.625

>>> from fractions import Fraction as F
>>> mean([F(3, 7), F(1, 21), F(5, 3), F(1, 3)])
Fraction(13, 21)

>>> from decimal import Decimal as D
>>> mean([D("0.5"), D("0.75"), D("0.625"), D("0.375
Decimal('0.5625')
```

Note

The mean is strongly affected by outliers [https://en.wikipedia.org/wiki/Outlier] and is not necessarily a typical example of the data points. For a more robust, although less efficient, measure of central tendency [https://en.wikipedia.org/wiki/Central_tendency], see **`median()`**.

The sample mean gives an unbiased estimate of the true population mean, so that when taken on average over all the possible samples, `mean(sample)` converges on the true mean of the entire population. If *data* represents the entire population rather than a sample, then `mean(data)` is equivalent to calculating the true population mean μ.

statistics.fmean(*data*, *weights*=*None*)

Convert *data* to floats and compute the arithmetic mean.

This runs faster than the **`mean()`** function and it always returns a **`float`**. The *data* may be a sequence or iterable. If the input dataset is empty, raises a **`StatisticsError`**.

```
>>> fmean([3.5, 4.0, 5.25])
4.25
```

Optional weighting is supported. For example, a professor assigns a grade for a course by weighting quizzes at 20%, homework at 20%, a midterm exam at 30%, and a final exam

at 30%:

```
>>> grades = [85, 92, 83, 91]
>>> weights = [0.20, 0.20, 0.30, 0.30]
>>> fmean(grades, weights)
87.6
```

If *weights* is supplied, it must be the same length as the *data* or a **ValueError** will be raised.

New in version 3.8.

Changed in version 3.11: Added support for *weights*.

statistics.geometric_mean(*data*)

Convert *data* to floats and compute the geometric mean.

The geometric mean indicates the central tendency or typical value of the *data* using the product of the values (as opposed to the arithmetic mean which uses their sum).

Raises a **StatisticsError** if the input dataset is empty, if it contains a zero, or if it contains a negative value. The *data* may be a sequence or iterable.

No special efforts are made to achieve exact results. (However, this may change in the future.)

```
>>> round(geometric_mean([54, 24, 36]), 1)
36.0
```

New in version 3.8.

statistics.harmonic_mean(*data*, *weights*=*None*)

Return the harmonic mean of *data*, a sequence or iterable of real-valued numbers. If *weights* is omitted or *None*, then equal weighting is assumed.

The harmonic mean is the reciprocal of the arithmetic **mean()** of the reciprocals of the data. For example, the

harmonic mean of three values *a*, *b* and *c* will be equivalent to `3/(1/a + 1/b + 1/c)`. If one of the values is zero, the result will be zero.

The harmonic mean is a type of average, a measure of the central location of the data. It is often appropriate when averaging ratios or rates, for example speeds.

Suppose a car travels 10 km at 40 km/hr, then another 10 km at 60 km/hr. What is the average speed?

```
>>> harmonic_mean([40, 60])
48.0
```

Suppose a car travels 40 km/hr for 5 km, and when traffic clears, speeds-up to 60 km/hr for the remaining 30 km of the journey. What is the average speed?

```
>>> harmonic_mean([40, 60], weights=[5, 30])
56.0
```

`StatisticsError` is raised if *data* is empty, any element is less than zero, or if the weighted sum isn't positive.

The current algorithm has an early-out when it encounters a zero in the input. This means that the subsequent inputs are not tested for validity. (This behavior may change in the future.)

New in version 3.6.

Changed in version 3.10: Added support for *weights*.

statistics.median(*data*)

Return the median (middle value) of numeric data, using the common "mean of middle two" method. If *data* is empty, **`StatisticsError`** is raised. *data* can be a sequence or iterable.

The median is a robust measure of central location and is less affected by the presence of outliers. When the number of data

points is odd, the middle data point is returned:

```
>>> median([1, 3, 5])
3
```

When the number of data points is even, the median is interpolated by taking the average of the two middle values:

```
>>> median([1, 3, 5, 7])
4.0
```

This is suited for when your data is discrete, and you don't mind that the median may not be an actual data point.

If the data is ordinal (supports order operations) but not numeric (doesn't support addition), consider using **median_low()** or **median_high()** instead.

statistics.median_low(*data*)

Return the low median of numeric data. If *data* is empty, **StatisticsError** is raised. *data* can be a sequence or iterable.

The low median is always a member of the data set. When the number of data points is odd, the middle value is returned. When it is even, the smaller of the two middle values is returned.

```
>>> median_low([1, 3, 5])
3
>>> median_low([1, 3, 5, 7])
3
```

Use the low median when your data are discrete and you prefer the median to be an actual data point rather than interpolated.

statistics.median_high(*data*)

Return the high median of data. If *data* is empty, **StatisticsError** is raised. *data* can be a sequence or

iterable.

The high median is always a member of the data set. When the number of data points is odd, the middle value is returned. When it is even, the larger of the two middle values is returned.

```
>>> median_high([1, 3, 5])
3
>>> median_high([1, 3, 5, 7])
5
```

Use the high median when your data are discrete and you prefer the median to be an actual data point rather than interpolated.

statistics.median_grouped(*data*, *interval=1*)

Return the median of grouped continuous data, calculated as the 50th percentile, using interpolation. If *data* is empty, **StatisticsError** is raised. *data* can be a sequence or iterable.

```
>>> median_grouped([52, 52, 53, 54])
52.5
```

In the following example, the data are rounded, so that each value represents the midpoint of data classes, e.g. 1 is the midpoint of the class 0.5–1.5, 2 is the midpoint of 1.5–2.5, 3 is the midpoint of 2.5–3.5, etc. With the data given, the middle value falls somewhere in the class 3.5–4.5, and interpolation is used to estimate it:

```
>>> median_grouped([1, 2, 2, 3, 4, 4, 4, 4, 4, 5])
3.7
```

Optional argument *interval* represents the class interval, and defaults to 1. Changing the class interval naturally will change the interpolation:

```
>>> median_grouped([1, 3, 3, 5, 7], interval=1)
```

```
3.25
>>> median_grouped([1, 3, 3, 5, 7], interval=2)
3.5
```

This function does not check whether the data points are at least *interval* apart.

CPython implementation detail: Under some circumstances, **`median_grouped()`** may coerce data points to floats. This behaviour is likely to change in the future.

- "Statistics for the Behavioral Sciences", Frederick J Gravetter and Larry B Wallnau (8th Edition).
- The SSMEDIAN [https://help.gnome.org/users/gnumeric/stable/gnumeric.html#gnumeric-function-SSMEDIAN] function in the Gnome Gnumeric spreadsheet, including this discussion [https://mail.gnome.org/archives/gnumeric-list/2011-April/msg00018.html].

statistics.mode(*data*)

Return the single most common data point from discrete or nominal *data*. The mode (when it exists) is the most typical value and serves as a measure of central location.

If there are multiple modes with the same frequency, returns the first one encountered in the *data*. If the smallest or largest of those is desired instead, use `min(multimode(data))` or `max(multimode(data))`. If the input *data* is empty, **`StatisticsError`** is raised.

`mode` assumes discrete data and returns a single value. This is the standard treatment of the mode as commonly taught in schools:

```
>>> mode([1, 1, 2, 3, 3, 3, 3, 4])
3
```

The mode is unique in that it is the only statistic in this package that also applies to nominal (non-numeric) data:

```
>>> mode(["red", "blue", "blue", "red", "green", "r
'red'
```

Changed in version 3.8: Now handles multimodal datasets by returning the first mode encountered. Formerly, it raised **StatisticsError** when more than one mode was found.

statistics.multimode(*data*)

Return a list of the most frequently occurring values in the order they were first encountered in the *data*. Will return more than one result if there are multiple modes or an empty list if the *data* is empty:

```
>>> multimode('aabbbbccddddeeffffgg')
['b', 'd', 'f']
>>> multimode('')
[]
```

New in version 3.8.

statistics.pstdev(*data*, *mu=None*)

Return the population standard deviation (the square root of the population variance). See **pvariance()** for arguments and other details.

```
>>> pstdev([1.5, 2.5, 2.5, 2.75, 3.25, 4.75])
0.986893273527251
```

statistics.pvariance(*data*, *mu=None*)

Return the population variance of *data*, a non-empty sequence or iterable of real-valued numbers. Variance, or second moment about the mean, is a measure of the variability (spread or dispersion) of data. A large variance indicates that the data is spread out; a small variance indicates it is clustered closely around the mean.

If the optional second argument *mu* is given, it is typically the mean of the *data*. It can also be used to compute the second moment around a point that is not the mean. If it is missing or `None` (the default), the arithmetic mean is automatically calculated.

Use this function to calculate the variance from the entire population. To estimate the variance from a sample, the **`variance()`** function is usually a better choice.

Raises **`StatisticsError`** if *data* is empty.

Examples:

```
>>> data = [0.0, 0.25, 0.25, 1.25, 1.5, 1.75, 2.75,
>>> pvariance(data)
1.25
```

If you have already calculated the mean of your data, you can pass it as the optional second argument *mu* to avoid recalculation:

```
>>> mu = mean(data)
>>> pvariance(data, mu)
1.25
```

Decimals and Fractions are supported:

```
>>> from decimal import Decimal as D
>>> pvariance([D("27.5"), D("30.25"), D("30.25"), D
Decimal('24.815')

>>> from fractions import Fraction as F
>>> pvariance([F(1, 4), F(5, 4), F(1, 2)])
Fraction(13, 72)
```

Note

When called with the entire population, this gives the population variance σ^2. When called on a sample instead, this is the biased sample variance s^2, also known as

variance with N degrees of freedom.

If you somehow know the true population mean μ, you may use this function to calculate the variance of a sample, giving the known population mean as the second argument. Provided the data points are a random sample of the population, the result will be an unbiased estimate of the population variance.

statistics.stdev(*data*, *xbar*=*None*)

Return the sample standard deviation (the square root of the sample variance). See **`variance()`** for arguments and other details.

```
>>> stdev([1.5, 2.5, 2.5, 2.75, 3.25, 4.75])
1.0810874155219827
```

statistics.variance(*data*, *xbar*=*None*)

Return the sample variance of *data*, an iterable of at least two real-valued numbers. Variance, or second moment about the mean, is a measure of the variability (spread or dispersion) of data. A large variance indicates that the data is spread out; a small variance indicates it is clustered closely around the mean.

If the optional second argument *xbar* is given, it should be the mean of *data*. If it is missing or `None` (the default), the mean is automatically calculated.

Use this function when your data is a sample from a population. To calculate the variance from the entire population, see **`pvariance()`**.

Raises **`StatisticsError`** if *data* has fewer than two values.

Examples:

```
>>> data = [2.75, 1.75, 1.25, 0.25, 0.5, 1.25, 3.5]
```

```
>>> variance(data)
1.3720238095238095
```

If you have already calculated the mean of your data, you can pass it as the optional second argument *xbar* to avoid recalculation:

```
>>> m = mean(data)
>>> variance(data, m)
1.3720238095238095
```

This function does not attempt to verify that you have passed the actual mean as *xbar*. Using arbitrary values for *xbar* can lead to invalid or impossible results.

Decimal and Fraction values are supported:

```
>>> from decimal import Decimal as D
>>> variance([D("27.5"), D("30.25"), D("30.25"), D(
Decimal('31.01875')

>>> from fractions import Fraction as F
>>> variance([F(1, 6), F(1, 2), F(5, 3)])
Fraction(67, 108)
```

Note

This is the sample variance s^2 with Bessel's correction, also known as variance with N-1 degrees of freedom. Provided that the data points are representative (e.g. independent and identically distributed), the result should be an unbiased estimate of the true population variance.

If you somehow know the actual population mean μ you should pass it to the **`pvariance()`** function as the *mu* parameter to get the variance of a sample.

statistics.quantiles(*data*, *, *n* = *4*, *method* = *'exclusive'*)

Divide *data* into *n* continuous intervals with equal

probability. Returns a list of `n - 1` cut points separating the intervals.

Set *n* to 4 for quartiles (the default). Set *n* to 10 for deciles. Set *n* to 100 for percentiles which gives the 99 cuts points that separate *data* into 100 equal sized groups. Raises **`StatisticsError`** if *n* is not least 1.

The *data* can be any iterable containing sample data. For meaningful results, the number of data points in *data* should be larger than *n*. Raises **`StatisticsError`** if there are not at least two data points.

The cut points are linearly interpolated from the two nearest data points. For example, if a cut point falls one-third of the distance between two sample values, `100` and `112`, the cut-point will evaluate to `104`.

The *method* for computing quantiles can be varied depending on whether the *data* includes or excludes the lowest and highest possible values from the population.

The default *method* is "exclusive" and is used for data sampled from a population that can have more extreme values than found in the samples. The portion of the population falling below the *i-th* of *m* sorted data points is computed as `i / (m + 1)`. Given nine sample values, the method sorts them and assigns the following percentiles: 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%.

Setting the *method* to "inclusive" is used for describing population data or for samples that are known to include the most extreme values from the population. The minimum value in *data* is treated as the 0th percentile and the maximum value is treated as the 100th percentile. The portion of the population falling below the *i-th* of *m* sorted data points is computed as `(i - 1) / (m - 1)`. Given 11 sample values, the method sorts them and assigns the following percentiles: 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, 100%.

```
# Decile cut points for empirically sampled data
>>> data = [105, 129, 87, 86, 111, 111, 89, 81, 108
...         100, 75, 105, 103, 109, 76, 119, 99, 91
...         106, 101, 84, 111, 74, 87, 86, 103, 103
...         111, 75, 87, 102, 121, 111, 88, 89, 101
...         103, 107, 101, 81, 109, 104]
>>> [round(q, 1) for q in quantiles(data, n=10)]
[81.0, 86.2, 89.0, 99.4, 102.5, 103.6, 106.0, 109.8
```

New in version 3.8.

statistics.covariance(*x*, *y*, */*)

Return the sample covariance of two inputs *x* and *y*. Covariance is a measure of the joint variability of two inputs.

Both inputs must be of the same length (no less than two), otherwise **StatisticsError** is raised.

Examples:

```
>>> x = [1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> y = [1, 2, 3, 1, 2, 3, 1, 2, 3]
>>> covariance(x, y)
0.75
>>> z = [9, 8, 7, 6, 5, 4, 3, 2, 1]
>>> covariance(x, z)
-7.5
>>> covariance(z, x)
-7.5
```

New in version 3.10.

statistics.correlation(*x*, *y*, */*)

Return the Pearson's correlation coefficient [https://en.wikipedia.org/wiki/Pearson_correlation_coefficient] for two inputs. Pearson's correlation coefficient *r* takes values between -1 and +1. It measures the strength and direction of the linear relationship, where +1 means very strong, positive linear relationship, -1 very strong, negative linear relationship, and

0 no linear relationship.

Both inputs must be of the same length (no less than two), and need not to be constant, otherwise **StatisticsError** is raised.

Examples:

```
>>> x = [1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> y = [9, 8, 7, 6, 5, 4, 3, 2, 1]
>>> correlation(x, x)
1.0
>>> correlation(x, y)
-1.0
```

New in version 3.10.

statistics.linear_regression(*x*, *y*, */*, ***, *proportional=False*)

Return the slope and intercept of simple linear regression [https://en.wikipedia.org/wiki/Simple_linear_regression] parameters estimated using ordinary least squares. Simple linear regression describes the relationship between an independent variable *x* and a dependent variable *y* in terms of this linear function:

$$y = slope * x + intercept + noise$$

where `slope` and `intercept` are the regression parameters that are estimated, and `noise` represents the variability of the data that was not explained by the linear regression (it is equal to the difference between predicted and actual values of the dependent variable).

Both inputs must be of the same length (no less than two), and the independent variable *x* cannot be constant; otherwise a **StatisticsError** is raised.

For example, we can use the release dates of the Monty Python films [https://en.wikipedia.org/wiki/Monty_Python#Films] to predict the cumulative number of Monty Python films that

would have been produced by 2019 assuming that they had kept the pace.

```
>>> year = [1971, 1975, 1979, 1982, 1983]
>>> films_total = [1, 2, 3, 4, 5]
>>> slope, intercept = linear_regression(year, film
>>> round(slope * 2019 + intercept)
16
```

If *proportional* is true, the independent variable *x* and the dependent variable *y* are assumed to be directly proportional. The data is fit to a line passing through the origin. Since the *intercept* will always be 0.0, the underlying linear function simplifies to:

$$y = slope * x + noise$$

New in version 3.10.

Changed in version 3.11: Added support for *proportional*.

Exceptions

A single exception is defined:

exception statistics.StatisticsError

Subclass of `ValueError` for statistics-related exceptions.

`NormalDist` objects

`NormalDist` is a tool for creating and manipulating normal distributions of a random variable [http://www.stat.yale.edu/Courses/1997-98/101/ranvar.htm]. It is a class that treats the mean and standard deviation of data measurements as a single entity.

Normal distributions arise from the Central Limit Theorem [https://en.wikipedia.org/wiki/Central_limit_theorem] and have a wide range of applications in statistics.

class statistics.NormalDist(*mu* = *0.0*, *sigma* = *1.0*)

Returns a new *NormalDist* object where *mu* represents the arithmetic mean [https://en.wikipedia.org/wiki/Arithmetic_mean] and *sigma* represents the standard deviation [https://en.wikipedia.org/wiki/Standard_deviation].

If *sigma* is negative, raises **`StatisticsError`**.

mean

A read-only property for the arithmetic mean [https://en.wikipedia.org/wiki/Arithmetic_mean] of a normal distribution.

median

A read-only property for the median [https://en.wikipedia.org/wiki/Median] of a normal distribution.

mode

A read-only property for the mode [https://en.wikipedia.org/wiki/Mode_(statistics)] of a normal distribution.

stdev

A read-only property for the standard deviation [https://en.wikipedia.org/wiki/Standard_deviation] of a normal distribution.

variance

A read-only property for the variance [https://en.wikipedia.org/wiki/Variance] of a normal distribution. Equal to the square of the standard deviation.

classmethod from_samples(*data*)

Makes a normal distribution instance with *mu* and *sigma* parameters estimated from the *data* using **`fmean()`** and **`stdev()`**.

The *data* can be any iterable and should consist of

values that can be converted to type **`float`**. If *data* does not contain at least two elements, raises **`StatisticsError`** because it takes at least one point to estimate a central value and at least two points to estimate dispersion.

samples(*n*, *, *seed*=*None*)

Generates *n* random samples for a given mean and standard deviation. Returns a **`list`** of **`float`** values.

If *seed* is given, creates a new instance of the underlying random number generator. This is useful for creating reproducible results, even in a multi-threading context.

pdf(*x*)

Using a probability density function (pdf) [https://en.wikipedia.org/wiki/Probability_density_function], compute the relative likelihood that a random variable *X* will be near the given value *x*. Mathematically, it is the limit of the ratio `P(x <= X < x+dx) / dx` as *dx* approaches zero.

The relative likelihood is computed as the probability of a sample occurring in a narrow range divided by the width of the range (hence the word “density”). Since the likelihood is relative to other points, its value can be greater than `1.0`.

cdf(*x*)

Using a cumulative distribution function (cdf) [https://en.wikipedia.org/wiki/Cumulative_distribution_function], compute the probability that a random variable *X* will be less than or equal to *x*. Mathematically, it is written `P(X <= x)`.

inv_cdf(*p*)

Compute the inverse cumulative distribution function, also known as the quantile function [https://

en.wikipedia.org/wiki/Quantile_function] or the percent-point [https://web.archive.org/web/20190203145224/https://www.statisticshowto.datasciencecentral.com/inverse-distribution-function/] function. Mathematically, it is written `x : P(X <= x) = p`.

Finds the value *x* of the random variable *X* such that the probability of the variable being less than or equal to that value equals the given probability *p*.

overlap(*other*)

Measures the agreement between two normal probability distributions. Returns a value between 0.0 and 1.0 giving the overlapping area for the two probability density functions [https://www.rasch.org/rmt/rmt101r.htm].

quantiles(*n*=*4*)

Divide the normal distribution into *n* continuous intervals with equal probability. Returns a list of (n - 1) cut points separating the intervals.

Set *n* to 4 for quartiles (the default). Set *n* to 10 for deciles. Set *n* to 100 for percentiles which gives the 99 cuts points that separate the normal distribution into 100 equal sized groups.

zscore(*x*)

Compute the Standard Score [https://www.statisticshowto.com/probability-and-statistics/z-score/] describing *x* in terms of the number of standard deviations above or below the mean of the normal distribution: `(x - mean) / stdev`.

New in version 3.9.

Instances of **`NormalDist`** support addition, subtraction, multiplication and division by a constant. These operations are used for translation and scaling. For example:

```
>>> temperature_february = NormalDist(5, 2.5)
>>> temperature_february * (9/5) + 32
NormalDist(mu=41.0, sigma=4.5)
```

Dividing a constant by an instance of **`NormalDist`** is not supported because the result wouldn't be normally distributed.

Since normal distributions arise from additive effects of independent variables, it is possible to add and subtract two independent normally distributed random variables [https://en.wikipedia.org/wiki/Sum_of_normally_distributed_random_variables] represented as instances of **`NormalDist`**. For example:

```
>>> birth_weights = NormalDist.from_samples([2.5, 3
>>> drug_effects = NormalDist(0.4, 0.15)
>>> combined = birth_weights + drug_effects
>>> round(combined.mean, 1)
3.1
>>> round(combined.stdev, 1)
0.5
```

New in version 3.8.

`NormalDist` Examples and Recipes

`NormalDist` readily solves classic probability problems.

For example, given historical data for SAT exams [https://nces.ed.gov/programs/digest/d17/tables/dt17_226.40.asp] showing that scores are normally distributed with a mean of 1060 and a standard deviation of 195, determine the percentage of students with test scores between 1100 and 1200, after rounding to the nearest whole number:

```
>>> sat = NormalDist(1060, 195)
>>> fraction = sat.cdf(1200 + 0.5) - sat.cdf(1100 - 0.5)
>>> round(fraction * 100.0, 1)
18.4
```

Find the quartiles [https://en.wikipedia.org/wiki/Quartile] and deciles [https://en.wikipedia.org/wiki/Decile] for the SAT scores:

```
>>> list(map(round, sat.quantiles()))
[928, 1060, 1192]
>>> list(map(round, sat.quantiles(n=10)))
[810, 896, 958, 1011, 1060, 1109, 1162, 1224, 1310]
```

To estimate the distribution for a model than isn't easy to solve analytically, **`NormalDist`** can generate input samples for a Monte Carlo simulation [https://en.wikipedia.org/wiki/Monte_Carlo_method]:

```
>>> def model(x, y, z):
...     return (3*x + 7*x*y - 5*y) / (11 * z)
...
>>> n = 100_000
>>> X = NormalDist(10, 2.5).samples(n, seed=3652260728)
>>> Y = NormalDist(15, 1.75).samples(n, seed=4582495471)
>>> Z = NormalDist(50, 1.25).samples(n, seed=6582483453)
>>> quantiles(map(model, X, Y, Z))
[1.4591308524824727, 1.8035946855390597, 2.175091447274
```

Normal distributions can be used to approximate Binomial distributions [https://mathworld.wolfram.com/BinomialDistribution.html] when the sample size is large and when the probability of a successful trial is near 50%.

For example, an open source conference has 750 attendees and two rooms with a 500 person capacity. There is a talk about Python and another about Ruby. In previous conferences, 65% of the attendees preferred to listen to Python talks. Assuming the population preferences haven't changed, what is the probability that the Python room will stay within its capacity limits?

```
>>> n = 750             # Sample size
>>> p = 0.65            # Preference for Python
>>> q = 1.0 - p         # Preference for Ruby
>>> k = 500             # Room capacity

>>> # Approximation using the cumulative normal distribu
```

```
>>> from math import sqrt
>>> round(NormalDist(mu=n*p, sigma=sqrt(n*p*q)).cdf(k +
0.8402

>>> # Solution using the cumulative binomial distributio
>>> from math import comb, fsum
>>> round(fsum(comb(n, r) * p**r * q**(n-r) for r in ran
0.8402

>>> # Approximation using a simulation
>>> from random import seed, choices
>>> seed(8675309)
>>> def trial():
...     return choices(('Python', 'Ruby'), (p, q), k=n).
>>> mean(trial() <= k for i in range(10_000))
0.8398
```

Normal distributions commonly arise in machine learning problems.

Wikipedia has a nice example of a Naive Bayesian Classifier [https://en.wikipedia.org/wiki/Naive_Bayes_classifier#Person_classification]. The challenge is to predict a person's gender from measurements of normally distributed features including height, weight, and foot size.

We're given a training dataset with measurements for eight people. The measurements are assumed to be normally distributed, so we summarize the data with **`NormalDist`**:

```
>>> height_male = NormalDist.from_samples([6, 5.92, 5.58
>>> height_female = NormalDist.from_samples([5, 5.5, 5.4
>>> weight_male = NormalDist.from_samples([180, 190, 170
>>> weight_female = NormalDist.from_samples([100, 150, 1
>>> foot_size_male = NormalDist.from_samples([12, 11, 12
>>> foot_size_female = NormalDist.from_samples([6, 8, 7,
```

Next, we encounter a new person whose feature measurements are known but whose gender is unknown:

```
>>> ht = 6.0        # height
```

```
>>> wt = 130          # weight
>>> fs = 8            # foot size
```

Starting with a 50% prior probability [https://en.wikipedia.org/wiki/Prior_probability] of being male or female, we compute the posterior as the prior times the product of likelihoods for the feature measurements given the gender:

```
>>> prior_male = 0.5
>>> prior_female = 0.5
>>> posterior_male = (prior_male * height_male.pdf(ht) *
...                   weight_male.pdf(wt) * foot_size_ma

>>> posterior_female = (prior_female * height_female.pdf
...                     weight_female.pdf(wt) * foot_siz
```

The final prediction goes to the largest posterior. This is known as the maximum a posteriori [https://en.wikipedia.org/wiki/Maximum_a_posteriori_estimation] or MAP:

```
>>> 'male' if posterior_male > posterior_female else 'fe
'female'
```

Functional Programming Modules

The modules described in this chapter provide functions and classes that support a functional programming style, and general operations on callables.

The following modules are documented in this chapter:

- **`itertools`** — Functions creating iterators for efficient looping
  - Itertool functions
  - Itertools Recipes
- **`functools`** — Higher-order functions and operations on callable objects
  - **`partial`** Objects
- **`operator`** — Standard operators as functions
  - Mapping Operators to Functions
  - In-place Operators

`itertools` — Functions creating iterators for efficient looping

This module implements a number of iterator building blocks inspired by constructs from APL, Haskell, and SML. Each has been recast in a form suitable for Python.

The module standardizes a core set of fast, memory efficient tools that are useful by themselves or in combination. Together, they form an “iterator algebra” making it possible to construct specialized tools succinctly and efficiently in pure Python.

For instance, SML provides a tabulation tool: `tabulate(f)` which produces a sequence `f(0), f(1), ...`. The same effect can be achieved in Python by combining `map()` and `count()` to form `map(f, count())`.

These tools and their built-in counterparts also work well with the high-speed functions in the `operator` module. For example, the multiplication operator can be mapped across two vectors to form an efficient dot-product: `sum(map(operator.mul, vector1, vector2))`.

Infinite iterators:

Iterator	Arguments	Results	Example
`count()`	`start, [step]`	`start, start+step, start+2*step, ...`	`count(10) --> 10 11 12 13 14 ...`
`cycle()`	`p`	`p0, p1, ... plast, p0, p1, ...`	`cycle('ABCD') --> A B C D A B C D ...`
`repeat()`	`elem [,n]`	`elem, elem, elem, ... endlessly or up to n times`	`repeat(10, 3) --> 10 10 10`

Iterators terminating on the shortest input sequence:

Iterator	Arguments	Results

```
accumulate([1,2,3,4,5]) --> 1 3 6 10 15
chain('ABC', 'DEF') --> A B C D E F
chain.from_iterable(['ABC', 'DEF']) --> A B C D
E F
compress('ABCDEF', [1,0,1,0,1,1]) --> A C E F
dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6 4 1
filterfalse(lambda x: x%2, range(10)) --> 0 2 4
6 8
groupby() --> group objects grouped by value of key(v)
islice('ABCDEFG', 2, None) --> C D E F G
pairwise('ABCDEFG') --> AB BC CD DE EF FG
starmap(pow, [(2,5), (3,2), (10,3)]) --> 32 9
1000
takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1 4
tee() --> it1, it2, ... itn splits one iterator into n
zip_longest('ABCD', 'xy', fillvalue='-') --> Ax
By C- D-
```

Combinatoric iterators:

Iterator	Arguments	Results
`product()`	`p, q, ... [repeat=1]`	cartesian product, equivalent to a nested for-loop
`permutations()`	`p[, r]`	r-length tuples, all possible orderings, no repeated elements
`combinations()`	`p, r`	r-length tuples, in sorted order, no repeated elements
`combinations_with_replacement()`	`p, r`	r-length tuples, in sorted order, with repeated elements

Examples

```
product('ABCD', repeat=2)   AA AB AC AD BA BB BC BD CA CB CC CD DA DB DC DD
permutations('ABCD', 2)     AB AC AD BA BC BD CA CB CD DA DB DC
combinations('ABCD', 2)     AB AC AD BC BD CD
combinations_with_replacement('ABCD', 2)    AA AB AC AD BB BC BD CC CD DD
```

Itertool functions

The following module functions all construct and return iterators. Some provide streams of infinite length, so they should only be accessed by functions or loops that truncate the stream.

itertools.accumulate(*iterable*[, *func*, *, *initial*=*None*])

Make an iterator that returns accumulated sums, or

accumulated results of other binary functions (specified via the optional *func* argument).

If *func* is supplied, it should be a function of two arguments. Elements of the input *iterable* may be any type that can be accepted as arguments to *func*. (For example, with the default operation of addition, elements may be any addable type including **`Decimal`** or **`Fraction`**.)

Usually, the number of elements output matches the input iterable. However, if the keyword argument *initial* is provided, the accumulation leads off with the *initial* value so that the output has one more element than the input iterable.

Roughly equivalent to:

```
def accumulate(iterable, func=operator.add, *, init
    'Return running totals'
    # accumulate([1,2,3,4,5]) --> 1 3 6 10 15
    # accumulate([1,2,3,4,5], initial=100) --> 100
    # accumulate([1,2,3,4,5], operator.mul) --> 1 2
    it = iter(iterable)
    total = initial
    if initial is None:
        try:
            total = next(it)
        except StopIteration:
            return
    yield total
    for element in it:
        total = func(total, element)
        yield total
```

There are a number of uses for the *func* argument. It can be set to **`min()`** for a running minimum, **`max()`** for a running maximum, or **`operator.mul()`** for a running product. Amortization tables can be built by accumulating interest and applying payments:

```
>>> data = [3, 4, 6, 2, 1, 9, 0, 7, 5, 8]
```

```
>>> list(accumulate(data, operator.mul))     # runn
[3, 12, 72, 144, 144, 1296, 0, 0, 0, 0]
>>> list(accumulate(data, max))              # runn
[3, 4, 6, 6, 6, 9, 9, 9, 9, 9]

# Amortize a 5% loan of 1000 with 4 annual payments
>>> cashflows = [1000, -90, -90, -90, -90]
>>> list(accumulate(cashflows, lambda bal, pmt: bal
[1000, 960.0, 918.0, 873.9000000000001, 827.5950000
```

See **`functools.reduce()`** for a similar function that returns only the final accumulated value.

New in version 3.2.

Changed in version 3.3: Added the optional *func* parameter.

Changed in version 3.8: Added the optional *initial* parameter.

itertools.chain(**iterables*)

Make an iterator that returns elements from the first iterable until it is exhausted, then proceeds to the next iterable, until all of the iterables are exhausted. Used for treating consecutive sequences as a single sequence. Roughly equivalent to:

```
def chain(*iterables):
    # chain('ABC', 'DEF') --> A B C D E F
    for it in iterables:
        for element in it:
            yield element
```

classmethod chain.from_iterable(*iterable*)

Alternate constructor for **`chain()`**. Gets chained inputs from a single iterable argument that is evaluated lazily. Roughly equivalent to:

```
def from_iterable(iterables):
    # chain.from_iterable(['ABC', 'DEF']) --> A B C
```

```
    for it in iterables:
        for element in it:
            yield element
```

itertools.combinations(*iterable*, *r*)

Return *r* length subsequences of elements from the input *iterable*.

The combination tuples are emitted in lexicographic ordering according to the order of the input *iterable*. So, if the input *iterable* is sorted, the output tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeated values in each combination.

Roughly equivalent to:

```
def combinations(iterable, r):
    # combinations('ABCD', 2) --> AB AC AD BC BD CD
    # combinations(range(4), 3) --> 012 013 023 123
    pool = tuple(iterable)
    n = len(pool)
    if r > n:
        return
    indices = list(range(r))
    yield tuple(pool[i] for i in indices)
    while True:
        for i in reversed(range(r)):
            if indices[i] != i + n - r:
                break
        else:
            return
        indices[i] += 1
        for j in range(i+1, r):
            indices[j] = indices[j-1] + 1
        yield tuple(pool[i] for i in indices)
```

The code for **`combinations()`** can be also expressed as a subsequence of **`permutations()`** after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```
def combinations(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in permutations(range(n), r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is `n! / r! / (n-r)!` when `0 <= r <= n` or zero when `r > n`.

itertools.combinations_with_replacement(*iterable*, *r*)

Return *r* length subsequences of elements from the input *iterable* allowing individual elements to be repeated more than once.

The combination tuples are emitted in lexicographic ordering according to the order of the input *iterable*. So, if the input *iterable* is sorted, the output tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, the generated combinations will also be unique.

Roughly equivalent to:

```
def combinations_with_replacement(iterable, r):
    # combinations_with_replacement('ABC', 2) --> A
    pool = tuple(iterable)
    n = len(pool)
    if not n and r:
        return
    indices = [0] * r
    yield tuple(pool[i] for i in indices)
    while True:
```

```
            for i in reversed(range(r)):
                if indices[i] != n - 1:
                    break
            else:
                return
            indices[i:] = [indices[i] + 1] * (r - i)
            yield tuple(pool[i] for i in indices)
```

The code for **combinations_with_replacement()** can be also expressed as a subsequence of **product()** after filtering entries where the elements are not in sorted order (according to their position in the input pool):

```
def combinations_with_replacement(iterable, r):
    pool = tuple(iterable)
    n = len(pool)
    for indices in product(range(n), repeat=r):
        if sorted(indices) == list(indices):
            yield tuple(pool[i] for i in indices)
```

The number of items returned is `(n+r-1)! / r! / (n-1)!` when `n > 0`.

New in version 3.1.

itertools.compress(*data*, *selectors*)

Make an iterator that filters elements from *data* returning only those that have a corresponding element in *selectors* that evaluates to `True`. Stops when either the *data* or *selectors* iterables has been exhausted. Roughly equivalent to:

```
def compress(data, selectors):
    # compress('ABCDEF', [1,0,1,0,1,1]) --> A C E F
    return (d for d, s in zip(data, selectors) if s
```

New in version 3.1.

itertools.count(*start=0*, *step=1*)

Make an iterator that returns evenly spaced values starting

with number *start*. Often used as an argument to **`map()`** to generate consecutive data points. Also, used with **`zip()`** to add sequence numbers. Roughly equivalent to:

```
def count(start=0, step=1):
    # count(10) --> 10 11 12 13 14 ...
    # count(2.5, 0.5) --> 2.5 3.0 3.5 ...
    n = start
    while True:
        yield n
        n += step
```

When counting with floating point numbers, better accuracy can sometimes be achieved by substituting multiplicative code such as: `(start + step * i for i in count())`.

Changed in version 3.1: Added *step* argument and allowed non-integer arguments.

itertools.cycle(*iterable*)

Make an iterator returning elements from the iterable and saving a copy of each. When the iterable is exhausted, return elements from the saved copy. Repeats indefinitely. Roughly equivalent to:

```
def cycle(iterable):
    # cycle('ABCD') --> A B C D A B C D A B C D ...
    saved = []
    for element in iterable:
        yield element
        saved.append(element)
    while saved:
        for element in saved:
              yield element
```

Note, this member of the toolkit may require significant auxiliary storage (depending on the length of the iterable).

itertools.dropwhile(*predicate*, *iterable*)

Make an iterator that drops elements from the iterable as long as the predicate is true; afterwards, returns every element. Note, the iterator does not produce *any* output until the predicate first becomes false, so it may have a lengthy start-up time. Roughly equivalent to:

```
def dropwhile(predicate, iterable):
    # dropwhile(lambda x: x<5, [1,4,6,4,1]) --> 6 4
    iterable = iter(iterable)
    for x in iterable:
        if not predicate(x):
            yield x
            break
    for x in iterable:
        yield x
```

itertools.filterfalse(*predicate*, *iterable*)

Make an iterator that filters elements from iterable returning only those for which the predicate is `False`. If *predicate* is `None`, return the items that are false. Roughly equivalent to:

```
def filterfalse(predicate, iterable):
    # filterfalse(lambda x: x%2, range(10)) --> 0 2
    if predicate is None:
        predicate = bool
    for x in iterable:
        if not predicate(x):
            yield x
```

itertools.groupby(*iterable*, *key=None*)

Make an iterator that returns consecutive keys and groups from the *iterable*. The *key* is a function computing a key value for each element. If not specified or is `None`, *key* defaults to an identity function and returns the element unchanged. Generally, the iterable needs to already be sorted on the same key function.

The operation of **`groupby()`** is similar to the `uniq` filter in Unix. It generates a break or new group every time the value of the key function changes (which is why it is usually necessary to have sorted the data using the same key function). That behavior differs from SQL's GROUP BY which aggregates common elements regardless of their input order.

The returned group is itself an iterator that shares the underlying iterable with **`groupby()`**. Because the source is shared, when the **`groupby()`** object is advanced, the previous group is no longer visible. So, if that data is needed later, it should be stored as a list:

```
groups = []
uniquekeys = []
data = sorted(data, key=keyfunc)
for k, g in groupby(data, keyfunc):
    groups.append(list(g))      # Store group itera
    uniquekeys.append(k)
```

`groupby()` is roughly equivalent to:

```
class groupby:
    # [k for k, g in groupby('AAAABBBCCDAABBB')] --
    # [list(g) for k, g in groupby('AAAABBBCCD')] -

    def __init__(self, iterable, key=None):
        if key is None:
            key = lambda x: x
        self.keyfunc = key
        self.it = iter(iterable)
        self.tgtkey = self.currkey = self.currvalue

    def __iter__(self):
        return self

    def __next__(self):
        self.id = object()
        while self.currkey == self.tgtkey:
            self.currvalue = next(self.it)    # Exi
```

```
                self.currkey = self.keyfunc(self.currva
            self.tgtkey = self.currkey
            return (self.currkey, self._grouper(self.tg

        def _grouper(self, tgtkey, id):
            while self.id is id and self.currkey == tgt
                yield self.currvalue
                try:
                    self.currvalue = next(self.it)
                except StopIteration:
                    return
                self.currkey = self.keyfunc(self.currva
```

itertools.islice(*iterable*, *stop*)

itertools.islice(*iterable*, *start*, *stop*[, *step*])

Make an iterator that returns selected elements from the iterable. If *start* is non-zero, then elements from the iterable are skipped until start is reached. Afterward, elements are returned consecutively unless *step* is set higher than one which results in items being skipped. If *stop* is `None`, then iteration continues until the iterator is exhausted, if at all; otherwise, it stops at the specified position.

If *start* is `None`, then iteration starts at zero. If *step* is `None`, then the step defaults to one.

Unlike regular slicing, **`islice()`** does not support negative values for *start*, *stop*, or *step*. Can be used to extract related fields from data where the internal structure has been flattened (for example, a multi-line report may list a name field on every third line).

Roughly equivalent to:

```
def islice(iterable, *args):
    # islice('ABCDEFG', 2) --> A B
    # islice('ABCDEFG', 2, 4) --> C D
    # islice('ABCDEFG', 2, None) --> C D E F G
    # islice('ABCDEFG', 0, None, 2) --> A C E G
```

```
        s = slice(*args)
        start, stop, step = s.start or 0, s.stop or sys
        it = iter(range(start, stop, step))
        try:
            nexti = next(it)
        except StopIteration:
            # Consume *iterable* up to the *start* posi
            for i, element in zip(range(start), iterabl
                pass
            return
        try:
            for i, element in enumerate(iterable):
                if i == nexti:
                    yield element
                    nexti = next(it)
        except StopIteration:
            # Consume to *stop*.
            for i, element in zip(range(i + 1, stop), i
                pass
```

itertools.pairwise(*iterable*)

Return successive overlapping pairs taken from the input *iterable*.

The number of 2-tuples in the output iterator will be one fewer than the number of inputs. It will be empty if the input iterable has fewer than two values.

Roughly equivalent to:

```
def pairwise(iterable):
    # pairwise('ABCDEFG') --> AB BC CD DE EF FG
    a, b = tee(iterable)
    next(b, None)
    return zip(a, b)
```

New in version 3.10.

itertools.permutations(*iterable*, *r=None*)

Return successive *r* length permutations of elements in the *iterable*.

If *r* is not specified or is `None`, then *r* defaults to the length of the *iterable* and all possible full-length permutations are generated.

The permutation tuples are emitted in lexicographic order according to the order of the input *iterable*. So, if the input *iterable* is sorted, the output tuples will be produced in sorted order.

Elements are treated as unique based on their position, not on their value. So if the input elements are unique, there will be no repeated values within a permutation.

Roughly equivalent to:

```
def permutations(iterable, r=None):
    # permutations('ABCD', 2) --> AB AC AD BA BC BD
    # permutations(range(3)) --> 012 021 102 120 20
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    if r > n:
        return
    indices = list(range(n))
    cycles = list(range(n, n-r, -1))
    yield tuple(pool[i] for i in indices[:r])
    while n:
        for i in reversed(range(r)):
            cycles[i] -= 1
            if cycles[i] == 0:
                indices[i:] = indices[i+1:] + indic
                cycles[i] = n - i
            else:
                j = cycles[i]
                indices[i], indices[-j] = indices[-
                yield tuple(pool[i] for i in indice
                break
```

```
            else:
                return
```

The code for **`permutations()`** can be also expressed as a subsequence of **`product()`**, filtered to exclude entries with repeated elements (those from the same position in the input pool):

```
def permutations(iterable, r=None):
    pool = tuple(iterable)
    n = len(pool)
    r = n if r is None else r
    for indices in product(range(n), repeat=r):
        if len(set(indices)) == r:
            yield tuple(pool[i] for i in indices)
```

The number of items returned is `n! / (n-r)!` when `0 <= r <= n` or zero when `r > n`.

itertools.product(**iterables*, *repeat = 1*)

Cartesian product of input iterables.

Roughly equivalent to nested for-loops in a generator expression. For example, `product(A, B)` returns the same as `((x,y) for x in A for y in B)`.

The nested loops cycle like an odometer with the rightmost element advancing on every iteration. This pattern creates a lexicographic ordering so that if the input's iterables are sorted, the product tuples are emitted in sorted order.

To compute the product of an iterable with itself, specify the number of repetitions with the optional *repeat* keyword argument. For example, `product(A, repeat=4)` means the same as `product(A, A, A, A)`.

This function is roughly equivalent to the following code, except that the actual implementation does not build up intermediate results in memory:

```
def product(*args, repeat=1):
    # product('ABCD', 'xy') --> Ax Ay Bx By Cx Cy D
    # product(range(2), repeat=3) --> 000 001 010 0
    pools = [tuple(pool) for pool in args] * repeat
    result = [[]]
    for pool in pools:
        result = [x+[y] for x in result for y in po
    for prod in result:
        yield tuple(prod)
```

Before **`product()`** runs, it completely consumes the input iterables, keeping pools of values in memory to generate the products. Accordingly, it is only useful with finite inputs.

itertools.repeat(*object*[, *times*])

Make an iterator that returns *object* over and over again. Runs indefinitely unless the *times* argument is specified.

Roughly equivalent to:

```
def repeat(object, times=None):
    # repeat(10, 3) --> 10 10 10
    if times is None:
        while True:
            yield object
    else:
        for i in range(times):
            yield object
```

A common use for *repeat* is to supply a stream of constant values to *map* or *zip*:

```
>>> list(map(pow, range(10), repeat(2)))
[0, 1, 4, 9, 16, 25, 36, 49, 64, 81]
```

itertools.starmap(*function*, *iterable*)

Make an iterator that computes the function using arguments obtained from the iterable. Used instead of **`map()`** when argument parameters are already grouped in tuples from a

single iterable (when the data has been "pre-zipped").

The difference between **`map()`** and **`starmap()`** parallels the distinction between `function(a,b)` and `function(*c)`. Roughly equivalent to:

```
def starmap(function, iterable):
    # starmap(pow, [(2,5), (3,2), (10,3)]) --> 32 9
    for args in iterable:
        yield function(*args)
```

itertools.takewhile(*predicate*, *iterable*)

Make an iterator that returns elements from the iterable as long as the predicate is true. Roughly equivalent to:

```
def takewhile(predicate, iterable):
    # takewhile(lambda x: x<5, [1,4,6,4,1]) --> 1 4
    for x in iterable:
        if predicate(x):
            yield x
        else:
            break
```

itertools.tee(*iterable*, *n*=*2*)

Return *n* independent iterators from a single iterable.

The following Python code helps explain what *tee* does (although the actual implementation is more complex and uses only a single underlying FIFO queue):

```
def tee(iterable, n=2):
    it = iter(iterable)
    deques = [collections.deque() for i in range(n)
    def gen(mydeque):
        while True:
            if not mydeque:             # when the
                try:
                    newval = next(it)   # fetch a n
                except StopIteration:
```

```
                    return
                for d in deques:          # load it t
                    d.append(newval)
            yield mydeque.popleft()
    return tuple(gen(d) for d in deques)
```

Once a **`tee()`** has been created, the original *iterable* should not be used anywhere else; otherwise, the *iterable* could get advanced without the tee objects being informed.

`tee` iterators are not threadsafe. A **`RuntimeError`** may be raised when using simultaneously iterators returned by the same **`tee()`** call, even if the original *iterable* is threadsafe.

This itertool may require significant auxiliary storage (depending on how much temporary data needs to be stored). In general, if one iterator uses most or all of the data before another iterator starts, it is faster to use **`list()`** instead of **`tee()`**.

itertools.zip_longest(**iterables*, *fillvalue*=*None*)

Make an iterator that aggregates elements from each of the iterables. If the iterables are of uneven length, missing values are filled-in with *fillvalue*. Iteration continues until the longest iterable is exhausted. Roughly equivalent to:

```
def zip_longest(*args, fillvalue=None):
    # zip_longest('ABCD', 'xy', fillvalue='-') --> 
    iterators = [iter(it) for it in args]
    num_active = len(iterators)
    if not num_active:
        return
    while True:
        values = []
        for i, it in enumerate(iterators):
            try:
                value = next(it)
            except StopIteration:
                num_active -= 1
```

```
                    if not num_active:
                        return
                    iterators[i] = repeat(fillvalue)
                    value = fillvalue
                values.append(value)
            yield tuple(values)
```

If one of the iterables is potentially infinite, then the **`zip_longest()`** function should be wrapped with something that limits the number of calls (for example **`islice()`** or **`takewhile()`**). If not specified, *fillvalue* defaults to `None`.

Itertools Recipes

This section shows recipes for creating an extended toolset using the existing itertools as building blocks.

The primary purpose of the itertools recipes is educational. The recipes show various ways of thinking about individual tools — for example, that `chain.from_iterable` is related to the concept of flattening. The recipes also give ideas about ways that the tools can be combined — for example, how `compress()` and `range()` can work together. The recipes also show patterns for using itertools with the **`operator`** and **`collections`** modules as well as with the built-in itertools such as `map()`, `filter()`, `reversed()`, and `enumerate()`.

A secondary purpose of the recipes is to serve as an incubator. The `accumulate()`, `compress()`, and `pairwise()` itertools started out as recipes. Currently, the `iter_index()` recipe is being tested to see whether it proves its worth.

Substantially all of these recipes and many, many others can be installed from the more-itertools project [https://pypi.org/project/more-itertools/] found on the Python Package Index:

```
python -m pip install more-itertools
```

Many of the recipes offer the same high performance as the

underlying toolset. Superior memory performance is kept by processing elements one at a time rather than bringing the whole iterable into memory all at once. Code volume is kept small by linking the tools together in a functional style which helps eliminate temporary variables. High speed is retained by preferring "vectorized" building blocks over the use of for-loops and generators which incur interpreter overhead.

    pool = tuple(iterable)
    n = len(pool)
    c = math.comb(n, r)
    if index < 0:
        index += c
    if index < 0 or index >= c:
        raise IndexError
    result = []
    while r:
        c, n, r = c*r//n, n-1, r-1
        while index >= c:
            index -= c
            c, n = c*(n-r)//n, n-1
```

```
    result.append(pool[-1-n])
return tuple(result)
```

`functools` — Higher-order functions and operations on callable objects

Source code: Lib/functools.py [https://github.com/python/cpython/tree/3.11/Lib/functools.py]

The `functools` module is for higher-order functions: functions that act on or return other functions. In general, any callable object can be treated as a function for the purposes of this module.

The `functools` module defines the following functions:

@functools.cache(*user_function*)

Simple lightweight unbounded function cache. Sometimes called "memoize" [https://en.wikipedia.org/wiki/Memoization].

Returns the same as `lru_cache(maxsize=None)`, creating a thin wrapper around a dictionary lookup for the function arguments. Because it never needs to evict old values, this is smaller and faster than `lru_cache()` with a size limit.

For example:

```
@cache
def factorial(n):
    return n * factorial(n-1) if n else 1

>>> factorial(10)      # no previously cached resul
3628800
>>> factorial(5)       # just looks up cached value
120
>>> factorial(12)      # makes two new recursive ca
```

```
479001600
```

New in version 3.9.

@functools.cached_property(*func*)

Transform a method of a class into a property whose value is computed once and then cached as a normal attribute for the life of the instance. Similar to **property()**, with the addition of caching. Useful for expensive computed properties of instances that are otherwise effectively immutable.

Example:

```
class DataSet:

    def __init__(self, sequence_of_numbers):
        self._data = tuple(sequence_of_numbers)

    @cached_property
    def stdev(self):
        return statistics.stdev(self._data)
```

The mechanics of **cached_property()** are somewhat different from **property()**. A regular property blocks attribute writes unless a setter is defined. In contrast, a *cached_property* allows writes.

The *cached_property* decorator only runs on lookups and only when an attribute of the same name doesn't exist. When it does run, the *cached_property* writes to the attribute with the same name. Subsequent attribute reads and writes take precedence over the *cached_property* method and it works like a normal attribute.

The cached value can be cleared by deleting the attribute. This allows the *cached_property* method to run again.

Note, this decorator interferes with the operation of **PEP 412** [https://peps.python.org/pep-0412/] key-sharing dictionaries. This means that instance dictionaries can take more space than

usual.

Also, this decorator requires that the `__dict__` attribute on each instance be a mutable mapping. This means it will not work with some types, such as metaclasses (since the `__dict__` attributes on type instances are read-only proxies for the class namespace), and those that specify `__slots__` without including `__dict__` as one of the defined slots (as such classes don't provide a `__dict__` attribute at all).

If a mutable mapping is not available or if space-efficient key sharing is desired, an effect similar to **`cached_property()`** can be achieved by a stacking **`property()`** on top of **`cache()`**:

```
class DataSet:
    def __init__(self, sequence_of_numbers):
        self._data = sequence_of_numbers

    @property
    @cache
    def stdev(self):
        return statistics.stdev(self._data)
```

New in version 3.8.

functools.cmp_to_key(*func*)

Transform an old-style comparison function to a key function. Used with tools that accept key functions (such as **`sorted()`**, **`min()`**, **`max()`**, **`heapq.nlargest()`**, **`heapq.nsmallest()`**, **`itertools.groupby()`**). This function is primarily used as a transition tool for programs being converted from Python 2 which supported the use of comparison functions.

A comparison function is any callable that accepts two arguments, compares them, and returns a negative number for less-than, zero for equality, or a positive number for greater-than. A key function is a callable that accepts one argument and returns another value to be used as the sort

key.

Example:

```
sorted(iterable, key=cmp_to_key(locale.strcoll))  #
```

For sorting examples and a brief sorting tutorial, see Sorting HOW TO.

New in version 3.2.

@functools.lru_cache(*user_function*)
@functools.lru_cache(*maxsize=128*, *typed=False*)

Decorator to wrap a function with a memoizing callable that saves up to the *maxsize* most recent calls. It can save time when an expensive or I/O bound function is periodically called with the same arguments.

Since a dictionary is used to cache results, the positional and keyword arguments to the function must be hashable.

Distinct argument patterns may be considered to be distinct calls with separate cache entries. For example, `f(a=1, b=2)` and `f(b=2, a=1)` differ in their keyword argument order and may have two separate cache entries.

If *user_function* is specified, it must be a callable. This allows the *lru_cache* decorator to be applied directly to a user function, leaving the *maxsize* at its default value of 128:

```
@lru_cache
def count_vowels(sentence):
    return sum(sentence.count(vowel) for vowel in '
```

If *maxsize* is set to `None`, the LRU feature is disabled and the cache can grow without bound.

If *typed* is set to true, function arguments of different types will be cached separately. If *typed* is false, the implementation will usually regard them as equivalent calls and only cache a single result. (Some types such as *str* and *int* may be cached

separately even when *typed* is false.)

Note, type specificity applies only to the function's immediate arguments rather than their contents. The scalar arguments, `Decimal(42)` and `Fraction(42)` are be treated as distinct calls with distinct results. In contrast, the tuple arguments `('answer', Decimal(42))` and `('answer', Fraction(42))` are treated as equivalent.

The wrapped function is instrumented with a **`cache_parameters()`** function that returns a new **`dict`** showing the values for *maxsize* and *typed*. This is for information purposes only. Mutating the values has no effect.

To help measure the effectiveness of the cache and tune the *maxsize* parameter, the wrapped function is instrumented with a **`cache_info()`** function that returns a named tuple showing *hits*, *misses*, *maxsize* and *currsize*.

The decorator also provides a **`cache_clear()`** function for clearing or invalidating the cache.

The original underlying function is accessible through the **`__wrapped__`** attribute. This is useful for introspection, for bypassing the cache, or for rewrapping the function with a different cache.

The cache keeps references to the arguments and return values until they age out of the cache or until the cache is cleared.

If a method is cached, the `self` instance argument is included in the cache. See How do I cache method calls?

An LRU (least recently used) cache [https://en.wikipedia.org/wiki/Cache_replacement_policies#Least_recently_used_(LRU)] works best when the most recent calls are the best predictors of upcoming calls (for example, the most popular articles on a news server tend to change each day). The cache's size limit assures that the cache does not grow without bound on long-running processes such as web servers.

In general, the LRU cache should only be used when you want to reuse previously computed values. Accordingly, it doesn't make sense to cache functions with side-effects, functions that need to create distinct mutable objects on each call, or impure functions such as time() or random().

Example of an LRU cache for static web content:

```
@lru_cache(maxsize=32)
def get_pep(num):
    'Retrieve text of a Python Enhancement Proposal
    resource = 'https://peps.python.org/pep-%04d/'
    try:
        with urllib.request.urlopen(resource) as s:
            return s.read()
    except urllib.error.HTTPError:
        return 'Not Found'

>>> for n in 8, 290, 308, 320, 8, 218, 320, 279, 28
...     pep = get_pep(n)
...     print(n, len(pep))

>>> get_pep.cache_info()
CacheInfo(hits=3, misses=8, maxsize=32, currsize=8)
```

Example of efficiently computing Fibonacci numbers [https://en.wikipedia.org/wiki/Fibonacci_number] using a cache to implement a dynamic programming [https://en.wikipedia.org/wiki/Dynamic_programming] technique:

```
@lru_cache(maxsize=None)
def fib(n):
    if n < 2:
        return n
    return fib(n-1) + fib(n-2)

>>> [fib(n) for n in range(16)]
[0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233,

>>> fib.cache_info()
```

```
CacheInfo(hits=28, misses=16, maxsize=None, currsiz
```

New in version 3.2.

Changed in version 3.3: Added the *typed* option.

Changed in version 3.8: Added the *user_function* option.

New in version 3.9: Added the function **`cache_parameters()`**

@functools.total_ordering

Given a class defining one or more rich comparison ordering methods, this class decorator supplies the rest. This simplifies the effort involved in specifying all of the possible rich comparison operations:

The class must define one of **`__lt__()`**, **`__le__()`**, **`__gt__()`**, or **`__ge__()`**. In addition, the class should supply an **`__eq__()`** method.

For example:

```
@total_ordering
class Student:
    def _is_valid_operand(self, other):
        return (hasattr(other, "lastname") and
                hasattr(other, "firstname"))
    def __eq__(self, other):
        if not self._is_valid_operand(other):
            return NotImplemented
        return ((self.lastname.lower(), self.firstn
                 (other.lastname.lower(), other.firs
    def __lt__(self, other):
        if not self._is_valid_operand(other):
            return NotImplemented
        return ((self.lastname.lower(), self.firstn
                 (other.lastname.lower(), other.firs
```

Note

While this decorator makes it easy to create well behaved totally ordered types, it *does* come at the cost of slower execution and more complex stack traces for the derived comparison methods. If performance benchmarking indicates this is a bottleneck for a given application, implementing all six rich comparison methods instead is likely to provide an easy speed boost.

Note

This decorator makes no attempt to override methods that have been declared in the class *or its superclasses*. Meaning that if a superclass defines a comparison operator, *total_ordering* will not implement it again, even if the original method is abstract.

New in version 3.2.

Changed in version 3.4: Returning NotImplemented from the underlying comparison function for unrecognised types is now supported.

functools.partial(*func*, /, **args*, ***keywords*)

Return a new partial object which when called will behave like *func* called with the positional arguments *args* and keyword arguments *keywords*. If more arguments are supplied to the call, they are appended to *args*. If additional keyword arguments are supplied, they extend and override *keywords*. Roughly equivalent to:

```
def partial(func, /, *args, **keywords):
    def newfunc(*fargs, **fkeywords):
        newkeywords = {**keywords, **fkeywords}
        return func(*args, *fargs, **newkeywords)
    newfunc.func = func
    newfunc.args = args
    newfunc.keywords = keywords
    return newfunc
```

The **partial()** is used for partial function application which “freezes” some portion of a function’s arguments and/or keywords resulting in a new object with a simplified signature. For example, **partial()** can be used to create a callable that behaves like the **int()** function where the *base* argument defaults to two:

```
>>> from functools import partial
>>> basetwo = partial(int, base=2)
>>> basetwo.__doc__ = 'Convert base 2 string to an
>>> basetwo('10010')
18
```

class functools.partialmethod(*func*, */*, **args*, ***keywords*)

Return a new **partialmethod** descriptor which behaves like **partial** except that it is designed to be used as a method definition rather than being directly callable.

func must be a descriptor or a callable (objects which are both, like normal functions, are handled as descriptors).

When *func* is a descriptor (such as a normal Python function, **classmethod()**, **staticmethod()**, **abstractmethod()** or another instance of **partialmethod**), calls to `__get__` are delegated to the underlying descriptor, and an appropriate partial object returned as the result.

When *func* is a non-descriptor callable, an appropriate bound method is created dynamically. This behaves like a normal Python function when used as a method: the *self* argument will be inserted as the first positional argument, even before the *args* and *keywords* supplied to the **partialmethod** constructor.

Example:

```
>>> class Cell:
...     def __init__(self):
...         self._alive = False
...     @property
```

```
...     def alive(self):
...         return self._alive
...     def set_state(self, state):
...         self._alive = bool(state)
...     set_alive = partialmethod(set_state, True)
...     set_dead = partialmethod(set_state, False)
...
>>> c = Cell()
>>> c.alive
False
>>> c.set_alive()
>>> c.alive
True
```

New in version 3.4.

functools.reduce(*function*, *iterable*[, *initializer*])

Apply *function* of two arguments cumulatively to the items of *iterable*, from left to right, so as to reduce the iterable to a single value. For example, `reduce(lambda x, y: x+y, [1, 2, 3, 4, 5])` calculates `(((1+2)+3)+4)+5)`. The left argument, *x*, is the accumulated value and the right argument, *y*, is the update value from the *iterable*. If the optional *initializer* is present, it is placed before the items of the iterable in the calculation, and serves as a default when the iterable is empty. If *initializer* is not given and *iterable* contains only one item, the first item is returned.

Roughly equivalent to:

```
def reduce(function, iterable, initializer=None):
    it = iter(iterable)
    if initializer is None:
        value = next(it)
    else:
        value = initializer
    for element in it:
        value = function(value, element)
    return value
```

See **`itertools.accumulate()`** for an iterator that yields all intermediate values.

@functools.singledispatch

Transform a function into a single-dispatch generic function.

To define a generic function, decorate it with the `@singledispatch` decorator. When defining a function using `@singledispatch`, note that the dispatch happens on the type of the first argument:

```
>>> from functools import singledispatch
>>> @singledispatch
... def fun(arg, verbose=False):
...     if verbose:
...         print("Let me just say,", end=" ")
...     print(arg)
```

To add overloaded implementations to the function, use the **`register()`** attribute of the generic function, which can be used as a decorator. For functions annotated with types, the decorator will infer the type of the first argument automatically:

```
>>> @fun.register
... def _(arg: int, verbose=False):
...     if verbose:
...         print("Strength in numbers, eh?", end="
...     print(arg)
...
>>> @fun.register
... def _(arg: list, verbose=False):
...     if verbose:
...         print("Enumerate this:")
...     for i, elem in enumerate(arg):
...         print(i, elem)
```

`types.UnionType` and **`typing.Union`** can also be used:

```
>>> @fun.register
```

```
... def _(arg: int | float, verbose=False):
...     if verbose:
...         print("Strength in numbers, eh?", end="
...     print(arg)
...
>>> from typing import Union
>>> @fun.register
... def _(arg: Union[list, set], verbose=False):
...     if verbose:
...         print("Enumerate this:")
...     for i, elem in enumerate(arg):
...         print(i, elem)
...
```

For code which doesn't use type annotations, the appropriate type argument can be passed explicitly to the decorator itself:

```
>>> @fun.register(complex)
... def _(arg, verbose=False):
...     if verbose:
...         print("Better than complicated.", end="
...     print(arg.real, arg.imag)
...
```

To enable registering lambdas and pre-existing functions, the **`register()`** attribute can also be used in a functional form:

```
>>> def nothing(arg, verbose=False):
...     print("Nothing.")
...
>>> fun.register(type(None), nothing)
```

The **`register()`** attribute returns the undecorated function. This enables decorator stacking, **`pickling`**, and the creation of unit tests for each variant independently:

```
>>> @fun.register(float)
... @fun.register(Decimal)
... def fun_num(arg, verbose=False):
...     if verbose:
```

```
...         print("Half of your number:", end=" ")
...     print(arg / 2)
...
>>> fun_num is fun
False
```

When called, the generic function dispatches on the type of the first argument:

```
>>> fun("Hello, world.")
Hello, world.
>>> fun("test.", verbose=True)
Let me just say, test.
>>> fun(42, verbose=True)
Strength in numbers, eh? 42
>>> fun(['spam', 'spam', 'eggs', 'spam'], verbose=T
Enumerate this:
0 spam
1 spam
2 eggs
3 spam
>>> fun(None)
Nothing.
>>> fun(1.23)
0.615
```

Where there is no registered implementation for a specific type, its method resolution order is used to find a more generic implementation. The original function decorated with `@singledispatch` is registered for the base **`object`** type, which means it is used if no better implementation is found.

If an implementation is registered to an abstract base class, virtual subclasses of the base class will be dispatched to that implementation:

```
>>> from collections.abc import Mapping
>>> @fun.register
... def _(arg: Mapping, verbose=False):
...     if verbose:
```

```
...          print("Keys & Values")
...      for key, value in arg.items():
...          print(key, "=>", value)
...
>>> fun({"a": "b"})
a => b
```

To check which implementation the generic function will choose for a given type, use the `dispatch()` attribute:

```
>>> fun.dispatch(float)
<function fun_num at 0x1035a2840>
>>> fun.dispatch(dict)    # note: default implement
<function fun at 0x103fe0000>
```

To access all registered implementations, use the read-only `registry` attribute:

```
>>> fun.registry.keys()
dict_keys([<class 'NoneType'>, <class 'int'>, <clas
           <class 'decimal.Decimal'>, <class 'list'>
           <class 'float'>])
>>> fun.registry[float]
<function fun_num at 0x1035a2840>
>>> fun.registry[object]
<function fun at 0x103fe0000>
```

New in version 3.4.

Changed in version 3.7: The **`register()`** attribute now supports using type annotations.

Changed in version 3.11: The **`register()`** attribute now supports **`types.UnionType`** and **`typing.Union`** as type annotations.

class functools.singledispatchmethod(*func*)

Transform a method into a single-dispatch generic function.

To define a generic method, decorate it with the

`@singledispatchmethod` decorator. When defining a function using `@singledispatchmethod`, note that the dispatch happens on the type of the first non-*self* or non-*cls* argument:

```
class Negator:
    @singledispatchmethod
    def neg(self, arg):
        raise NotImplementedError("Cannot negate a"

    @neg.register
    def _(self, arg: int):
        return -arg

    @neg.register
    def _(self, arg: bool):
        return not arg
```

`@singledispatchmethod` supports nesting with other decorators such as **`@classmethod`**. Note that to allow for `dispatcher.register`, `singledispatchmethod` must be the *outer most* decorator. Here is the `Negator` class with the `neg` methods bound to the class, rather than an instance of the class:

```
class Negator:
    @singledispatchmethod
    @classmethod
    def neg(cls, arg):
        raise NotImplementedError("Cannot negate a"

    @neg.register
    @classmethod
    def _(cls, arg: int):
        return -arg

    @neg.register
    @classmethod
    def _(cls, arg: bool):
```

```
        return not arg
```

The same pattern can be used for other similar decorators: **@staticmethod**, **@abstractmethod**, and others.

New in version 3.8.

functools.update_wrapper(*wrapper*, *wrapped*, *assigned* = *WRAPPER_ASSIGNMENTS*, *updated* = *WRAPPER_UPDATES*)

Update a *wrapper* function to look like the *wrapped* function. The optional arguments are tuples to specify which attributes of the original function are assigned directly to the matching attributes on the wrapper function and which attributes of the wrapper function are updated with the corresponding attributes from the original function. The default values for these arguments are the module level constants `WRAPPER_ASSIGNMENTS` (which assigns to the wrapper function's `__module__`, `__name__`, `__qualname__`, `__annotations__` and `__doc__`, the documentation string) and `WRAPPER_UPDATES` (which updates the wrapper function's `__dict__`, i.e. the instance dictionary).

To allow access to the original function for introspection and other purposes (e.g. bypassing a caching decorator such as **lru_cache()**), this function automatically adds a `__wrapped__` attribute to the wrapper that refers to the function being wrapped.

The main intended use for this function is in decorator functions which wrap the decorated function and return the wrapper. If the wrapper function is not updated, the metadata of the returned function will reflect the wrapper definition rather than the original function definition, which is typically less than helpful.

update_wrapper() may be used with callables other than functions. Any attributes named in *assigned* or *updated* that are missing from the object being wrapped are ignored (i.e. this function will not attempt to set them on the wrapper

function). **AttributeError** is still raised if the wrapper function itself is missing any attributes named in *updated*.

New in version 3.2: Automatic addition of the `__wrapped__` attribute.

New in version 3.2: Copying of the `__annotations__` attribute by default.

Changed in version 3.2: Missing attributes no longer trigger an **AttributeError**.

Changed in version 3.4: The `__wrapped__` attribute now always refers to the wrapped function, even if that function defined a `__wrapped__` attribute. (see bpo-17482 [https://bugs.python.org/issue?@action=redirect&bpo=17482])

@functools.wraps(*wrapped*, *assigned*=*WRAPPER_ASSIGNMENTS*, *updated*=*WRAPPER_UPDATES*)

This is a convenience function for invoking **update_wrapper()** as a function decorator when defining a wrapper function. It is equivalent to `partial(update_wrapper, wrapped=wrapped, assigned=assigned, updated=updated)`. For example:

```
>>> from functools import wraps
>>> def my_decorator(f):
...     @wraps(f)
...     def wrapper(*args, **kwds):
...         print('Calling decorated function')
...         return f(*args, **kwds)
...     return wrapper
...
>>> @my_decorator
... def example():
...     """Docstring"""
...     print('Called example function')
...
>>> example()
```

```
Calling decorated function
Called example function
>>> example.__name__
'example'
>>> example.__doc__
'Docstring'
```

Without the use of this decorator factory, the name of the example function would have been `'wrapper'`, and the docstring of the original **`example()`** would have been lost.

`partial` Objects

`partial` objects are callable objects created by **`partial()`**. They have three read-only attributes:

partial.func

A callable object or function. Calls to the **`partial`** object will be forwarded to **`func`** with new arguments and keywords.

partial.args

The leftmost positional arguments that will be prepended to the positional arguments provided to a **`partial`** object call.

partial.keywords

The keyword arguments that will be supplied when the **`partial`** object is called.

`partial` objects are like **`function`** objects in that they are callable, weak referencable, and can have attributes. There are some important differences. For instance, the **`__name__`** and **`__doc__`** attributes are not created automatically. Also, **`partial`** objects defined in classes behave like static methods and do not transform into bound methods during instance attribute look-up.

`operator` — Standard operators as functions

Source code: Lib/operator.py [https://github.com/python/cpython/tree/3.11/Lib/operator.py]

The `operator` module exports a set of efficient functions corresponding to the intrinsic operators of Python. For example, `operator.add(x, y)` is equivalent to the expression `x+y`. Many function names are those used for special methods, without the double underscores. For backward compatibility, many of these have a variant with the double underscores kept. The variants without the double underscores are preferred for clarity.

The functions fall into categories that perform object comparisons, logical operations, mathematical operations and sequence operations.

The object comparison functions are useful for all objects, and are named after the rich comparison operators they support:

operator.lt(*a*, *b*)
operator.le(*a*, *b*)
operator.eq(*a*, *b*)
operator.ne(*a*, *b*)
operator.ge(*a*, *b*)
operator.gt(*a*, *b*)
operator.__lt__(*a*, *b*)
operator.__le__(*a*, *b*)
operator.__eq__(*a*, *b*)
operator.__ne__(*a*, *b*)
operator.__ge__(*a*, *b*)

operator._gt_(*a*, *b*)

Perform “rich comparisons” between *a* and *b*. Specifically, `lt(a, b)` is equivalent to `a < b`, `le(a, b)` is equivalent to `a <= b`, `eq(a, b)` is equivalent to `a == b`, `ne(a, b)` is equivalent to `a != b`, `gt(a, b)` is equivalent to `a > b` and `ge(a, b)` is equivalent to `a >= b`. Note that these functions can return any value, which may or may not be interpretable as a Boolean value. See Comparisons for more information about rich comparisons.

The logical operations are also generally applicable to all objects, and support truth tests, identity tests, and boolean operations:

operator.not_(*obj*)
operator._not_(*obj*)

Return the outcome of **not** *obj*. (Note that there is no **__not__()** method for object instances; only the interpreter core defines this operation. The result is affected by the **__bool__()** and **__len__()** methods.)

operator.truth(*obj*)

Return **True** if *obj* is true, and **False** otherwise. This is equivalent to using the **bool** constructor.

operator.is_(*a*, *b*)

Return `a is b`. Tests object identity.

operator.is_not(*a*, *b*)

Return `a is not b`. Tests object identity.

The mathematical and bitwise operations are the most numerous:

operator.abs(*obj*)
operator._abs_(*obj*)

Return the absolute value of *obj*.

operator.add(*a*, *b*)
operator._add_(*a*, *b*)

Return `a + b`, for *a* and *b* numbers.

operator.and_(*a*, *b*)
operator._and_(*a*, *b*)

Return the bitwise and of *a* and *b*.

operator.floordiv(*a*, *b*)
operator._floordiv_(*a*, *b*)

Return `a // b`.

operator.index(*a*)
operator._index_(*a*)

Return *a* converted to an integer. Equivalent to `a.__index__()`.

Changed in version 3.10: The result always has exact type **`int`**. Previously, the result could have been an instance of a subclass of `int`.

operator.inv(*obj*)
operator.invert(*obj*)
operator._inv_(*obj*)
operator._invert_(*obj*)

Return the bitwise inverse of the number *obj*. This is equivalent to `~obj`.

operator.lshift(*a*, *b*)
operator._lshift_(*a*, *b*)

Return *a* shifted left by *b*.

operator.mod(*a*, *b*)
operator._mod_(*a*, *b*)

Return `a % b`.

operator.mul(*a*, *b*)
operator._mul_(*a*, *b*)
Return `a * b`, for *a* and *b* numbers.

operator.matmul(*a*, *b*)
operator._matmul_(*a*, *b*)
Return `a @ b`.

New in version 3.5.

operator.neg(*obj*)
operator._neg_(*obj*)
Return *obj* negated (`-obj`).

operator.or_(*a*, *b*)
operator._or_(*a*, *b*)
Return the bitwise or of *a* and *b*.

operator.pos(*obj*)
operator._pos_(*obj*)
Return *obj* positive (`+obj`).

operator.pow(*a*, *b*)
operator._pow_(*a*, *b*)
Return `a ** b`, for *a* and *b* numbers.

operator.rshift(*a*, *b*)
operator._rshift_(*a*, *b*)
Return *a* shifted right by *b*.

operator.sub(*a*, *b*)
operator._sub_(*a*, *b*)
Return `a - b`.

operator.truediv(*a*, *b*)
operator._truediv_(*a*, *b*)

Return `a / b` where 2/3 is .66 rather than 0. This is also known as “true” division.

operator.xor(*a*, *b*)
operator._xor_(*a*, *b*)

Return the bitwise exclusive or of *a* and *b*.

Operations which work with sequences (some of them with mappings too) include:

operator.concat(*a*, *b*)
operator._concat_(*a*, *b*)

Return `a + b` for *a* and *b* sequences.

operator.contains(*a*, *b*)
operator._contains_(*a*, *b*)

Return the outcome of the test `b in a`. Note the reversed operands.

operator.countOf(*a*, *b*)

Return the number of occurrences of *b* in *a*.

operator.delitem(*a*, *b*)
operator._delitem_(*a*, *b*)

Remove the value of *a* at index *b*.

operator.getitem(*a*, *b*)
operator._getitem_(*a*, *b*)

Return the value of *a* at index *b*.

operator.indexOf(*a*, *b*)

Return the index of the first of occurrence of *b* in *a*.

operator.setitem(*a*, *b*, *c*)
operator._setitem_(*a*, *b*, *c*)

Set the value of *a* at index *b* to *c*.

operator.length_hint(*obj*, *default=0*)

Return an estimated length for the object *o*. First try to return its actual length, then an estimate using **object.__length_hint__()**, and finally return the default value.

New in version 3.4.

The following operation works with callables:

operator.call(*obj*, */*, **args*, ***kwargs*)
operator._call_(*obj*, */*, **args*, ***kwargs*)

Return `obj(*args, **kwargs)`.

New in version 3.11.

The **operator** module also defines tools for generalized attribute and item lookups. These are useful for making fast field extractors as arguments for **map()**, **sorted()**, **itertools.groupby()**, or other functions that expect a function argument.

operator.attrgetter(*attr*)
operator.attrgetter(**attrs*)

Return a callable object that fetches *attr* from its operand. If more than one attribute is requested, returns a tuple of attributes. The attribute names can also contain dots. For example:

- After `f = attrgetter('name')`, the call `f(b)` returns `b.name`.
- After `f = attrgetter('name', 'date')`, the call `f(b)` returns `(b.name, b.date)`.
- After `f = attrgetter('name.first', 'name.last')`, the call `f(b)` returns

```
(b.name.first, b.name.last).
```

Equivalent to:

```
def attrgetter(*items):
    if any(not isinstance(item, str) for item in it
        raise TypeError('attribute name must be a s
    if len(items) == 1:
        attr = items[0]
        def g(obj):
            return resolve_attr(obj, attr)
    else:
        def g(obj):
            return tuple(resolve_attr(obj, attr) fo
    return g

def resolve_attr(obj, attr):
    for name in attr.split("."):
        obj = getattr(obj, name)
    return obj
```

operator.itemgetter(*item*)
operator.itemgetter(**items*)

Return a callable object that fetches *item* from its operand using the operand's **`__getitem__()`** method. If multiple items are specified, returns a tuple of lookup values. For example:

- After `f = itemgetter(2)`, the call `f(r)` returns `r[2]`.
- After `g = itemgetter(2, 5, 3)`, the call `g(r)` returns `(r[2], r[5], r[3])`.

Equivalent to:

```
def itemgetter(*items):
    if len(items) == 1:
        item = items[0]
        def g(obj):
```

```
            return obj[item]
    else:
        def g(obj):
            return tuple(obj[item] for item in item
    return g
```

The items can be any type accepted by the operand's **`__getitem__()`** method. Dictionaries accept any hashable value. Lists, tuples, and strings accept an index or a slice:

```
>>> itemgetter(1)('ABCDEFG')
'B'
>>> itemgetter(1, 3, 5)('ABCDEFG')
('B', 'D', 'F')
>>> itemgetter(slice(2, None))('ABCDEFG')
'CDEFG'
>>> soldier = dict(rank='captain', name='dotterbart
>>> itemgetter('rank')(soldier)
'captain'
```

Example of using **`itemgetter()`** to retrieve specific fields from a tuple record:

```
>>> inventory = [('apple', 3), ('banana', 2), ('pea
>>> getcount = itemgetter(1)
>>> list(map(getcount, inventory))
[3, 2, 5, 1]
>>> sorted(inventory, key=getcount)
[('orange', 1), ('banana', 2), ('apple', 3), ('pear
```

operator.methodcaller(*name*, */*, **args*, ***kwargs*)

Return a callable object that calls the method *name* on its operand. If additional arguments and/or keyword arguments are given, they will be given to the method as well. For example:

- After `f = methodcaller('name')`, the call `f(b)` returns `b.name()`.
- After `f = methodcaller('name', 'foo',`

`bar=1)`, the call `f(b)` returns `b.name('foo', bar=1)`.

Equivalent to:

```
def methodcaller(name, /, *args, **kwargs):
    def caller(obj):
        return getattr(obj, name)(*args, **kwargs)
    return caller
```

Mapping Operators to Functions

This table shows how abstract operations correspond to operator symbols in the Python syntax and the functions in the **operator** module.

Operation	Syntax	Function
Addition	`a + b`	`add(a, b)`
Concatenation	`seq1 + seq2`	`concat(seq1, seq2)`
Containment Test	`obj in seq`	`contains(seq, obj)`
Division	`a / b`	`truediv(a, b)`
Division	`a // b`	`floordiv(a, b)`
Bitwise And	`a & b`	`and_(a, b)`
Bitwise Exclusive Or	`a ^ b`	`xor(a, b)`
Bitwise Inversion	`~ a`	`invert(a)`
Bitwise Or	`a | b`	`or_(a, b)`
Exponentiation	`a ** b`	`pow(a, b)`
Identity	`a is b`	`is_(a, b)`
Identity	`a is not b`	`is_not(a, b)`
Indexed Assignment	`obj[k] = v`	`setitem(obj, k, v)`
Indexed Deletion	`del obj[k]`	`delitem(obj, k)`
Indexing	`obj[k]`	`getitem(obj, k)`
Left Shift	`a << b`	`lshift(a, b)`
Modulo	`a % b`	`mod(a, b)`
Multiplication	`a * b`	`mul(a, b)`
Matrix Multiplication	`a @ b`	`matmul(a, b)`
Negation (Arithmetic)	`- a`	`neg(a)`
Negation (Logical)	`not a`	`not_(a)`
Positive	`+ a`	`pos(a)`
Right Shift	`a >> b`	`rshift(a, b)`

Slice Assignment	`seq[i:j] = values`
Slice Deletion	`del seq[i:j]`
Slicing	`seq[i:j]`
String Formatting	`s % obj`
Subtraction	`a - b`
Truth Test	`obj`
Ordering	`a < b`
Ordering	`a <= b`
Equality	`a == b`
Difference	`a != b`
Ordering	`a >= b`
Ordering	`a > b`

In-place Operators

Many operations have an “in-place” version. Listed below are functions providing a more primitive access to in-place operators than the usual syntax does; for example, the statement `x += y` is equivalent to `x = operator.iadd(x, y)`. Another way to put it is to say that `z = operator.iadd(x, y)` is equivalent to the compound statement `z = x; z += y`.

In those examples, note that when an in-place method is called, the computation and assignment are performed in two separate steps. The in-place functions listed below only do the first step, calling the in-place method. The second step, assignment, is not handled.

For immutable targets such as strings, numbers, and tuples, the updated value is computed, but not assigned back to the input variable:

```
>>> a = 'hello'
>>> iadd(a, ' world')
'hello world'
>>> a
'hello'
```

For mutable targets such as lists and dictionaries, the in-place method will perform the update, so no subsequent assignment is necessary:

```
>>> s = ['h', 'e', 'l', 'l', 'o']
>>> iadd(s, [' ', 'w', 'o', 'r', 'l', 'd'])
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
>>> s
['h', 'e', 'l', 'l', 'o', ' ', 'w', 'o', 'r', 'l', 'd']
```

operator.iadd(*a*, *b*)
operator._iadd_(*a*, *b*)

`a = iadd(a, b)` is equivalent to `a += b`.

operator.iand(*a*, *b*)
operator._iand_(*a*, *b*)

`a = iand(a, b)` is equivalent to `a &= b`.

operator.iconcat(*a*, *b*)
operator._iconcat_(*a*, *b*)

`a = iconcat(a, b)` is equivalent to `a += b` for *a* and *b* sequences.

operator.ifloordiv(*a*, *b*)
operator._ifloordiv_(*a*, *b*)

`a = ifloordiv(a, b)` is equivalent to `a //= b`.

operator.ilshift(*a*, *b*)
operator._ilshift_(*a*, *b*)

`a = ilshift(a, b)` is equivalent to `a <<= b`.

operator.imod(*a*, *b*)
operator._imod_(*a*, *b*)

`a = imod(a, b)` is equivalent to `a %= b`.

operator.imul(*a*, *b*)
operator._imul_(*a*, *b*)

`a = imul(a, b)` is equivalent to `a *= b`.

operator.imatmul(*a*, *b*)
operator._imatmul_(*a*, *b*)

`a = imatmul(a, b)` is equivalent to `a @= b`.

New in version 3.5.

operator.ior(*a*, *b*)
operator._ior_(*a*, *b*)

`a = ior(a, b)` is equivalent to `a |= b`.

operator.ipow(*a*, *b*)
operator._ipow_(*a*, *b*)

`a = ipow(a, b)` is equivalent to `a **= b`.

operator.irshift(*a*, *b*)
operator._irshift_(*a*, *b*)

`a = irshift(a, b)` is equivalent to `a >>= b`.

operator.isub(*a*, *b*)
operator._isub_(*a*, *b*)

`a = isub(a, b)` is equivalent to `a -= b`.

operator.itruediv(*a*, *b*)
operator._itruediv_(*a*, *b*)

`a = itruediv(a, b)` is equivalent to `a /= b`.

operator.ixor(*a*, *b*)
operator._ixor_(*a*, *b*)

`a = ixor(a, b)` is equivalent to `a ^= b`.

File and Directory Access

The modules described in this chapter deal with disk files and directories. For example, there are modules for reading the properties of files, manipulating paths in a portable way, and creating temporary files. The full list of modules in this chapter is:

- **pathlib** — Object-oriented filesystem paths
  - Basic use
  - Pure paths
    - General properties
    - Operators
    - Accessing individual parts
    - Methods and properties
  - Concrete paths
    - Methods
  - Correspondence to tools in the **os** module
- **os.path** — Common pathname manipulations
- **fileinput** — Iterate over lines from multiple input streams
- **stat** — Interpreting **stat()** results
- **filecmp** — File and Directory Comparisons
  - The **dircmp** class
- **tempfile** — Generate temporary files and directories
  - Examples
  - Deprecated functions and variables
- **glob** — Unix style pathname pattern expansion
- **fnmatch** — Unix filename pattern matching
- **linecache** — Random access to text lines

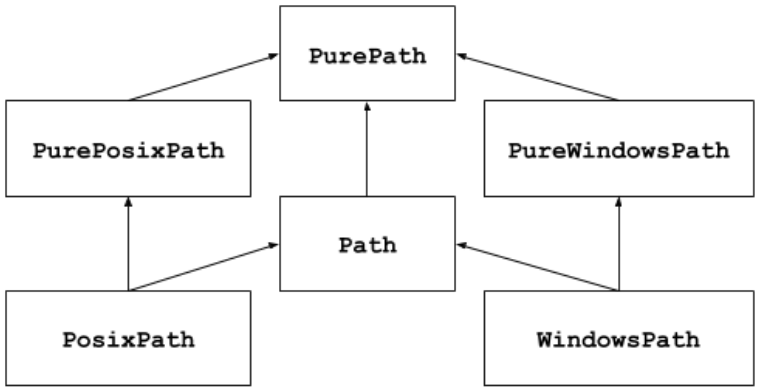
- **shutil** — High-level file operations
  - Directory and files operations
    - Platform-dependent efficient copy operations
    - copytree example
    - rmtree example
  - Archiving operations
    - Archiving example
    - Archiving example with *base_dir*
  - Querying the size of the output terminal

See also

Module **os**
: Operating system interfaces, including functions to work with files at a lower level than Python file objects.

Module **io**
: Python's built-in I/O library, including both abstract classes and some concrete classes such as file I/O.

Built-in function **open()**
: The standard way to open files for reading and writing with Python.



`pathlib` — Object-oriented filesystem paths

New in version 3.4.

Source code: Lib/pathlib.py [https://github.com/python/cpython/tree/3.11/Lib/pathlib.py]

This module offers classes representing filesystem paths with semantics appropriate for different operating systems. Path classes are divided between pure paths, which provide purely computational operations without I/O, and concrete paths, which inherit from pure paths but also provide I/O operations.

If you've never used this module before or just aren't sure which class is right for your task, `Path` is most likely what you need. It instantiates a concrete path for the platform the code is running on.

Pure paths are useful in some special cases; for example:

1. If you want to manipulate Windows paths on a Unix machine (or vice versa). You cannot instantiate a `WindowsPath`

when running on Unix, but you can instantiate **PureWindowsPath**.

2. You want to make sure that your code only manipulates paths without actually accessing the OS. In this case, instantiating one of the pure classes may be useful since those simply don't have any OS-accessing operations.

See also

PEP 428 [https://peps.python.org/pep-0428/]: The pathlib module – object-oriented filesystem paths.

See also

For low-level path manipulation on strings, you can also use the **os.path** module.

Basic use

Importing the main class:

```
>>> from pathlib import Path
```

Listing subdirectories:

```
>>> p = Path('.')
>>> [x for x in p.iterdir() if x.is_dir()]
[PosixPath('.hg'), PosixPath('docs'), PosixPath('dist'),
 PosixPath('__pycache__'), PosixPath('build')]
```

Listing Python source files in this directory tree:

```
>>> list(p.glob('**/*.py'))
[PosixPath('test_pathlib.py'), PosixPath('setup.py'),
 PosixPath('pathlib.py'), PosixPath('docs/conf.py'),
 PosixPath('build/lib/pathlib.py')]
```

Navigating inside a directory tree:

```
>>> p = Path('/etc')
>>> q = p / 'init.d' / 'reboot'
>>> q
PosixPath('/etc/init.d/reboot')
>>> q.resolve()
PosixPath('/etc/rc.d/init.d/halt')
```

Querying path properties:

```
>>> q.exists()
True
>>> q.is_dir()
False
```

Opening a file:

```
>>> with q.open() as f: f.readline()
...
'#!/bin/bash\n'
```

Pure paths

Pure path objects provide path-handling operations which don't actually access a filesystem. There are three ways to access these classes, which we also call *flavours*:

class pathlib.PurePath(**pathsegments*)

A generic class that represents the system's path flavour (instantiating it creates either a **PurePosixPath** or a **PureWindowsPath**):

```
>>> PurePath('setup.py')       # Running on a Unix m
PurePosixPath('setup.py')
```

Each element of *pathsegments* can be either a string representing a path segment, an object implementing the **os.PathLike** interface which returns a string, or another path object:

```
>>> PurePath('foo', 'some/path', 'bar')
```

```
PurePosixPath('foo/some/path/bar')
>>> PurePath(Path('foo'), Path('bar'))
PurePosixPath('foo/bar')
```

When *pathsegments* is empty, the current directory is assumed:

```
>>> PurePath()
PurePosixPath('.')
```

When several absolute paths are given, the last is taken as an anchor (mimicking **`os.path.join()`**'s behaviour):

```
>>> PurePath('/etc', '/usr', 'lib64')
PurePosixPath('/usr/lib64')
>>> PureWindowsPath('c:/Windows', 'd:bar')
PureWindowsPath('d:bar')
```

However, in a Windows path, changing the local root doesn't discard the previous drive setting:

```
>>> PureWindowsPath('c:/Windows', '/Program Files')
PureWindowsPath('c:/Program Files')
```

Spurious slashes and single dots are collapsed, but double dots (`'..'`) and leading double slashes (`'//'`) are not, since this would change the meaning of a path for various reasons (e.g. symbolic links, UNC paths):

```
>>> PurePath('foo//bar')
PurePosixPath('foo/bar')
>>> PurePath('//foo/bar')
PurePosixPath('//foo/bar')
>>> PurePath('foo/./bar')
PurePosixPath('foo/bar')
>>> PurePath('foo/../bar')
PurePosixPath('foo/../bar')
```

(a naïve approach would make `PurePosixPath('foo/../bar')` equivalent to `PurePosixPath('bar')`, which is wrong if `foo` is a symbolic link to another directory)

Pure path objects implement the **os.PathLike** interface, allowing them to be used anywhere the interface is accepted.

Changed in version 3.6: Added support for the **os.PathLike** interface.

class pathlib.PurePosixPath(**pathsegments*)

A subclass of **PurePath**, this path flavour represents non-Windows filesystem paths:

```
>>> PurePosixPath('/etc')
PurePosixPath('/etc')
```

pathsegments is specified similarly to **PurePath**.

class pathlib.PureWindowsPath(**pathsegments*)

A subclass of **PurePath**, this path flavour represents Windows filesystem paths, including UNC paths [https://en.wikipedia.org/wiki/Path_(computing)#UNC]:

```
>>> PureWindowsPath('c:/Program Files/')
PureWindowsPath('c:/Program Files')
>>> PureWindowsPath('//server/share/file')
PureWindowsPath('//server/share/file')
```

pathsegments is specified similarly to **PurePath**.

Regardless of the system you're running on, you can instantiate all of these classes, since they don't provide any operation that does system calls.

General properties

Paths are immutable and hashable. Paths of a same flavour are comparable and orderable. These properties respect the flavour's case-folding semantics:

```
>>> PurePosixPath('foo') == PurePosixPath('FOO')
False
```

```
>>> PureWindowsPath('foo') == PureWindowsPath('FOO')
True
>>> PureWindowsPath('FOO') in { PureWindowsPath('foo') }
True
>>> PureWindowsPath('C:') < PureWindowsPath('d:')
True
```

Paths of a different flavour compare unequal and cannot be ordered:

```
>>> PureWindowsPath('foo') == PurePosixPath('foo')
False
>>> PureWindowsPath('foo') < PurePosixPath('foo')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: '<' not supported between instances of 'PureW
```

Operators

The slash operator helps create child paths, similarly to **`os.path.join()`**:

```
>>> p = PurePath('/etc')
>>> p
PurePosixPath('/etc')
>>> p / 'init.d' / 'apache2'
PurePosixPath('/etc/init.d/apache2')
>>> q = PurePath('bin')
>>> '/usr' / q
PurePosixPath('/usr/bin')
```

A path object can be used anywhere an object implementing **`os.PathLike`** is accepted:

```
>>> import os
>>> p = PurePath('/etc')
>>> os.fspath(p)
'/etc'
```

The string representation of a path is the raw filesystem path itself

(in native form, e.g. with backslashes under Windows), which you can pass to any function taking a file path as a string:

```
>>> p = PurePath('/etc')
>>> str(p)
'/etc'
>>> p = PureWindowsPath('c:/Program Files')
>>> str(p)
'c:\\Program Files'
```

Similarly, calling **bytes** on a path gives the raw filesystem path as a bytes object, as encoded by **os.fsencode()**:

```
>>> bytes(p)
b'/etc'
```

Note

Calling **bytes** is only recommended under Unix. Under Windows, the unicode form is the canonical representation of filesystem paths.

Accessing individual parts

To access the individual “parts” (components) of a path, use the following property:

PurePath.parts

A tuple giving access to the path’s various components:

```
>>> p = PurePath('/usr/bin/python3')
>>> p.parts
('/', 'usr', 'bin', 'python3')

>>> p = PureWindowsPath('c:/Program Files/PSF')
>>> p.parts
('c:\\', 'Program Files', 'PSF')
```

(note how the drive and local root are regrouped in a single

part)

Methods and properties

Pure paths provide the following methods and properties:

PurePath.drive

A string representing the drive letter or name, if any:

```
>>> PureWindowsPath('c:/Program Files/').drive
'c:'
>>> PureWindowsPath('/Program Files/').drive
''
>>> PurePosixPath('/etc').drive
''
```

UNC shares are also considered drives:

```
>>> PureWindowsPath('//host/share/foo.txt').drive
'\\\\host\\share'
```

PurePath.root

A string representing the (local or global) root, if any:

```
>>> PureWindowsPath('c:/Program Files/').root
'\\'
>>> PureWindowsPath('c:Program Files/').root
''
>>> PurePosixPath('/etc').root
'/'
```

UNC shares always have a root:

```
>>> PureWindowsPath('//host/share').root
'\\'
```

If the path starts with more than two successive slashes, **PurePosixPath** collapses them:

```
>>> PurePosixPath('//etc').root
```

```
'//'
>>> PurePosixPath('///etc').root
'/'
>>> PurePosixPath('////etc').root
'/'
```

Note

This behavior conforms to *The Open Group Base Specifications Issue 6*, paragraph 4.11 Pathname Resolution [https://pubs.opengroup.org/onlinepubs/009695399/basedefs/xbd_chap04.html#tag_04_11]:

"A pathname that begins with two successive slashes may be interpreted in an implementation-defined manner, although more than two leading slashes shall be treated as a single slash."

PurePath.anchor

The concatenation of the drive and root:

```
>>> PureWindowsPath('c:/Program Files/').anchor
'c:\\'
>>> PureWindowsPath('c:Program Files/').anchor
'c:'
>>> PurePosixPath('/etc').anchor
'/'
>>> PureWindowsPath('//host/share').anchor
'\\\\host\\share\\'
```

PurePath.parents

An immutable sequence providing access to the logical ancestors of the path:

```
>>> p = PureWindowsPath('c:/foo/bar/setup.py')
>>> p.parents[0]
PureWindowsPath('c:/foo/bar')
>>> p.parents[1]
```

```
PureWindowsPath('c:/foo')
>>> p.parents[2]
PureWindowsPath('c:/')
```

Changed in version 3.10: The parents sequence now supports slices and negative index values.

PurePath.parent

The logical parent of the path:

```
>>> p = PurePosixPath('/a/b/c/d')
>>> p.parent
PurePosixPath('/a/b/c')
```

You cannot go past an anchor, or empty path:

```
>>> p = PurePosixPath('/')
>>> p.parent
PurePosixPath('/')
>>> p = PurePosixPath('.')
>>> p.parent
PurePosixPath('.')
```

Note

This is a purely lexical operation, hence the following behaviour:

```
>>> p = PurePosixPath('foo/..')
>>> p.parent
PurePosixPath('foo')
```

If you want to walk an arbitrary filesystem path upwards, it is recommended to first call `Path.resolve()` so as to resolve symlinks and eliminate `".."` components.

PurePath.name

A string representing the final path component, excluding the

drive and root, if any:

```
>>> PurePosixPath('my/library/setup.py').name
'setup.py'
```

UNC drive names are not considered:

```
>>> PureWindowsPath('//some/share/setup.py').name
'setup.py'
>>> PureWindowsPath('//some/share').name
''
```

PurePath.suffix

The file extension of the final component, if any:

```
>>> PurePosixPath('my/library/setup.py').suffix
'.py'
>>> PurePosixPath('my/library.tar.gz').suffix
'.gz'
>>> PurePosixPath('my/library').suffix
''
```

PurePath.suffixes

A list of the path's file extensions:

```
>>> PurePosixPath('my/library.tar.gar').suffixes
['.tar', '.gar']
>>> PurePosixPath('my/library.tar.gz').suffixes
['.tar', '.gz']
>>> PurePosixPath('my/library').suffixes
[]
```

PurePath.stem

The final path component, without its suffix:

```
>>> PurePosixPath('my/library.tar.gz').stem
'library.tar'
>>> PurePosixPath('my/library.tar').stem
'library'
```

```
>>> PurePosixPath('my/library').stem
'library'
```

PurePath.as_posix()

Return a string representation of the path with forward slashes (`/`):

```
>>> p = PureWindowsPath('c:\\windows')
>>> str(p)
'c:\\windows'
>>> p.as_posix()
'c:/windows'
```

PurePath.as_uri()

Represent the path as a `file` URI. **`ValueError`** is raised if the path isn't absolute.

```
>>> p = PurePosixPath('/etc/passwd')
>>> p.as_uri()
'file:///etc/passwd'
>>> p = PureWindowsPath('c:/Windows')
>>> p.as_uri()
'file:///c:/Windows'
```

PurePath.is_absolute()

Return whether the path is absolute or not. A path is considered absolute if it has both a root and (if the flavour allows) a drive:

```
>>> PurePosixPath('/a/b').is_absolute()
True
>>> PurePosixPath('a/b').is_absolute()
False

>>> PureWindowsPath('c:/a/b').is_absolute()
True
>>> PureWindowsPath('/a/b').is_absolute()
False
```

```
>>> PureWindowsPath('c:').is_absolute()
False
>>> PureWindowsPath('//some/share').is_absolute()
True
```

PurePath.is_relative_to(**other*)

Return whether or not this path is relative to the *other* path.

```
>>> p = PurePath('/etc/passwd')
>>> p.is_relative_to('/etc')
True
>>> p.is_relative_to('/usr')
False
```

New in version 3.9.

PurePath.is_reserved()

With **PureWindowsPath**, return `True` if the path is considered reserved under Windows, `False` otherwise. With **PurePosixPath**, `False` is always returned.

```
>>> PureWindowsPath('nul').is_reserved()
True
>>> PurePosixPath('nul').is_reserved()
False
```

File system calls on reserved paths can fail mysteriously or have unintended effects.

PurePath.joinpath(**other*)

Calling this method is equivalent to combining the path with each of the *other* arguments in turn:

```
>>> PurePosixPath('/etc').joinpath('passwd')
PurePosixPath('/etc/passwd')
>>> PurePosixPath('/etc').joinpath(PurePosixPath('p
PurePosixPath('/etc/passwd')
>>> PurePosixPath('/etc').joinpath('init.d', 'apach
```

```
PurePosixPath('/etc/init.d/apache2')
>>> PureWindowsPath('c:').joinpath('/Program Files'
PureWindowsPath('c:/Program Files')
```

PurePath.match(*pattern*)

Match this path against the provided glob-style pattern. Return `True` if matching is successful, `False` otherwise.

If *pattern* is relative, the path can be either relative or absolute, and matching is done from the right:

```
>>> PurePath('a/b.py').match('*.py')
True
>>> PurePath('/a/b/c.py').match('b/*.py')
True
>>> PurePath('/a/b/c.py').match('a/*.py')
False
```

If *pattern* is absolute, the path must be absolute, and the whole path must match:

```
>>> PurePath('/a.py').match('/*.py')
True
>>> PurePath('a/b.py').match('/*.py')
False
```

As with other methods, case-sensitivity follows platform defaults:

```
>>> PurePosixPath('b.py').match('*.PY')
False
>>> PureWindowsPath('b.py').match('*.PY')
True
```

PurePath.relative_to(**other*)

Compute a version of this path relative to the path represented by *other*. If it's impossible, ValueError is raised:

```
>>> p = PurePosixPath('/etc/passwd')
```

```
>>> p.relative_to('/')
PurePosixPath('etc/passwd')
>>> p.relative_to('/etc')
PurePosixPath('passwd')
>>> p.relative_to('/usr')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "pathlib.py", line 694, in relative_to
    .format(str(self), str(formatted)))
ValueError: '/etc/passwd' is not in the subpath of
```

NOTE: This function is part of **PurePath** and works with strings. It does not check or access the underlying file structure.

PurePath.with_name(*name*)

Return a new path with the **name** changed. If the original path doesn't have a name, ValueError is raised:

```
>>> p = PureWindowsPath('c:/Downloads/pathlib.tar.g
>>> p.with_name('setup.py')
PureWindowsPath('c:/Downloads/setup.py')
>>> p = PureWindowsPath('c:/')
>>> p.with_name('setup.py')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/home/antoine/cpython/default/Lib/pathlib.p
    raise ValueError("%r has an empty name" % (self
ValueError: PureWindowsPath('c:/') has an empty nam
```

PurePath.with_stem(*stem*)

Return a new path with the **stem** changed. If the original path doesn't have a name, ValueError is raised:

```
>>> p = PureWindowsPath('c:/Downloads/draft.txt')
>>> p.with_stem('final')
PureWindowsPath('c:/Downloads/final.txt')
>>> p = PureWindowsPath('c:/Downloads/pathlib.tar.g
```

```
>>> p.with_stem('lib')
PureWindowsPath('c:/Downloads/lib.gz')
>>> p = PureWindowsPath('c:/')
>>> p.with_stem('')
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "/home/antoine/cpython/default/Lib/pathlib.p
    return self.with_name(stem + self.suffix)
  File "/home/antoine/cpython/default/Lib/pathlib.p
    raise ValueError("%r has an empty name" % (self
ValueError: PureWindowsPath('c:/') has an empty nam
```

New in version 3.9.

PurePath.with_suffix(*suffix*)

Return a new path with the **suffix** changed. If the original path doesn't have a suffix, the new *suffix* is appended instead. If the *suffix* is an empty string, the original suffix is removed:

```
>>> p = PureWindowsPath('c:/Downloads/pathlib.tar.g
>>> p.with_suffix('.bz2')
PureWindowsPath('c:/Downloads/pathlib.tar.bz2')
>>> p = PureWindowsPath('README')
>>> p.with_suffix('.txt')
PureWindowsPath('README.txt')
>>> p = PureWindowsPath('README.txt')
>>> p.with_suffix('')
PureWindowsPath('README')
```

Concrete paths

Concrete paths are subclasses of the pure path classes. In addition to operations provided by the latter, they also provide methods to do system calls on path objects. There are three ways to instantiate concrete paths:

class pathlib.Path(**pathsegments*)

A subclass of **PurePath**, this class represents concrete paths

of the system's path flavour (instantiating it creates either a **PosixPath** or a **WindowsPath**):

```
>>> Path('setup.py')
PosixPath('setup.py')
```

pathsegments is specified similarly to **PurePath**.

class pathlib.PosixPath(**pathsegments*)

A subclass of **Path** and **PurePosixPath**, this class represents concrete non-Windows filesystem paths:

```
>>> PosixPath('/etc')
PosixPath('/etc')
```

pathsegments is specified similarly to **PurePath**.

class pathlib.WindowsPath(**pathsegments*)

A subclass of **Path** and **PureWindowsPath**, this class represents concrete Windows filesystem paths:

```
>>> WindowsPath('c:/Program Files/')
WindowsPath('c:/Program Files')
```

pathsegments is specified similarly to **PurePath**.

You can only instantiate the class flavour that corresponds to your system (allowing system calls on non-compatible path flavours could lead to bugs or failures in your application):

```
>>> import os
>>> os.name
'posix'
>>> Path('setup.py')
PosixPath('setup.py')
>>> PosixPath('setup.py')
PosixPath('setup.py')
>>> WindowsPath('setup.py')
Traceback (most recent call last):
```

```
  File "<stdin>", line 1, in <module>
  File "pathlib.py", line 798, in __new__
    % (cls.__name__,))
NotImplementedError: cannot instantiate 'WindowsPath' or
```

Methods

Concrete paths provide the following methods in addition to pure paths methods. Many of these methods can raise an **OSError** if a system call fails (for example because the path doesn't exist).

Changed in version 3.8: **exists()**, **is_dir()**, **is_file()**, **is_mount()**, **is_symlink()**, **is_block_device()**, **is_char_device()**, **is_fifo()**, **is_socket()** now return `False` instead of raising an exception for paths that contain characters unrepresentable at the OS level.

classmethod Path.cwd()

Return a new path object representing the current directory (as returned by **os.getcwd()**):

```
>>> Path.cwd()
PosixPath('/home/antoine/pathlib')
```

classmethod Path.home()

Return a new path object representing the user's home directory (as returned by **os.path.expanduser()** with `~` construct). If the home directory can't be resolved, **RuntimeError** is raised.

```
>>> Path.home()
PosixPath('/home/antoine')
```

New in version 3.5.

Path.stat(*, *follow_symlinks* = *True*)

Return a **os.stat_result** object containing information about this path, like **os.stat()**. The result is looked up at each call to this method.

This method normally follows symlinks; to stat a symlink add the argument `follow_symlinks=False`, or use **`lstat()`**.

```
>>> p = Path('setup.py')
>>> p.stat().st_size
956
>>> p.stat().st_mtime
1327883547.852554
```

Changed in version 3.10: The *follow_symlinks* parameter was added.

Path.chmod(*mode*, *, *follow_symlinks=True*)

Change the file mode and permissions, like **`os.chmod()`**.

This method normally follows symlinks. Some Unix flavours support changing permissions on the symlink itself; on these platforms you may add the argument `follow_symlinks=False`, or use **`lchmod()`**.

```
>>> p = Path('setup.py')
>>> p.stat().st_mode
33277
>>> p.chmod(0o444)
>>> p.stat().st_mode
33060
```

Changed in version 3.10: The *follow_symlinks* parameter was added.

Path.exists()

Whether the path points to an existing file or directory:

```
>>> Path('.').exists()
True
>>> Path('setup.py').exists()
True
>>> Path('/etc').exists()
True
```

```
>>> Path('nonexistentfile').exists()
False
```

Note

If the path points to a symlink, **`exists()`** returns whether the symlink *points to* an existing file or directory.

Path.expanduser()

Return a new path with expanded `~` and `~user` constructs, as returned by **`os.path.expanduser()`**. If a home directory can't be resolved, **`RuntimeError`** is raised.

```
>>> p = PosixPath('~/films/Monty Python')
>>> p.expanduser()
PosixPath('/home/eric/films/Monty Python')
```

New in version 3.5.

Path.glob(*pattern*)

Glob the given relative *pattern* in the directory represented by this path, yielding all matching files (of any kind):

```
>>> sorted(Path('.').glob('*.py'))
[PosixPath('pathlib.py'), PosixPath('setup.py'), Po
>>> sorted(Path('.').glob('*/*.py'))
[PosixPath('docs/conf.py')]
```

Patterns are the same as for **`fnmatch`**, with the addition of "`**`" which means "this directory and all subdirectories, recursively". In other words, it enables recursive globbing:

```
>>> sorted(Path('.').glob('**/*.py'))
[PosixPath('build/lib/pathlib.py'),
 PosixPath('docs/conf.py'),
 PosixPath('pathlib.py'),
 PosixPath('setup.py'),
 PosixPath('test_pathlib.py')]
```

Note

Using the "`**`" pattern in large directory trees may consume an inordinate amount of time.

Raises an auditing event `pathlib.Path.glob` with arguments `self, pattern`.

Changed in version 3.11: Return only directories if *pattern* ends with a pathname components separator (**`sep`** or **`altsep`**).

Path.group()

Return the name of the group owning the file. **`KeyError`** is raised if the file's gid isn't found in the system database.

Path.is_dir()

Return `True` if the path points to a directory (or a symbolic link pointing to a directory), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.is_file()

Return `True` if the path points to a regular file (or a symbolic link pointing to a regular file), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.is_mount()

Return `True` if the path is a *mount point*: a point in a file system where a different file system has been mounted. On POSIX, the function checks whether *path*'s parent, `path/..`, is on a different device than *path*, or whether `path/..` and

path point to the same i-node on the same device — this should detect mount points for all Unix and POSIX variants. Not implemented on Windows.

New in version 3.7.

Path.is_symlink()

Return `True` if the path points to a symbolic link, `False` otherwise.

`False` is also returned if the path doesn't exist; other errors (such as permission errors) are propagated.

Path.is_socket()

Return `True` if the path points to a Unix socket (or a symbolic link pointing to a Unix socket), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.is_fifo()

Return `True` if the path points to a FIFO (or a symbolic link pointing to a FIFO), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.is_block_device()

Return `True` if the path points to a block device (or a symbolic link pointing to a block device), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.is_char_device()

Return `True` if the path points to a character device (or a symbolic link pointing to a character device), `False` if it points to another kind of file.

`False` is also returned if the path doesn't exist or is a broken symlink; other errors (such as permission errors) are propagated.

Path.iterdir()

When the path points to a directory, yield path objects of the directory contents:

```
>>> p = Path('docs')
>>> for child in p.iterdir(): child
...
PosixPath('docs/conf.py')
PosixPath('docs/_templates')
PosixPath('docs/make.bat')
PosixPath('docs/index.rst')
PosixPath('docs/_build')
PosixPath('docs/_static')
PosixPath('docs/Makefile')
```

The children are yielded in arbitrary order, and the special entries `'.'` and `'..'` are not included. If a file is removed from or added to the directory after creating the iterator, whether a path object for that file be included is unspecified.

Path.lchmod(*mode*)

Like **`Path.chmod()`** but, if the path points to a symbolic link, the symbolic link's mode is changed rather than its target's.

Path.lstat()

Like **`Path.stat()`** but, if the path points to a symbolic link, return the symbolic link's information rather than its target's.

Path.mkdir(*mode=0o777*, *parents=False*, *exist_ok=False*)

Create a new directory at this given path. If *mode* is given, it is combined with the process' `umask` value to determine the file mode and access flags. If the path already exists, **`FileExistsError`** is raised.

If *parents* is true, any missing parents of this path are created as needed; they are created with the default permissions without taking *mode* into account (mimicking the POSIX `mkdir -p` command).

If *parents* is false (the default), a missing parent raises **`FileNotFoundError`**.

If *exist_ok* is false (the default), **`FileExistsError`** is raised if the target directory already exists.

If *exist_ok* is true, **`FileExistsError`** exceptions will be ignored (same behavior as the POSIX `mkdir -p` command), but only if the last path component is not an existing non-directory file.

Changed in version 3.5: The *exist_ok* parameter was added.

Path.open(*mode='r'*, *buffering=-1*, *encoding=None*, *errors=None*, *newline=None*)

Open the file pointed to by the path, like the built-in **`open()`** function does:

```
>>> p = Path('setup.py')
>>> with p.open() as f:
...     f.readline()
...
'#!/usr/bin/env python3\n'
```

Path.owner()

Return the name of the user owning the file. **`KeyError`** is raised if the file's uid isn't found in the system database.

Path.read_bytes()

Return the binary contents of the pointed-to file as a bytes object:

```
>>> p = Path('my_binary_file')
>>> p.write_bytes(b'Binary file contents')
20
>>> p.read_bytes()
b'Binary file contents'
```

New in version 3.5.

Path.read_text(*encoding=None*, *errors=None*)

Return the decoded contents of the pointed-to file as a string:

```
>>> p = Path('my_text_file')
>>> p.write_text('Text file contents')
18
>>> p.read_text()
'Text file contents'
```

The file is opened and then closed. The optional parameters have the same meaning as in **open()**.

New in version 3.5.

Path.readlink()

Return the path to which the symbolic link points (as returned by **os.readlink()**):

```
>>> p = Path('mylink')
>>> p.symlink_to('setup.py')
>>> p.readlink()
PosixPath('setup.py')
```

New in version 3.9.

Path.rename(*target*)

Rename this file or directory to the given *target*, and return a new Path instance pointing to *target*. On Unix, if *target* exists and is a file, it will be replaced silently if the user has permission. On Windows, if *target* exists, **FileExistsError** will be raised. *target* can be either a string or another path object:

```
>>> p = Path('foo')
>>> p.open('w').write('some text')
9
>>> target = Path('bar')
>>> p.rename(target)
PosixPath('bar')
>>> target.open().read()
'some text'
```

The target path may be absolute or relative. Relative paths are interpreted relative to the current working directory, *not* the directory of the Path object.

Changed in version 3.8: Added return value, return the new Path instance.

Path.replace(*target*)

Rename this file or directory to the given *target*, and return a new Path instance pointing to *target*. If *target* points to an existing file or empty directory, it will be unconditionally replaced.

The target path may be absolute or relative. Relative paths are interpreted relative to the current working directory, *not* the directory of the Path object.

Changed in version 3.8: Added return value, return the new Path instance.

Path.absolute()

Make the path absolute, without normalization or resolving symlinks. Returns a new path object:

```
>>> p = Path('tests')
>>> p
PosixPath('tests')
>>> p.absolute()
PosixPath('/home/antoine/pathlib/tests')
```

Path.resolve(*strict=False*)

Make the path absolute, resolving any symlinks. A new path object is returned:

```
>>> p = Path()
>>> p
PosixPath('.')
>>> p.resolve()
PosixPath('/home/antoine/pathlib')
```

"`..`" components are also eliminated (this is the only method to do so):

```
>>> p = Path('docs/../setup.py')
>>> p.resolve()
PosixPath('/home/antoine/pathlib/setup.py')
```

If the path doesn't exist and *strict* is `True`, **`FileNotFoundError`** is raised. If *strict* is `False`, the path is resolved as far as possible and any remainder is appended without checking whether it exists. If an infinite loop is encountered along the resolution path, **`RuntimeError`** is raised.

New in version 3.6: The *strict* argument (pre-3.6 behavior is strict).

Path.rglob(*pattern*)

This is like calling **`Path.glob()`** with "`**/`" added in front of the given relative *pattern*:

```
>>> sorted(Path().rglob("*.py"))
[PosixPath('build/lib/pathlib.py'),
```

```
 PosixPath('docs/conf.py'),
 PosixPath('pathlib.py'),
 PosixPath('setup.py'),
 PosixPath('test_pathlib.py')]
```

Raises an auditing event `pathlib.Path.rglob` with arguments `self`, `pattern`.

Changed in version 3.11: Return only directories if *pattern* ends with a pathname components separator (**`sep`** or **`altsep`**).

Path.rmdir()

Remove this directory. The directory must be empty.

Path.samefile(*other_path*)

Return whether this path points to the same file as *other_path*, which can be either a Path object, or a string. The semantics are similar to **`os.path.samefile()`** and **`os.path.samestat()`**.

An **`OSError`** can be raised if either file cannot be accessed for some reason.

```
>>> p = Path('spam')
>>> q = Path('eggs')
>>> p.samefile(q)
False
>>> p.samefile('spam')
True
```

New in version 3.5.

Path.symlink_to(*target*, *target_is_directory*=*False*)

Make this path a symbolic link to *target*. Under Windows, *target_is_directory* must be true (default `False`) if the link's target is a directory. Under POSIX, *target_is_directory*'s value is ignored.

```
>>> p = Path('mylink')
```

```
>>> p.symlink_to('setup.py')
>>> p.resolve()
PosixPath('/home/antoine/pathlib/setup.py')
>>> p.stat().st_size
956
>>> p.lstat().st_size
8
```

Note

The order of arguments (link, target) is the reverse of **`os.symlink()`**'s.

Path.hardlink_to(*target*)

Make this path a hard link to the same file as *target*.

Note

The order of arguments (link, target) is the reverse of **`os.link()`**'s.

New in version 3.10.

Path.link_to(*target*)

Make *target* a hard link to this path.

Warning

This function does not make this path a hard link to *target*, despite the implication of the function and argument names. The argument order (target, link) is the reverse of **`Path.symlink_to()`** and **`Path.hardlink_to()`**, but matches that of **`os.link()`**.

New in version 3.8.

Deprecated since version 3.10: This method is deprecated in

favor of **`Path.hardlink_to()`**, as the argument order of **`Path.link_to()`** does not match that of **`Path.symlink_to()`**.

Path.touch(*mode=0o666*, *exist_ok=True*)

Create a file at this given path. If *mode* is given, it is combined with the process' `umask` value to determine the file mode and access flags. If the file already exists, the function succeeds if *exist_ok* is true (and its modification time is updated to the current time), otherwise **`FileExistsError`** is raised.

Path.unlink(*missing_ok=False*)

Remove this file or symbolic link. If the path points to a directory, use **`Path.rmdir()`** instead.

If *missing_ok* is false (the default), **`FileNotFoundError`** is raised if the path does not exist.

If *missing_ok* is true, **`FileNotFoundError`** exceptions will be ignored (same behavior as the POSIX `rm -f` command).

Changed in version 3.8: The *missing_ok* parameter was added.

Path.write_bytes(*data*)

Open the file pointed to in bytes mode, write *data* to it, and close the file:

```
>>> p = Path('my_binary_file')
>>> p.write_bytes(b'Binary file contents')
20
>>> p.read_bytes()
b'Binary file contents'
```

An existing file of the same name is overwritten.

New in version 3.5.

Path.write_text(*data*, *encoding=None*, *errors=None*, *newline=None*)

Open the file pointed to in text mode, write *data* to it, and close the file:

```
>>> p = Path('my_text_file')
>>> p.write_text('Text file contents')
18
>>> p.read_text()
'Text file contents'
```

An existing file of the same name is overwritten. The optional parameters have the same meaning as in `open()`.

New in version 3.5.

Changed in version 3.10: The *newline* parameter was added.

Correspondence to tools in the `os` module

Below is a table mapping various `os` functions to their corresponding `PurePath`/`Path` equivalent.

Note

Not all pairs of functions/methods below are equivalent. Some of them, despite having some overlapping use-cases, have different semantics. They include `os.path.abspath()` and `Path.absolute()`, `os.path.relpath()` and `PurePath.relative_to()`.

os and os.path	pathlib
`os.path.abspath()`	`Path.absolute()`
`os.path.realpath()`	`Path.resolve()`
`os.chmod()`	`Path.chmod()`
`os.mkdir()`	`Path.mkdir()`
`os.makedirs()`	`Path.mkdir()`
`os.rename()`	`Path.rename()`
`os.replace()`	`Path.replace()`
`os.rmdir()`	`Path.rmdir()`

`Path.remove()`, `Path.unlink()`	`os.unlink()`
`Path.getcwd()`	`os.getcwd()`
`Path.exists()`	`os.path.exists()`
`Path.expanduser()` and `Path.home()`	`os.path.expanduser()`
`Path.is_dir()`	`os.path.isdir()`
`Path.is_file()`	`os.path.isfile()`
`Path.is_symlink()`	`os.path.islink()`
`Path.link_to()`	`os.symlink()`
`Path.symlink_to()`	`os.readlink()`
`Path.readlink()`	`os.path.relpath()` [2]
`Path.relpath()`	`os.stat()`, `Path.owner()`, `Path.group()`
`Path.is_absolute()`	`os.path.abspath()` [1]
`Path.absolute()`	`os.path.join()`
`Path.resolve()`	`os.path.basename()`
`Path.joinpath()`	`os.path.dirname()`
`Path.basename()`	`os.path.splitext()`
`Path.dirname()`	`PurePath.suffix`
`Path.splitext()` and `PurePath.suffix`	

Footnotes

1

`os.path.abspath()` normalizes the resulting path, which may change its meaning in the presence of symlinks, while `Path.absolute()` does not.

2

`PurePath.relative_to()` requires `self` to be the subpath of the argument, but `os.path.relpath()` does not.

`os.path` — Common pathname manipulations

Source code: Lib/posixpath.py [https://github.com/python/cpython/tree/3.11/Lib/posixpath.py] (for POSIX) and Lib/ntpath.py [https://github.com/python/cpython/tree/3.11/Lib/ntpath.py] (for Windows).

This module implements some useful functions on pathnames. To read or write files see `open()`, and for accessing the filesystem see the `os` module. The path parameters can be passed as strings, or bytes, or any object implementing the `os.PathLike` protocol.

Unlike a Unix shell, Python does not do any *automatic* path expansions. Functions such as `expanduser()` and `expandvars()` can be invoked explicitly when an application desires shell-like path expansion. (See also the `glob` module.)

See also

The `pathlib` module offers high-level path objects.

Note

All of these functions accept either only bytes or only string objects as their parameters. The result is an object of the same type, if a path or file name is returned.

Note

Since different operating systems have different path name conventions, there are several versions of this module in the standard library. The `os.path` module is always the path module suitable for the operating system Python is running on,

and therefore usable for local paths. However, you can also import and use the individual modules if you want to manipulate a path that is *always* in one of the different formats. They all have the same interface:

- **posixpath** for UNIX-style paths
- **ntpath** for Windows paths

Changed in version 3.8: **exists()**, **lexists()**, **isdir()**, **isfile()**, **islink()**, and **ismount()** now return `False` instead of raising an exception for paths that contain characters or bytes unrepresentable at the OS level.

os.path.abspath(*path*)

Return a normalized absolutized version of the pathname *path*. On most platforms, this is equivalent to calling the function **normpath()** as follows: `normpath(join(os.getcwd(), path))`.

Changed in version 3.6: Accepts a path-like object.

os.path.basename(*path*)

Return the base name of pathname *path*. This is the second element of the pair returned by passing *path* to the function **split()**. Note that the result of this function is different from the Unix **basename** program; where **basename** for `'/foo/bar/'` returns `'bar'`, the **basename()** function returns an empty string (`''`).

Changed in version 3.6: Accepts a path-like object.

os.path.commonpath(*paths*)

Return the longest common sub-path of each pathname in the sequence *paths*. Raise **ValueError** if *paths* contain both absolute and relative pathnames, the *paths* are on the different drives or if *paths* is empty. Unlike **commonprefix()**, this returns a valid path.

Availability: Unix, Windows.

New in version 3.5.

Changed in version 3.6: Accepts a sequence of path-like objects.

os.path.commonprefix(*list*)

Return the longest path prefix (taken character-by-character) that is a prefix of all paths in *list*. If *list* is empty, return the empty string (`''`).

Note

This function may return invalid paths because it works a character at a time. To obtain a valid path, see **`commonpath()`**.

```
>>> os.path.commonprefix(['/usr/lib', '/usr/local/
'/usr/l'

>>> os.path.commonpath(['/usr/lib', '/usr/local/li
'/usr'
```

Changed in version 3.6: Accepts a path-like object.

os.path.dirname(*path*)

Return the directory name of pathname *path*. This is the first element of the pair returned by passing *path* to the function **`split()`**.

Changed in version 3.6: Accepts a path-like object.

os.path.exists(*path*)

Return `True` if *path* refers to an existing path or an open file descriptor. Returns `False` for broken symbolic links. On some platforms, this function may return `False` if permission is not granted to execute **`os.stat()`** on the requested file, even if the *path* physically exists.

Changed in version 3.3: path can now be an integer: `True` is

returned if it is an open file descriptor, `False` otherwise.

Changed in version 3.6: Accepts a path-like object.

os.path.lexists(*path*)

Return `True` if *path* refers to an existing path. Returns `True` for broken symbolic links. Equivalent to **`exists()`** on platforms lacking **`os.lstat()`**.

Changed in version 3.6: Accepts a path-like object.

os.path.expanduser(*path*)

On Unix and Windows, return the argument with an initial component of `~` or `~user` replaced by that *user*'s home directory.

On Unix, an initial `~` is replaced by the environment variable **`HOME`** if it is set; otherwise the current user's home directory is looked up in the password directory through the built-in module **`pwd`**. An initial `~user` is looked up directly in the password directory.

On Windows, **`USERPROFILE`** will be used if set, otherwise a combination of **`HOMEPATH`** and **`HOMEDRIVE`** will be used. An initial `~user` is handled by checking that the last directory component of the current user's home directory matches **`USERNAME`**, and replacing it if so.

If the expansion fails or if the path does not begin with a tilde, the path is returned unchanged.

Changed in version 3.6: Accepts a path-like object.

Changed in version 3.8: No longer uses **`HOME`** on Windows.

os.path.expandvars(*path*)

Return the argument with environment variables expanded. Substrings of the form `$name` or `${name}` are replaced by the value of environment variable *name*. Malformed variable

names and references to non-existing variables are left unchanged.

On Windows, `%name%` expansions are supported in addition to `$name` and `${name}`.

Changed in version 3.6: Accepts a path-like object.

os.path.getatime(*path*)

Return the time of last access of *path*. The return value is a floating point number giving the number of seconds since the epoch (see the **`time`** module). Raise **`OSError`** if the file does not exist or is inaccessible.

os.path.getmtime(*path*)

Return the time of last modification of *path*. The return value is a floating point number giving the number of seconds since the epoch (see the **`time`** module). Raise **`OSError`** if the file does not exist or is inaccessible.

Changed in version 3.6: Accepts a path-like object.

os.path.getctime(*path*)

Return the system's ctime which, on some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time for *path*. The return value is a number giving the number of seconds since the epoch (see the **`time`** module). Raise **`OSError`** if the file does not exist or is inaccessible.

Changed in version 3.6: Accepts a path-like object.

os.path.getsize(*path*)

Return the size, in bytes, of *path*. Raise **`OSError`** if the file does not exist or is inaccessible.

Changed in version 3.6: Accepts a path-like object.

os.path.isabs(*path*)

Return `True` if *path* is an absolute pathname. On Unix, that means it begins with a slash, on Windows that it begins with a (back)slash after chopping off a potential drive letter.

Changed in version 3.6: Accepts a path-like object.

os.path.isfile(*path*)

Return `True` if *path* is an **`existing`** regular file. This follows symbolic links, so both **`islink()`** and **`isfile()`** can be true for the same path.

Changed in version 3.6: Accepts a path-like object.

os.path.isdir(*path*)

Return `True` if *path* is an **`existing`** directory. This follows symbolic links, so both **`islink()`** and **`isdir()`** can be true for the same path.

Changed in version 3.6: Accepts a path-like object.

os.path.islink(*path*)

Return `True` if *path* refers to an **`existing`** directory entry that is a symbolic link. Always `False` if symbolic links are not supported by the Python runtime.

Changed in version 3.6: Accepts a path-like object.

os.path.ismount(*path*)

Return `True` if pathname *path* is a *mount point*: a point in a file system where a different file system has been mounted. On POSIX, the function checks whether *path*'s parent, *`path`*`/..`, is on a different device than *path*, or whether *`path`*`/..` and *path* point to the same i-node on the same device — this should detect mount points for all Unix and POSIX variants. It is not able to reliably detect bind mounts on the same filesystem. On Windows, a drive letter root and a share UNC are always mount points, and for any other path

`GetVolumePathName` is called to see if it is different from the input path.

New in version 3.4: Support for detecting non-root mount points on Windows.

Changed in version 3.6: Accepts a path-like object.

os.path.join(*path*, **paths*)

Join one or more path components intelligently. The return value is the concatenation of *path* and any members of **paths* with exactly one directory separator following each non-empty part except the last, meaning that the result will only end in a separator if the last part is empty. If a component is an absolute path, all previous components are thrown away and joining continues from the absolute path component.

On Windows, the drive letter is not reset when an absolute path component (e.g., `r'\foo'`) is encountered. If a component contains a drive letter, all previous components are thrown away and the drive letter is reset. Note that since there is a current directory for each drive, `os.path.join("c:", "foo")` represents a path relative to the current directory on drive `C:` (`c:foo`), not `c:\foo`.

Changed in version 3.6: Accepts a path-like object for *path* and *paths*.

os.path.normcase(*path*)

Normalize the case of a pathname. On Windows, convert all characters in the pathname to lowercase, and also convert forward slashes to backward slashes. On other operating systems, return the path unchanged.

Changed in version 3.6: Accepts a path-like object.

os.path.normpath(*path*)

Normalize a pathname by collapsing

redundant separators and up-level references so that `A//B`, `A/B/`, `A/./B` and `A/foo/../B` all become `A/B`. This string manipulation may change the meaning of a path that contains symbolic links. On Windows, it converts forward slashes to backward slashes. To normalize case, use **`normcase()`**.

Note

On POSIX systems, in accordance with IEEE Std 1003.1 2013 Edition; 4.13 Pathname Resolution [https://pubs.opengroup.org/onlinepubs/9699919799/basedefs/V1_chap04.html#tag_04_13], if a pathname begins with exactly two slashes, the first component following the leading characters may be interpreted in an implementation-defined manner, although more than two leading characters shall be treated as a single character.

Changed in version 3.6: Accepts a path-like object.

os.path.realpath(*path*, *, *strict*=*False*)

Return the canonical path of the specified filename, eliminating any symbolic links encountered in the path (if they are supported by the operating system).

If a path doesn't exist or a symlink loop is encountered, and *strict* is `True`, **`OSError`** is raised. If *strict* is `False`, the path is resolved as far as possible and any remainder is appended without checking whether it exists.

Note

This function emulates the operating system's procedure for making a path canonical, which differs slightly

between Windows and UNIX with respect to how links and subsequent path components interact.

Operating system APIs make paths canonical as needed, so it's not normally necessary to call this function.

Changed in version 3.6: Accepts a path-like object.

Changed in version 3.8: Symbolic links and junctions are now resolved on Windows.

Changed in version 3.10: The *strict* parameter was added.

os.path.relpath(*path*, *start=os.curdir*)

Return a relative filepath to *path* either from the current directory or from an optional *start* directory. This is a path computation: the filesystem is not accessed to confirm the existence or nature of *path* or *start*. On Windows, **`ValueError`** is raised when *path* and *start* are on different drives.

start defaults to **`os.curdir`**.

Availability: Unix, Windows.

Changed in version 3.6: Accepts a path-like object.

os.path.samefile(*path1*, *path2*)

Return `True` if both pathname arguments refer to the same file or directory. This is determined by the device number and i-node number and raises an exception if an **`os.stat()`** call on either pathname fails.

Availability: Unix, Windows.

Changed in version 3.2: Added Windows support.

Changed in version 3.4: Windows now uses the same implementation as all other platforms.

Changed in version 3.6: Accepts a path-like object.

os.path.sameopenfile(*fp1*, *fp2*)

Return `True` if the file descriptors *fp1* and *fp2* refer to the same file.

Availability: Unix, Windows.

Changed in version 3.2: Added Windows support.

Changed in version 3.6: Accepts a path-like object.

os.path.samestat(*stat1*, *stat2*)

Return `True` if the stat tuples *stat1* and *stat2* refer to the same file. These structures may have been returned by **`os.fstat()`**, **`os.lstat()`**, or **`os.stat()`**. This function implements the underlying comparison used by **`samefile()`** and **`sameopenfile()`**.

Availability: Unix, Windows.

Changed in version 3.4: Added Windows support.

Changed in version 3.6: Accepts a path-like object.

os.path.split(*path*)

Split the pathname *path* into a pair, `(head, tail)` where *tail* is the last pathname component and *head* is everything leading up to that. The *tail* part will never contain a slash; if *path* ends in a slash, *tail* will be empty. If there is no slash in *path*, *head* will be empty. If *path* is empty, both *head* and *tail* are empty. Trailing slashes are stripped from *head* unless it is the root (one or more slashes only). In all cases, `join(head, tail)` returns a path to the same location as *path* (but the strings may differ). Also see the functions **`dirname()`** and **`basename()`**.

Changed in version 3.6: Accepts a path-like object.

os.path.splitdrive(*path*)

Split the pathname *path* into a pair `(drive, tail)` where *drive* is either a mount point or the empty string. On systems which do not use drive specifications, *drive* will always be the empty string. In all cases, `drive + tail` will be the same as *path*.

On Windows, splits a pathname into drive/UNC sharepoint and relative path.

If the path contains a drive letter, drive will contain everything up to and including the colon:

```
>>> splitdrive("c:/dir")
("c:", "/dir")
```

If the path contains a UNC path, drive will contain the host name and share, up to but not including the fourth separator:

```
>>> splitdrive("//host/computer/dir")
("//host/computer", "/dir")
```

Changed in version 3.6: Accepts a path-like object.

os.path.splitext(*path*)

Split the pathname *path* into a pair `(root, ext)` such that `root + ext == path`, and the extension, *ext*, is empty or begins with a period and contains at most one period.

If the path contains no extension, *ext* will be `''`:

```
>>> splitext('bar')
('bar', '')
```

If the path contains an extension, then *ext* will be set to this extension, including the leading period. Note that previous periods will be ignored:

```
>>> splitext('foo.bar.exe')
('foo.bar', '.exe')
```

```
>>> splitext('/foo/bar.exe')
('/foo/bar', '.exe')
```

Leading periods of the last component of the path are considered to be part of the root:

```
>>> splitext('.cshrc')
('.cshrc', '')
>>> splitext('/foo/....jpg')
('/foo/....jpg', '')
```

Changed in version 3.6: Accepts a path-like object.

os.path.supports_unicode_filenames

`True` if arbitrary Unicode strings can be used as file names (within limitations imposed by the file system).

`fileinput` — Iterate over lines from multiple input streams

Source code: Lib/fileinput.py [https://github.com/python/cpython/tree/3.11/Lib/fileinput.py]

This module implements a helper class and functions to quickly write a loop over standard input or a list of files. If you just want to read or write one file see `open()`.

The typical use is:

```
import fileinput
for line in fileinput.input(encoding="utf-8"):
    process(line)
```

This iterates over the lines of all files listed in `sys.argv[1:]`, defaulting to `sys.stdin` if the list is empty. If a filename is `'-'`, it is also replaced by `sys.stdin` and the optional arguments *mode* and *openhook* are ignored. To specify an alternative list of filenames, pass it as the first argument to `input()`. A single file name is also allowed.

All files are opened in text mode by default, but you can override this by specifying the *mode* parameter in the call to `input()` or `FileInput`. If an I/O error occurs during opening or reading a file, `OSError` is raised.

Changed in version 3.3: `IOError` used to be raised; it is now an alias of `OSError`.

If `sys.stdin` is used more than once, the second and further use will return no lines, except perhaps for interactive use, or if it has been explicitly reset (e.g. using `sys.stdin.seek(0)`).

Empty files are opened and immediately closed; the only time their presence in the list of filenames is noticeable at all is when the last file opened is empty.

Lines are returned with any newlines intact, which means that the last line in a file may not have one.

You can control how files are opened by providing an opening hook via the *openhook* parameter to **fileinput.input()** or **FileInput()**. The hook must be a function that takes two arguments, *filename* and *mode*, and returns an accordingly opened file-like object. If *encoding* and/or *errors* are specified, they will be passed to the hook as additional keyword arguments. This module provides a **hook_compressed()** to support compressed files.

The following function is the primary interface of this module:

fileinput.input(*files=None*, *inplace=False*, *backup=''*, ***, *mode='r'*, *openhook=None*, *encoding=None*, *errors=None*)

Create an instance of the **FileInput** class. The instance will be used as global state for the functions of this module, and is also returned to use during iteration. The parameters to this function will be passed along to the constructor of the **FileInput** class.

The **FileInput** instance can be used as a context manager in the **with** statement. In this example, *input* is closed after the **with** statement is exited, even if an exception occurs:

```
with fileinput.input(files=('spam.txt', 'eggs.txt')
    for line in f:
        process(line)
```

Changed in version 3.2: Can be used as a context manager.

Changed in version 3.8: The keyword parameters *mode* and *openhook* are now keyword-only.

Changed in version 3.10: The keyword-only parameter *encoding* and *errors* are added.

The following functions use the global state created by **`fileinput.input()`**; if there is no active state, **`RuntimeError`** is raised.

fileinput.filename()

Return the name of the file currently being read. Before the first line has been read, returns `None`.

fileinput.fileno()

Return the integer “file descriptor” for the current file. When no file is opened (before the first line and between files), returns `-1`.

fileinput.lineno()

Return the cumulative line number of the line that has just been read. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line.

fileinput.filelineno()

Return the line number in the current file. Before the first line has been read, returns `0`. After the last line of the last file has been read, returns the line number of that line within the file.

fileinput.isfirstline()

Return `True` if the line just read is the first line of its file, otherwise return `False`.

fileinput.isstdin()

Return `True` if the last line was read from `sys.stdin`, otherwise return `False`.

fileinput.nextfile()

Close the current file so that the next iteration will read the first line from the next file (if any); lines not read from the file will not count towards the cumulative line count. The

filename is not changed until after the first line of the next file has been read. Before the first line has been read, this function has no effect; it cannot be used to skip the first file. After the last line of the last file has been read, this function has no effect.

fileinput.close()

Close the sequence.

The class which implements the sequence behavior provided by the module is available for subclassing as well:

class fileinput.FileInput(*files=None*, *inplace=False*, *backup=''*, ***, *mode='r'*, *openhook=None*, *encoding=None*, *errors=None*)

Class **`FileInput`** is the implementation; its methods **`filename()`**, **`fileno()`**, **`lineno()`**, **`filelineno()`**, **`isfirstline()`**, **`isstdin()`**, **`nextfile()`** and **`close()`** correspond to the functions of the same name in the module. In addition it is iterable and has a **`readline()`** method which returns the next input line. The sequence must be accessed in strictly sequential order; random access and **`readline()`** cannot be mixed.

With *mode* you can specify which file mode will be passed to **`open()`**. It must be one of `'r'` and `'rb'`.

The *openhook*, when given, must be a function that takes two arguments, *filename* and *mode*, and returns an accordingly opened file-like object. You cannot use *inplace* and *openhook* together.

You can specify *encoding* and *errors* that is passed to **`open()`** or *openhook*.

A **`FileInput`** instance can be used as a context manager in the **`with`** statement. In this example, *input* is closed after the **`with`** statement is exited, even if an exception occurs:

```
with FileInput(files=('spam.txt', 'eggs.txt')) as i
    process(input)
```

Changed in version 3.2: Can be used as a context manager.

Changed in version 3.8: The keyword parameter *mode* and *openhook* are now keyword-only.

Changed in version 3.10: The keyword-only parameter *encoding* and *errors* are added.

Changed in version 3.11: The `'rU'` and `'U'` modes and the **`__getitem__()`** method have been removed.

Optional in-place filtering: if the keyword argument `inplace=True` is passed to **`fileinput.input()`** or to the **`FileInput`** constructor, the file is moved to a backup file and standard output is directed to the input file (if a file of the same name as the backup file already exists, it will be replaced silently). This makes it possible to write a filter that rewrites its input file in place. If the *backup* parameter is given (typically as `backup='.<some extension>'`), it specifies the extension for the backup file, and the backup file remains around; by default, the extension is `'.bak'` and it is deleted when the output file is closed. In-place filtering is disabled when standard input is read.

The two following opening hooks are provided by this module:

fileinput.hook_compressed(*filename*, *mode*, ***, *encoding=None*, *errors=None*)

Transparently opens files compressed with gzip and bzip2 (recognized by the extensions `'.gz'` and `'.bz2'`) using the **`gzip`** and **`bz2`** modules. If the filename extension is not `'.gz'` or `'.bz2'`, the file is opened normally (ie, using **`open()`** without any decompression).

The *encoding* and *errors* values are passed to **`io.TextIOWrapper`** for compressed files and open for normal files.

Usage example: `fi = fileinput.FileInput(openhook=fileinput.hook_compres encoding="utf-8")`

Changed in version 3.10: The keyword-only parameter *encoding* and *errors* are added.

fileinput.hook_encoded(*encoding*, *errors*=*None*)

Returns a hook which opens each file with **open()**, using the given *encoding* and *errors* to read the file.

Usage example: `fi = fileinput.FileInput(openhook=fileinput.hook_encoded "surrogateescape"))`

Changed in version 3.6: Added the optional *errors* parameter.

Deprecated since version 3.10: This function is deprecated since **fileinput.input()** and **FileInput** now have *encoding* and *errors* parameters.

`stat` — Interpreting `stat()` results

Source code: Lib/stat.py [https://github.com/python/cpython/tree/3.11/Lib/stat.py]

The `stat` module defines constants and functions for interpreting the results of `os.stat()`, `os.fstat()` and `os.lstat()` (if they exist). For complete details about the `stat()`, `fstat()` and `lstat()` calls, consult the documentation for your system.

Changed in version 3.4: The stat module is backed by a C implementation.

The `stat` module defines the following functions to test for specific file types:

stat.S_ISDIR(*mode*)

Return non-zero if the mode is from a directory.

stat.S_ISCHR(*mode*)

Return non-zero if the mode is from a character special device file.

stat.S_ISBLK(*mode*)

Return non-zero if the mode is from a block special device file.

stat.S_ISREG(*mode*)

Return non-zero if the mode is from a regular file.

stat.S_ISFIFO(*mode*)

Return non-zero if the mode is from a FIFO (named pipe).

stat.S_ISLNK(*mode*)
Return non-zero if the mode is from a symbolic link.

stat.S_ISSOCK(*mode*)
Return non-zero if the mode is from a socket.

stat.S_ISDOOR(*mode*)
Return non-zero if the mode is from a door.

New in version 3.4.

stat.S_ISPORT(*mode*)
Return non-zero if the mode is from an event port.

New in version 3.4.

stat.S_ISWHT(*mode*)
Return non-zero if the mode is from a whiteout.

New in version 3.4.

Two additional functions are defined for more general manipulation of the file's mode:

stat.S_IMODE(*mode*)
Return the portion of the file's mode that can be set by `os.chmod()`—that is, the file's permission bits, plus the sticky bit, set-group-id, and set-user-id bits (on systems that support them).

stat.S_IFMT(*mode*)
Return the portion of the file's mode that describes the file type (used by the `S_IS*()` functions above).

Normally, you would use the `os.path.is*()` functions for

testing the type of a file; the functions here are useful when you are doing multiple tests of the same file and wish to avoid the overhead of the **`stat()`** system call for each test. These are also useful when checking for information about a file that isn't handled by **`os.path`**, like the tests for block and character devices.

Example:

```
import os, sys
from stat import *

def walktree(top, callback):
    '''recursively descend the directory tree rooted at
       calling the callback function for each regular fi

    for f in os.listdir(top):
        pathname = os.path.join(top, f)
        mode = os.lstat(pathname).st_mode
        if S_ISDIR(mode):
            # It's a directory, recurse into it
            walktree(pathname, callback)
        elif S_ISREG(mode):
            # It's a file, call the callback function
            callback(pathname)
        else:
            # Unknown file type, print a message
            print('Skipping %s' % pathname)

def visitfile(file):
    print('visiting', file)

if __name__ == '__main__':
    walktree(sys.argv[1], visitfile)
```

An additional utility function is provided to convert a file's mode in a human readable string:

stat.filemode(*mode*)

Convert a file's mode to a string of the form '-rwxrwxrwx'.

New in version 3.3.

Changed in version 3.4: The function supports `S_IFDOOR`, `S_IFPORT` and `S_IFWHT`.

All the variables below are simply symbolic indexes into the 10-tuple returned by `os.stat()`, `os.fstat()` or `os.lstat()`.

stat.ST_MODE
: Inode protection mode.

stat.ST_INO
: Inode number.

stat.ST_DEV
: Device inode resides on.

stat.ST_NLINK
: Number of links to the inode.

stat.ST_UID
: User id of the owner.

stat.ST_GID
: Group id of the owner.

stat.ST_SIZE
: Size in bytes of a plain file; amount of data waiting on some special files.

stat.ST_ATIME
: Time of last access.

stat.ST_MTIME
: Time of last modification.

stat.ST_CTIME

The “ctime” as reported by the operating system. On some systems (like Unix) is the time of the last metadata change, and, on others (like Windows), is the creation time (see platform documentation for details).

The interpretation of “file size” changes according to the file type. For plain files this is the size of the file in bytes. For FIFOs and sockets under most flavors of Unix (including Linux in particular), the “size” is the number of bytes waiting to be read at the time of the call to `os.stat()`, `os.fstat()`, or `os.lstat()`; this can sometimes be useful, especially for polling one of these special files after a non-blocking open. The meaning of the size field for other character and block devices varies more, depending on the implementation of the underlying system call.

The variables below define the flags used in the `ST_MODE` field.

Use of the functions above is more portable than use of the first set of flags:

stat.S_IFSOCK
: Socket.

stat.S_IFLNK
: Symbolic link.

stat.S_IFREG
: Regular file.

stat.S_IFBLK
: Block device.

stat.S_IFDIR
: Directory.

stat.S_IFCHR
: Character device.

stat.S_IFIFO
: FIFO.

stat.S_IFDOOR
: Door.

  New in version 3.4.

stat.S_IFPORT
: Event port.

  New in version 3.4.

stat.S_IFWHT
: Whiteout.

  New in version 3.4.

Note

S_IFDOOR, **S_IFPORT** or **S_IFWHT** are defined as 0 when the platform does not have support for the file types.

The following flags can also be used in the *mode* argument of **os.chmod()**:

stat.S_ISUID
: Set UID bit.

stat.S_ISGID
: Set-group-ID bit. This bit has several special uses. For a directory it indicates that BSD semantics is to be used for that directory: files created there inherit their group ID from the directory, not from the effective group ID of the creating process, and directories created there will also get the **S_ISGID** bit set. For a file that does not have the group execution bit (**S_IXGRP**) set, the set-group-ID bit indicates mandatory file/record locking (see also **S_ENFMT**).

stat.S_ISVTX

Sticky bit. When this bit is set on a directory it means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, or by a privileged process.

stat.S_IRWXU

Mask for file owner permissions.

stat.S_IRUSR

Owner has read permission.

stat.S_IWUSR

Owner has write permission.

stat.S_IXUSR

Owner has execute permission.

stat.S_IRWXG

Mask for group permissions.

stat.S_IRGRP

Group has read permission.

stat.S_IWGRP

Group has write permission.

stat.S_IXGRP

Group has execute permission.

stat.S_IRWXO

Mask for permissions for others (not in group).

stat.S_IROTH

Others have read permission.

stat.S_IWOTH
: Others have write permission.

stat.S_IXOTH
: Others have execute permission.

stat.S_ENFMT
: System V file locking enforcement. This flag is shared with **S_ISGID**: file/record locking is enforced on files that do not have the group execution bit (**S_IXGRP**) set.

stat.S_IREAD
: Unix V7 synonym for **S_IRUSR**.

stat.S_IWRITE
: Unix V7 synonym for **S_IWUSR**.

stat.S_IEXEC
: Unix V7 synonym for **S_IXUSR**.

The following flags can be used in the *flags* argument of **os.chflags()**:

stat.UF_NODUMP
: Do not dump the file.

stat.UF_IMMUTABLE
: The file may not be changed.

stat.UF_APPEND
: The file may only be appended to.

stat.UF_OPAQUE
: The directory is opaque when viewed through a union stack.

stat.UF_NOUNLINK

The file may not be renamed or deleted.

stat.UF_COMPRESSED
: The file is stored compressed (macOS 10.6+).

stat.UF_HIDDEN
: The file should not be displayed in a GUI (macOS 10.5+).

stat.SF_ARCHIVED
: The file may be archived.

stat.SF_IMMUTABLE
: The file may not be changed.

stat.SF_APPEND
: The file may only be appended to.

stat.SF_NOUNLINK
: The file may not be renamed or deleted.

stat.SF_SNAPSHOT
: The file is a snapshot file.

See the *BSD or macOS systems man page *chflags(2)* for more information.

On Windows, the following file attribute constants are available for use when testing bits in the `st_file_attributes` member returned by **`os.stat()`**. See the Windows API documentation [https://msdn.microsoft.com/en-us/library/windows/desktop/gg258117.aspx] for more detail on the meaning of these constants.

stat.FILE_ATTRIBUTE_ARCHIVE
stat.FILE_ATTRIBUTE_COMPRESSED
stat.FILE_ATTRIBUTE_DEVICE
stat.FILE_ATTRIBUTE_DIRECTORY
stat.FILE_ATTRIBUTE_ENCRYPTED
stat.FILE_ATTRIBUTE_HIDDEN

stat.FILE_ATTRIBUTE_INTEGRITY_STREAM
stat.FILE_ATTRIBUTE_NORMAL
stat.FILE_ATTRIBUTE_NOT_CONTENT_INDEXED
stat.FILE_ATTRIBUTE_NO_SCRUB_DATA
stat.FILE_ATTRIBUTE_OFFLINE
stat.FILE_ATTRIBUTE_READONLY
stat.FILE_ATTRIBUTE_REPARSE_POINT
stat.FILE_ATTRIBUTE_SPARSE_FILE
stat.FILE_ATTRIBUTE_SYSTEM
stat.FILE_ATTRIBUTE_TEMPORARY
stat.FILE_ATTRIBUTE_VIRTUAL

New in version 3.5.

On Windows, the following constants are available for comparing against the `st_reparse_tag` member returned by **`os.lstat()`**. These are well-known constants, but are not an exhaustive list.

stat.IO_REPARSE_TAG_SYMLINK
stat.IO_REPARSE_TAG_MOUNT_POINT
stat.IO_REPARSE_TAG_APPEXECLINK

New in version 3.8.

`filecmp` — File and Directory Comparisons

Source code: Lib/filecmp.py [https://github.com/python/cpython/tree/3.11/Lib/filecmp.py]

The `filecmp` module defines functions to compare files and directories, with various optional time/correctness trade-offs. For comparing files, see also the `difflib` module.

The `filecmp` module defines the following functions:

filecmp.cmp(*f1*, *f2*, *shallow* = *True*)

Compare the files named *f1* and *f2*, returning `True` if they seem equal, `False` otherwise.

If *shallow* is true and the `os.stat()` signatures (file type, size, and modification time) of both files are identical, the files are taken to be equal.

Otherwise, the files are treated as different if their sizes or contents differ.

Note that no external programs are called from this function, giving it portability and efficiency.

This function uses a cache for past comparisons and the results, with cache entries invalidated if the `os.stat()` information for the file changes. The entire cache may be cleared using `clear_cache()`.

filecmp.cmpfiles(*dir1*, *dir2*, *common*, *shallow* = *True*)

Compare the files in the two directories *dir1* and *dir2* whose names are given by *common*.

Returns three lists of file names: *match*, *mismatch*, *errors*. *match* contains the list of files that match, *mismatch* contains the names of those that don't, and *errors* lists the names of files which could not be compared. Files are listed in *errors* if they don't exist in one of the directories, the user lacks permission to read them or if the comparison could not be done for some other reason.

The *shallow* parameter has the same meaning and default value as for `filecmp.cmp()`.

For example, `cmpfiles('a', 'b', ['c', 'd/e'])` will compare `a/c` with `b/c` and `a/d/e` with `b/d/e`. `'c'` and `'d/e'` will each be in one of the three returned lists.

filecmp.clear_cache()

Clear the filecmp cache. This may be useful if a file is compared so quickly after it is modified that it is within the mtime resolution of the underlying filesystem.

New in version 3.4.

The `dircmp` class

class filecmp.dircmp(*a*, *b*, *ignore=None*, *hide=None*)

Construct a new directory comparison object, to compare the directories *a* and *b*. *ignore* is a list of names to ignore, and defaults to `filecmp.DEFAULT_IGNORES`. *hide* is a list of names to hide, and defaults to `[os.curdir, os.pardir]`.

The `dircmp` class compares files by doing *shallow* comparisons as described for `filecmp.cmp()`.

The `dircmp` class provides the following methods:

report()

Print (to `sys.stdout`) a comparison between *a* and *b*.

report_partial_closure()

Print a comparison between *a* and *b* and common immediate subdirectories.

report_full_closure()

Print a comparison between *a* and *b* and common subdirectories (recursively).

The **dircmp** class offers a number of interesting attributes that may be used to get various bits of information about the directory trees being compared.

Note that via **__getattr__()** hooks, all attributes are computed lazily, so there is no speed penalty if only those attributes which are lightweight to compute are used.

left

The directory *a*.

right

The directory *b*.

left_list

Files and subdirectories in *a*, filtered by *hide* and *ignore*.

right_list

Files and subdirectories in *b*, filtered by *hide* and *ignore*.

common

Files and subdirectories in both *a* and *b*.

left_only

Files and subdirectories only in *a*.

right_only

Files and subdirectories only in *b*.

common_dirs

Subdirectories in both *a* and *b*.

common_files

Files in both *a* and *b*.

common_funny

Names in both *a* and *b*, such that the type differs between the directories, or names for which **os.stat()** reports an error.

same_files

Files which are identical in both *a* and *b*, using the class's file comparison operator.

diff_files

Files which are in both *a* and *b*, whose contents differ according to the class's file comparison operator.

funny_files

Files which are in both *a* and *b*, but could not be compared.

subdirs

A dictionary mapping names in **common_dirs** to **dircmp** instances (or MyDirCmp instances if this instance is of type MyDirCmp, a subclass of **dircmp**).

Changed in version 3.10: Previously entries were always **dircmp** instances. Now entries are the same type as *self*, if *self* is a subclass of **dircmp**.

filecmp.DEFAULT_IGNORES

New in version 3.4.

List of directories ignored by **dircmp** by default.

Here is a simplified example of using the `subdirs` attribute to search recursively through two directories to show common

different files:

```
>>> from filecmp import dircmp
>>> def print_diff_files(dcmp):
...     for name in dcmp.diff_files:
...         print("diff_file %s found in %s and %s" % (n
...               dcmp.right))
...     for sub_dcmp in dcmp.subdirs.values():
...         print_diff_files(sub_dcmp)
...
>>> dcmp = dircmp('dir1', 'dir2')
>>> print_diff_files(dcmp)
```

`tempfile` — Generate temporary files and directories

Source code: Lib/tempfile.py [https://github.com/python/cpython/tree/3.11/Lib/tempfile.py]

This module creates temporary files and directories. It works on all supported platforms. `TemporaryFile`, `NamedTemporaryFile`, `TemporaryDirectory`, and `SpooledTemporaryFile` are high-level interfaces which provide automatic cleanup and can be used as context managers. `mkstemp()` and `mkdtemp()` are lower-level functions which require manual cleanup.

All the user-callable functions and constructors take additional arguments which allow direct control over the location and name of temporary files and directories. Files names used by this module include a string of random characters which allows those files to be securely created in shared temporary directories. To maintain backward compatibility, the argument order is somewhat odd; it is recommended to use keyword arguments for clarity.

The module defines the following user-callable items:

tempfile.TemporaryFile(*mode='w+b'*, *buffering=-1*, *encoding=None*, *newline=None*, *suffix=None*, *prefix=None*, *dir=None*, ***, *errors=None*)

Return a file-like object that can be used as a temporary storage area. The file is created securely, using the same rules as `mkstemp()`. It will be destroyed as soon as it is closed (including an implicit close when the object is garbage collected). Under Unix, the directory entry for the file is either not created at all or is removed immediately after the file is created. Other platforms do not support this; your code should not rely on a temporary file created using this function

having or not having a visible name in the file system.

The resulting object can be used as a context manager (see Examples). On completion of the context or destruction of the file object the temporary file will be removed from the filesystem.

The *mode* parameter defaults to `'w+b'` so that the file created can be read and written without being closed. Binary mode is used so that it behaves consistently on all platforms without regard for the data that is stored. *buffering*, *encoding*, *errors* and *newline* are interpreted as for **`open()`**.

The *dir*, *prefix* and *suffix* parameters have the same meaning and defaults as with **`mkstemp()`**.

The returned object is a true file object on POSIX platforms. On other platforms, it is a file-like object whose **`file`** attribute is the underlying true file object.

The **`os.O_TMPFILE`** flag is used if it is available and works (Linux-specific, requires Linux kernel 3.11 or later).

On platforms that are neither Posix nor Cygwin, TemporaryFile is an alias for NamedTemporaryFile.

Raises an auditing event `tempfile.mkstemp` with argument `fullpath`.

Changed in version 3.5: The **`os.O_TMPFILE`** flag is now used if available.

Changed in version 3.8: Added *errors* parameter.

tempfile.NamedTemporaryFile(*mode='w+b'*, *buffering=-1*, *encoding=None*, *newline=None*, *suffix=None*, *prefix=None*, *dir=None*, *delete=True*, ***, *errors=None*)

This function operates exactly as **`TemporaryFile()`** does, except that the file is guaranteed to have a visible name in the file system (on Unix, the directory entry is not unlinked). That name can be retrieved from the **`name`** attribute of the

returned file-like object. Whether the name can be used to open the file a second time, while the named temporary file is still open, varies across platforms (it can be so used on Unix; it cannot on Windows). If *delete* is true (the default), the file is deleted as soon as it is closed. The returned object is always a file-like object whose **file** attribute is the underlying true file object. This file-like object can be used in a **with** statement, just like a normal file.

On POSIX (only), a process that is terminated abruptly with SIGKILL cannot automatically delete any NamedTemporaryFiles it created.

Raises an auditing event `tempfile.mkstemp` with argument `fullpath`.

Changed in version 3.8: Added *errors* parameter.

class tempfile.SpooledTemporaryFile(*max_size=0*, *mode='w+b'*, *buffering=-1*, *encoding=None*, *newline=None*, *suffix=None*, *prefix=None*, *dir=None*, ***, *errors=None*)

This class operates exactly as **TemporaryFile()** does, except that data is spooled in memory until the file size exceeds *max_size*, or until the file's **fileno()** method is called, at which point the contents are written to disk and operation proceeds as with **TemporaryFile()**.

The resulting file has one additional method, **rollover()**, which causes the file to roll over to an on-disk file regardless of its size.

The returned object is a file-like object whose **_file** attribute is either an **io.BytesIO** or **io.TextIOWrapper** object (depending on whether binary or text *mode* was specified) or a true file object, depending on whether **rollover()** has been called. This file-like object can be used in a **with** statement, just like a normal file.

Changed in version 3.3: the truncate method now accepts a `size` argument.

Changed in version 3.8: Added *errors* parameter.

Changed in version 3.11: Fully implements the **io.BufferedIOBase** and **io.TextIOBase** abstract base classes (depending on whether binary or text *mode* was specified).

class tempfile.TemporaryDirectory(*suffix=None, prefix=None, dir=None, ignore_cleanup_errors=False*)

This class securely creates a temporary directory using the same rules as **mkdtemp()**. The resulting object can be used as a context manager (see Examples). On completion of the context or destruction of the temporary directory object, the newly created temporary directory and all its contents are removed from the filesystem.

The directory name can be retrieved from the **name** attribute of the returned object. When the returned object is used as a context manager, the **name** will be assigned to the target of the **as** clause in the **with** statement, if there is one.

The directory can be explicitly cleaned up by calling the **cleanup()** method. If *ignore_cleanup_errors* is true, any unhandled exceptions during explicit or implicit cleanup (such as a **PermissionError** removing open files on Windows) will be ignored, and the remaining removable items deleted on a "best-effort" basis. Otherwise, errors will be raised in whatever context cleanup occurs (the **cleanup()** call, exiting the context manager, when the object is garbage-collected or during interpreter shutdown).

Raises an auditing event `tempfile.mkdtemp` with argument `fullpath`.

New in version 3.2.

Changed in version 3.10: Added *ignore_cleanup_errors* parameter.

tempfile.mkstemp(*suffix=None, prefix=None, dir=None,*

text=False)

Creates a temporary file in the most secure manner possible. There are no race conditions in the file's creation, assuming that the platform properly implements the **`os.O_EXCL`** flag for **`os.open()`**. The file is readable and writable only by the creating user ID. If the platform uses permission bits to indicate whether a file is executable, the file is executable by no one. The file descriptor is not inherited by child processes.

Unlike **`TemporaryFile()`**, the user of **`mkstemp()`** is responsible for deleting the temporary file when done with it.

If *suffix* is not `None`, the file name will end with that suffix, otherwise there will be no suffix. **`mkstemp()`** does not put a dot between the file name and the suffix; if you need one, put it at the beginning of *suffix*.

If *prefix* is not `None`, the file name will begin with that prefix; otherwise, a default prefix is used. The default is the return value of **`gettempprefix()`** or **`gettempprefixb()`**, as appropriate.

If *dir* is not `None`, the file will be created in that directory; otherwise, a default directory is used. The default directory is chosen from a platform-dependent list, but the user of the application can control the directory location by setting the *TMPDIR*, *TEMP* or *TMP* environment variables. There is thus no guarantee that the generated filename will have any nice properties, such as not requiring quoting when passed to external commands via `os.popen()`.

If any of *suffix*, *prefix*, and *dir* are not `None`, they must be the same type. If they are bytes, the returned name will be bytes instead of str. If you want to force a bytes return value with otherwise default behavior, pass `suffix=b''`.

If *text* is specified and true, the file is opened in text mode. Otherwise, (the default) the file is opened in binary mode.

`mkstemp()` returns a tuple containing an OS-level handle to an open file (as would be returned by **`os.open()`**) and the

absolute pathname of that file, in that order.

Raises an auditing event `tempfile.mkstemp` with argument `fullpath`.

Changed in version 3.5: *suffix*, *prefix*, and *dir* may now be supplied in bytes in order to obtain a bytes return value. Prior to this, only str was allowed. *suffix* and *prefix* now accept and default to `None` to cause an appropriate default value to be used.

Changed in version 3.6: The *dir* parameter now accepts a path-like object.

tempfile.mkdtemp(*suffix=None*, *prefix=None*, *dir=None*)

Creates a temporary directory in the most secure manner possible. There are no race conditions in the directory's creation. The directory is readable, writable, and searchable only by the creating user ID.

The user of **`mkdtemp()`** is responsible for deleting the temporary directory and its contents when done with it.

The *prefix*, *suffix*, and *dir* arguments are the same as for **`mkstemp()`**.

`mkdtemp()` returns the absolute pathname of the new directory.

Raises an auditing event `tempfile.mkdtemp` with argument `fullpath`.

Changed in version 3.5: *suffix*, *prefix*, and *dir* may now be supplied in bytes in order to obtain a bytes return value. Prior to this, only str was allowed. *suffix* and *prefix* now accept and default to `None` to cause an appropriate default value to be used.

Changed in version 3.6: The *dir* parameter now accepts a path-like object.

tempfile.gettempdir()

Return the name of the directory used for temporary files. This defines the default value for the *dir* argument to all functions in this module.

Python searches a standard list of directories to find one which the calling user can create files in. The list is:

1. The directory named by the **`TMPDIR`** environment variable.
2. The directory named by the **`TEMP`** environment variable.
3. The directory named by the **`TMP`** environment variable.
4. A platform-specific location:
    - On Windows, the directories `C:\TEMP`, `C:\TMP`, `\TEMP`, and `\TMP`, in that order.
    - On all other platforms, the directories `/tmp`, `/var/tmp`, and `/usr/tmp`, in that order.
7. As a last resort, the current working directory.

The result of this search is cached, see the description of **`tempdir`** below.

Changed in version 3.10: Always returns a str. Previously it would return any **`tempdir`** value regardless of type so long as it was not `None`.

tempfile.gettempdirb()

Same as **`gettempdir()`** but the return value is in bytes.

New in version 3.5.

tempfile.gettempprefix()

Return the filename prefix used to create temporary files. This does not contain the directory component.

tempfile.gettempprefixb()

Same as **`gettempprefix()`** but the return value is in bytes.

New in version 3.5.

The module uses a global variable to store the name of the directory used for temporary files returned by **gettempdir()**. It can be set directly to override the selection process, but this is discouraged. All functions in this module take a *dir* argument which can be used to specify the directory. This is the recommended approach that does not surprise other unsuspecting code by changing global API behavior.

tempfile.tempdir

When set to a value other than `None`, this variable defines the default value for the *dir* argument to the functions defined in this module, including its type, bytes or str. It cannot be a path-like object.

If `tempdir` is `None` (the default) at any call to any of the above functions except **gettempprefix()** it is initialized following the algorithm described in **gettempdir()**.

Note

Beware that if you set `tempdir` to a bytes value, there is a nasty side effect: The global default return type of **mkstemp()** and **mkdtemp()** changes to bytes when no explicit `prefix`, `suffix`, or `dir` arguments of type str are supplied. Please do not write code expecting or depending on this. This awkward behavior is maintained for compatibility with the historical implementation.

Examples

Here are some examples of typical usage of the **tempfile** module:

```
>>> import tempfile

# create a temporary file and write some data to it
>>> fp = tempfile.TemporaryFile()
```

```
>>> fp.write(b'Hello world!')
# read data from file
>>> fp.seek(0)
>>> fp.read()
b'Hello world!'
# close the file, it will be removed
>>> fp.close()

# create a temporary file using a context manager
>>> with tempfile.TemporaryFile() as fp:
...     fp.write(b'Hello world!')
...     fp.seek(0)
...     fp.read()
b'Hello world!'
>>>
# file is now closed and removed

# create a temporary directory using the context manager
>>> with tempfile.TemporaryDirectory() as tmpdirname:
...     print('created temporary directory', tmpdirname)
>>>
# directory and contents have been removed
```

Deprecated functions and variables

A historical way to create temporary files was to first generate a file name with the **`mktemp()`** function and then create a file using this name. Unfortunately this is not secure, because a different process may create a file with this name in the time between the call to **`mktemp()`** and the subsequent attempt to create the file by the first process. The solution is to combine the two steps and create the file immediately. This approach is used by **`mkstemp()`** and the other functions described above.

tempfile.mktemp(*suffix=''*, *prefix='tmp'*, *dir=None*)

Deprecated since version 2.3: Use **`mkstemp()`** instead.

Return an absolute pathname of a file that did not exist at the

time the call is made. The *prefix*, *suffix*, and *dir* arguments are similar to those of **`mkstemp()`**, except that bytes file names, `suffix=None` and `prefix=None` are not supported.

Warning

Use of this function may introduce a security hole in your program. By the time you get around to doing anything with the file name it returns, someone else may have beaten you to the punch. **`mktemp()`** usage can be replaced easily with **`NamedTemporaryFile()`**, passing it the `delete=False` parameter:

```
>>> f = NamedTemporaryFile(delete=False)
>>> f.name
'/tmp/tmptjujjt'
>>> f.write(b"Hello World!\n")
13
>>> f.close()
>>> os.unlink(f.name)
>>> os.path.exists(f.name)
False
```

`glob` — Unix style pathname pattern expansion

Source code: Lib/glob.py [https://github.com/python/cpython/tree/3.11/Lib/glob.py]

The `glob` module finds all the pathnames matching a specified pattern according to the rules used by the Unix shell, although results are returned in arbitrary order. No tilde expansion is done, but `*`, `?`, and character ranges expressed with `[]` will be correctly matched. This is done by using the `os.scandir()` and `fnmatch.fnmatch()` functions in concert, and not by actually invoking a subshell.

Note that files beginning with a dot (`.`) can only be matched by patterns that also start with a dot, unlike `fnmatch.fnmatch()` or `pathlib.Path.glob()`. (For tilde and shell variable expansion, use `os.path.expanduser()` and `os.path.expandvars()`.)

For a literal match, wrap the meta-characters in brackets. For example, `'[?]'` matches the character `'?'`.

See also

The `pathlib` module offers high-level path objects.

glob.glob(*pathname*, ***, *root_dir=None*, *dir_fd=None*, *recursive=False*, *include_hidden=False*)

Return a possibly empty list of path names that match *pathname*, which must be a string containing a path specification. *pathname* can be either absolute (like `/usr/src/Python-1.5/Makefile`) or relative (like `../../Tools/*/*.gif`), and can contain shell-style wildcards.

Broken symlinks are included in the results (as in the shell). Whether or not the results are sorted depends on the file system. If a file that satisfies conditions is removed or added during the call of this function, whether a path name for that file be included is unspecified.

If *root_dir* is not `None`, it should be a path-like object specifying the root directory for searching. It has the same effect on **`glob()`** as changing the current directory before calling it. If *pathname* is relative, the result will contain paths relative to *root_dir*.

This function can support paths relative to directory descriptors with the *dir_fd* parameter.

If *recursive* is true, the pattern "`**`" will match any files and zero or more directories, subdirectories and symbolic links to directories. If the pattern is followed by an **`os.sep`** or **`os.altsep`** then files will not match.

If *include_hidden* is true, "`**`" pattern will match hidden directories.

Raises an auditing event `glob.glob` with arguments `pathname, recursive`.

Raises an auditing event `glob.glob/2` with arguments `pathname, recursive, root_dir, dir_fd`.

Note

Using the "`**`" pattern in large directory trees may consume an inordinate amount of time.

Changed in version 3.5: Support for recursive globs using "`**`".

Changed in version 3.10: Added the *root_dir* and *dir_fd* parameters.

Changed in version 3.11: Added the *include_hidden* parameter.

glob.iglob(*pathname*, *, *root_dir*=*None*, *dir_fd*=*None*, *recursive*=*False*, *include_hidden*=*False*)

Return an iterator which yields the same values as **glob()** without actually storing them all simultaneously.

Raises an auditing event `glob.glob` with arguments `pathname, recursive`.

Raises an auditing event `glob.glob/2` with arguments `pathname, recursive, root_dir, dir_fd`.

Changed in version 3.5: Support for recursive globs using "`**`".

Changed in version 3.10: Added the *root_dir* and *dir_fd* parameters.

Changed in version 3.11: Added the *include_hidden* parameter.

glob.escape(*pathname*)

Escape all special characters (`'?'`, `'*'` and `'['`). This is useful if you want to match an arbitrary literal string that may have special characters in it. Special characters in drive/UNC sharepoints are not escaped, e.g. on Windows `escape('//?/c:/Quo vadis?.txt')` returns `'//?/c:/Quo vadis[?].txt'`.

New in version 3.4.

For example, consider a directory containing the following files: `1.gif`, `2.txt`, `card.gif` and a subdirectory `sub` which contains only the file `3.txt`. **glob()** will produce the following results. Notice how any leading components of the path are preserved.

```
>>> import glob
>>> glob.glob('./[0-9].*')
['./1.gif', './2.txt']
>>> glob.glob('*.gif')
['1.gif', 'card.gif']
>>> glob.glob('?.gif')
```

```
['1.gif']
>>> glob.glob('**/*.txt', recursive=True)
['2.txt', 'sub/3.txt']
>>> glob.glob('./**/', recursive=True)
['./', './sub/']
```

If the directory contains files starting with `.` they won't be matched by default. For example, consider a directory containing `card.gif` and `.card.gif`:

```
>>> import glob
>>> glob.glob('*.gif')
['card.gif']
>>> glob.glob('.c*')
['.card.gif']
```

Module `fnmatch`
Shell-style filename (not path) expansion

`fnmatch` — Unix filename pattern matching

Source code: Lib/fnmatch.py [https://github.com/python/cpython/tree/3.11/Lib/fnmatch.py]

This module provides support for Unix shell-style wildcards, which are *not* the same as regular expressions (which are documented in the `re` module). The special characters used in shell-style wildcards are:

Pattern	Meaning
`*`	matches everything
`?`	matches any single character
`[seq]`	matches any character in *seq*
`[!seq]`	matches any character not in *seq*

For a literal match, wrap the meta-characters in brackets. For example, `'[?]'` matches the character `'?'`.

Note that the filename separator (`'/'` on Unix) is *not* special to this module. See module `glob` for pathname expansion (`glob` uses `filter()` to match pathname segments). Similarly, filenames starting with a period are not special for this module, and are matched by the `*` and `?` patterns.

Also note that `functools.lru_cache()` with the *maxsize* of 32768 is used to cache the compiled regex patterns in the following functions: `fnmatch()`, `fnmatchcase()`, `filter()`.

fnmatch.fnmatch(*filename*, *pattern*)

Test whether the *filename* string matches the *pattern* string, returning `True` or `False`. Both parameters are case-normalized using `os.path.normcase()`. `fnmatchcase()` can be used to perform a case-sensitive

comparison, regardless of whether that's standard for the operating system.

This example will print all file names in the current directory with the extension `.txt`:

```
import fnmatch
import os

for file in os.listdir('.'):
    if fnmatch.fnmatch(file, '*.txt'):
        print(file)
```

fnmatch.fnmatchcase(*filename*, *pattern*)

Test whether *filename* matches *pattern*, returning **`True`** or **`False`**; the comparison is case-sensitive and does not apply **`os.path.normcase()`**.

fnmatch.filter(*names*, *pattern*)

Construct a list from those elements of the iterable *names* that match *pattern*. It is the same as `[n for n in names if fnmatch(n, pattern)]`, but implemented more efficiently.

fnmatch.translate(*pattern*)

Return the shell-style *pattern* converted to a regular expression for using with **`re.match()`**.

Example:

```
>>> import fnmatch, re
>>>
>>> regex = fnmatch.translate('*.txt')
>>> regex
'(?s:.*\\.txt)\\Z'
>>> reobj = re.compile(regex)
>>> reobj.match('foobar.txt')
<re.Match object; span=(0, 10), match='foobar.txt'>
```

Module `glob`
: Unix shell-style path expansion.

`linecache` — Random access to text lines

Source code: Lib/linecache.py [https://github.com/python/cpython/tree/3.11/Lib/linecache.py]

The `linecache` module allows one to get any line from a Python source file, while attempting to optimize internally, using a cache, the common case where many lines are read from a single file. This is used by the `traceback` module to retrieve source lines for inclusion in the formatted traceback.

The `tokenize.open()` function is used to open files. This function uses `tokenize.detect_encoding()` to get the encoding of the file; in the absence of an encoding token, the file encoding defaults to UTF-8.

The `linecache` module defines the following functions:

linecache.getline(*filename*, *lineno*, *module_globals=None*)

> Get line *lineno* from file named *filename*. This function will never raise an exception — it will return `''` on errors (the terminating newline character will be included for lines that are found).
>
> If a file named *filename* is not found, the function first checks for a **PEP 302** [https://peps.python.org/pep-0302/] `__loader__` in *module_globals*. If there is such a loader and it defines a `get_source` method, then that determines the source lines (if `get_source()` returns `None`, then `''` is returned). Finally, if *filename* is a relative filename, it is looked up relative to the entries in the module search path, `sys.path`.

linecache.clearcache()

Clear the cache. Use this function if you no longer need lines from files previously read using **`getline()`**.

linecache.checkcache(*filename=None*)

Check the cache for validity. Use this function if files in the cache may have changed on disk, and you require the updated version. If *filename* is omitted, it will check all the entries in the cache.

linecache.lazycache(*filename*, *module_globals*)

Capture enough detail about a non-file-based module to permit getting its lines later via **`getline()`** even if *module_globals* is `None` in the later call. This avoids doing I/O until a line is actually needed, without having to carry the module globals around indefinitely.

New in version 3.5.

Example:

```
>>> import linecache
>>> linecache.getline(linecache.__file__, 8)
'import sys\n'
```

`shutil` — High-level file operations

Source code: Lib/shutil.py [https://github.com/python/cpython/tree/3.11/Lib/shutil.py]

The `shutil` module offers a number of high-level operations on files and collections of files. In particular, functions are provided which support file copying and removal. For operations on individual files, see also the `os` module.

Warning

Even the higher-level file copying functions (`shutil.copy()`, `shutil.copy2()`) cannot copy all file metadata.

On POSIX platforms, this means that file owner and group are lost as well as ACLs. On Mac OS, the resource fork and other metadata are not used. This means that resources will be lost and file type and creator codes will not be correct. On Windows, file owners, ACLs and alternate data streams are not copied.

Directory and files operations

shutil.copyfileobj(*fsrc*, *fdst*[, *length*])

Copy the contents of the file-like object *fsrc* to the file-like object *fdst*. The integer *length*, if given, is the buffer size. In particular, a negative *length* value means to copy the data without looping over the source data in chunks; by default the data is read in chunks to avoid uncontrolled memory consumption. Note that if the current file position of the *fsrc* object is not 0, only the contents from the current file position to the end of the file will be copied.

shutil.copyfile(*src*, *dst*, ***, *follow_symlinks=True*)

Copy the contents (no metadata) of the file named *src* to a file named *dst* and return *dst* in the most efficient way possible. *src* and *dst* are path-like objects or path names given as strings.

dst must be the complete target file name; look at **copy()** for a copy that accepts a target directory path. If *src* and *dst* specify the same file, **SameFileError** is raised.

The destination location must be writable; otherwise, an **OSError** exception will be raised. If *dst* already exists, it will be replaced. Special files such as character or block devices and pipes cannot be copied with this function.

If *follow_symlinks* is false and *src* is a symbolic link, a new symbolic link will be created instead of copying the file *src* points to.

Raises an auditing event `shutil.copyfile` with arguments `src, dst`.

Changed in version 3.3: **IOError** used to be raised instead of **OSError**. Added *follow_symlinks* argument. Now returns *dst*.

Changed in version 3.4: Raise **SameFileError** instead of **Error**. Since the former is a subclass of the latter, this change is backward compatible.

Changed in version 3.8: Platform-specific fast-copy syscalls may be used internally in order to copy the file more efficiently. See Platform-dependent efficient copy operations section.

exception shutil.SameFileError

This exception is raised if source and destination in **copyfile()** are the same file.

New in version 3.4.

shutil.copymode(*src*, *dst*, ***, *follow_symlinks=True*)

Copy the permission bits from *src* to *dst*. The file contents, owner, and group are unaffected. *src* and *dst* are path-like objects or path names given as strings. If *follow_symlinks* is false, and both *src* and *dst* are symbolic links, **`copymode()`** will attempt to modify the mode of *dst* itself (rather than the file it points to). This functionality is not available on every platform; please see **`copystat()`** for more information. If **`copymode()`** cannot modify symbolic links on the local platform, and it is asked to do so, it will do nothing and return.

Raises an auditing event `shutil.copymode` with arguments `src, dst`.

Changed in version 3.3: Added *follow_symlinks* argument.

shutil.copystat(*src*, *dst*, ***, *follow_symlinks=True*)

Copy the permission bits, last access time, last modification time, and flags from *src* to *dst*. On Linux, **`copystat()`** also copies the "extended attributes" where possible. The file contents, owner, and group are unaffected. *src* and *dst* are path-like objects or path names given as strings.

If *follow_symlinks* is false, and *src* and *dst* both refer to symbolic links, **`copystat()`** will operate on the symbolic links themselves rather than the files the symbolic links refer to—reading the information from the *src* symbolic link, and writing the information to the *dst* symbolic link.

Note

Not all platforms provide the ability to examine and modify symbolic links. Python itself can tell you what functionality is locally available.

- If `os.chmod in os.supports_follow_symlinks` is `True`, **`copystat()`** can modify the permission bits of a symbolic link.

- If `os.utime in os.supports_follow_symlinks` is `True`, **`copystat()`** can modify the last access and modification times of a symbolic link.
- If `os.chflags in os.supports_follow_symlinks` is `True`, **`copystat()`** can modify the flags of a symbolic link. (`os.chflags` is not available on all platforms.)

On platforms where some or all of this functionality is unavailable, when asked to modify a symbolic link, **`copystat()`** will copy everything it can. **`copystat()`** never returns failure.

Please see **`os.supports_follow_symlinks`** for more information.

Raises an auditing event `shutil.copystat` with arguments `src`, `dst`.

Changed in version 3.3: Added *follow_symlinks* argument and support for Linux extended attributes.

shutil.copy(*src*, *dst*, ***, *follow_symlinks = True*)

Copies the file *src* to the file or directory *dst*. *src* and *dst* should be path-like objects or strings. If *dst* specifies a directory, the file will be copied into *dst* using the base filename from *src*. If *dst* specifies a file that already exists, it will be replaced. Returns the path to the newly created file.

If *follow_symlinks* is false, and *src* is a symbolic link, *dst* will be created as a symbolic link. If *follow_symlinks* is true and *src* is a symbolic link, *dst* will be a copy of the file *src* refers to.

`copy()` copies the file data and the file's permission mode (see **`os.chmod()`**). Other metadata, like the file's creation and modification times, is not preserved. To preserve all file metadata from the original, use **`copy2()`** instead.

Raises an auditing event `shutil.copyfile` with arguments `src`, `dst`.

Raises an auditing event `shutil.copymode` with arguments `src`, `dst`.

Changed in version 3.3: Added *follow_symlinks* argument. Now returns path to the newly created file.

Changed in version 3.8: Platform-specific fast-copy syscalls may be used internally in order to copy the file more efficiently. See Platform-dependent efficient copy operations section.

shutil.copy2(*src*, *dst*, *, *follow_symlinks=True*)

Identical to **`copy()`** except that **`copy2()`** also attempts to preserve file metadata.

When *follow_symlinks* is false, and *src* is a symbolic link, **`copy2()`** attempts to copy all metadata from the *src* symbolic link to the newly created *dst* symbolic link. However, this functionality is not available on all platforms. On platforms where some or all of this functionality is unavailable, **`copy2()`** will preserve all the metadata it can; **`copy2()`** never raises an exception because it cannot preserve file metadata.

`copy2()` uses **`copystat()`** to copy the file metadata. Please see **`copystat()`** for more information about platform support for modifying symbolic link metadata.

Raises an auditing event `shutil.copyfile` with arguments `src`, `dst`.

Raises an auditing event `shutil.copystat` with arguments `src`, `dst`.

Changed in version 3.3: Added *follow_symlinks* argument, try to copy extended file system attributes too (currently Linux only). Now returns path to the newly created file.

Changed in version 3.8: Platform-specific fast-copy syscalls may be used internally in order to copy the file more efficiently. See Platform-dependent efficient copy operations section.

shutil.ignore_patterns(**patterns*)

This factory function creates a function that can be used as a callable for `copytree()`'s *ignore* argument, ignoring files and directories that match one of the glob-style *patterns* provided. See the example below.

shutil.copytree(*src*, *dst*, *symlinks=False*, *ignore=None*, *copy_function=copy2*, *ignore_dangling_symlinks=False*, *dirs_exist_ok=False*)

Recursively copy an entire directory tree rooted at *src* to a directory named *dst* and return the destination directory. All intermediate directories needed to contain *dst* will also be created by default.

Permissions and times of directories are copied with `copystat()`, individual files are copied using `copy2()`.

If *symlinks* is true, symbolic links in the source tree are represented as symbolic links in the new tree and the metadata of the original links will be copied as far as the platform allows; if false or omitted, the contents and metadata of the linked files are copied to the new tree.

When *symlinks* is false, if the file pointed by the symlink doesn't exist, an exception will be added in the list of errors raised in an `Error` exception at the end of the copy process. You can set the optional *ignore_dangling_symlinks* flag to true if you want to silence this exception. Notice that this option has no effect on platforms that don't support `os.symlink()`.

If *ignore* is given, it must be a callable that will receive as its arguments the directory being visited by `copytree()`, and a list of its contents, as returned by `os.listdir()`. Since `copytree()` is called recursively, the *ignore* callable will be

called once for each directory that is copied. The callable must return a sequence of directory and file names relative to the current directory (i.e. a subset of the items in its second argument); these names will then be ignored in the copy process. **`ignore_patterns()`** can be used to create such a callable that ignores names based on glob-style patterns.

If exception(s) occur, an **`Error`** is raised with a list of reasons.

If *copy_function* is given, it must be a callable that will be used to copy each file. It will be called with the source path and the destination path as arguments. By default, **`copy2()`** is used, but any function that supports the same signature (like **`copy()`**) can be used.

If *dirs_exist_ok* is false (the default) and *dst* already exists, a **`FileExistsError`** is raised. If *dirs_exist_ok* is true, the copying operation will continue if it encounters existing directories, and files within the *dst* tree will be overwritten by corresponding files from the *src* tree.

Raises an auditing event `shutil.copytree` with arguments `src, dst`.

Changed in version 3.3: Copy metadata when *symlinks* is false. Now returns *dst*.

Changed in version 3.2: Added the *copy_function* argument to be able to provide a custom copy function. Added the *ignore_dangling_symlinks* argument to silence dangling symlinks errors when *symlinks* is false.

Changed in version 3.8: Platform-specific fast-copy syscalls may be used internally in order to copy the file more efficiently. See Platform-dependent efficient copy operations section.

New in version 3.8: The *dirs_exist_ok* parameter.

shutil.rmtree(*path*, *ignore_errors*=*False*, *onerror*=*None*, *,

dir_fd=None)

Delete an entire directory tree; *path* must point to a directory (but not a symbolic link to a directory). If *ignore_errors* is true, errors resulting from failed removals will be ignored; if false or omitted, such errors are handled by calling a handler specified by *onerror* or, if that is omitted, they raise an exception.

This function can support paths relative to directory descriptors.

Note

On platforms that support the necessary fd-based functions a symlink attack resistant version of **`rmtree()`** is used by default. On other platforms, the **`rmtree()`** implementation is susceptible to a symlink attack: given proper timing and circumstances, attackers can manipulate symlinks on the filesystem to delete files they wouldn't be able to access otherwise. Applications can use the **`rmtree.avoids_symlink_attacks`** function attribute to determine which case applies.

If *onerror* is provided, it must be a callable that accepts three parameters: *function*, *path*, and *excinfo*.

The first parameter, *function*, is the function which raised the exception; it depends on the platform and implementation. The second parameter, *path*, will be the path name passed to *function*. The third parameter, *excinfo*, will be the exception information returned by **`sys.exc_info()`**. Exceptions raised by *onerror* will not be caught.

Raises an auditing event `shutil.rmtree` with arguments `path`, `dir_fd`.

Changed in version 3.3: Added a symlink attack resistant version that is used automatically if platform supports fd-based functions.

Changed in version 3.8: On Windows, will no longer delete the contents of a directory junction before removing the junction.

Changed in version 3.11: The *dir_fd* parameter.

rmtree.avoids_symlink_attacks

Indicates whether the current platform and implementation provides a symlink attack resistant version of **rmtree()**. Currently this is only true for platforms supporting fd-based directory access functions.

New in version 3.3.

shutil.move(*src*, *dst*, *copy_function*=*copy2*)

Recursively move a file or directory (*src*) to another location (*dst*) and return the destination.

If the destination is an existing directory, then *src* is moved inside that directory. If the destination already exists but is not a directory, it may be overwritten depending on **os.rename()** semantics.

If the destination is on the current filesystem, then **os.rename()** is used. Otherwise, *src* is copied to *dst* using *copy_function* and then removed. In case of symlinks, a new symlink pointing to the target of *src* will be created in or as *dst* and *src* will be removed.

If *copy_function* is given, it must be a callable that takes two arguments *src* and *dst*, and will be used to copy *src* to *dst* if **os.rename()** cannot be used. If the source is a directory, **copytree()** is called, passing it the **copy_function()**. The default *copy_function* is **copy2()**. Using **copy()** as the *copy_function* allows the move to succeed when it is not possible to also copy the metadata, at the expense of not copying any of the metadata.

Raises an auditing event `shutil.move` with arguments `src`, `dst`.

Changed in version 3.3: Added explicit symlink handling for foreign filesystems, thus adapting it to the behavior of GNU's **mv**. Now returns *dst*.

Changed in version 3.5: Added the *copy_function* keyword argument.

Changed in version 3.8: Platform-specific fast-copy syscalls may be used internally in order to copy the file more efficiently. See Platform-dependent efficient copy operations section.

Changed in version 3.9: Accepts a path-like object for both *src* and *dst*.

shutil.disk_usage(*path*)

Return disk usage statistics about the given path as a named tuple with the attributes *total*, *used* and *free*, which are the amount of total, used and free space, in bytes. *path* may be a file or a directory.

New in version 3.3.

Changed in version 3.8: On Windows, *path* can now be a file or directory.

Availability: Unix, Windows.

shutil.chown(*path*, *user=None*, *group=None*)

Change owner *user* and/or *group* of the given *path*.

user can be a system user name or a uid; the same applies to *group*. At least one argument is required.

See also **`os.chown()`**, the underlying function.

Raises an auditing event `shutil.chown` with arguments `path`, `user`, `group`.

Availability: Unix.

New in version 3.3.

shutil.which(*cmd*, *mode*=*os.F_OK* | *os.X_OK*, *path*=*None*)

Return the path to an executable which would be run if the given *cmd* was called. If no *cmd* would be called, return `None`.

mode is a permission mask passed to **`os.access()`**, by default determining if the file exists and executable.

When no *path* is specified, the results of **`os.environ()`** are used, returning either the "PATH" value or a fallback of **`os.defpath`**.

On Windows, the current directory is always prepended to the *path* whether or not you use the default or provide your own, which is the behavior the command shell uses when finding executables. Additionally, when finding the *cmd* in the *path*, the `PATHEXT` environment variable is checked. For example, if you call `shutil.which("python")`, **`which()`** will search `PATHEXT` to know that it should look for `python.exe` within the *path* directories. For example, on Windows:

```
>>> shutil.which("python")
'C:\\Python33\\python.EXE'
```

New in version 3.3.

Changed in version 3.8: The **`bytes`** type is now accepted. If *cmd* type is **`bytes`**, the result type is also **`bytes`**.

exception shutil.Error

This exception collects exceptions that are raised during a multi-file operation. For **`copytree()`**, the exception argument is a list of 3-tuples (*srcname*, *dstname*, *exception*).

Platform-dependent efficient copy operations

Starting from Python 3.8, all functions involving a file copy

(**copyfile()**, **copy()**, **copy2()**, **copytree()**, and **move()**) may use platform-specific "fast-copy" syscalls in order to copy the file more efficiently (see bpo-33671 [https://bugs.python.org/issue?@action=redirect&bpo=33671]). "fast-copy" means that the copying operation occurs within the kernel, avoiding the use of userspace buffers in Python as in "`outfd.write(infd.read())`".

On macOS fcopyfile [http://www.manpagez.com/man/3/copyfile/] is used to copy the file content (not metadata).

On Linux **os.sendfile()** is used.

On Windows **shutil.copyfile()** uses a bigger default buffer size (1 MiB instead of 64 KiB) and a **memoryview()**-based variant of **shutil.copyfileobj()** is used.

If the fast-copy operation fails and no data was written in the destination file then shutil will silently fallback on using less efficient **copyfileobj()** function internally.

Changed in version 3.8.

copytree example

An example that uses the **ignore_patterns()** helper:

```
from shutil import copytree, ignore_patterns

copytree(source, destination, ignore=ignore_patterns('*.
```

This will copy everything except `.pyc` files and files or directories whose name starts with `tmp`.

Another example that uses the *ignore* argument to add a logging call:

```
from shutil import copytree
import logging

def _logpath(path, names):
    logging.info('Working in %s', path)
```

```
    return []   # nothing will be ignored

copytree(source, destination, ignore=_logpath)
```

rmtree example

This example shows how to remove a directory tree on Windows where some of the files have their read-only bit set. It uses the onerror callback to clear the readonly bit and reattempt the remove. Any subsequent failure will propagate.

```
import os, stat
import shutil

def remove_readonly(func, path, _):
    "Clear the readonly bit and reattempt the removal"
    os.chmod(path, stat.S_IWRITE)
    func(path)

shutil.rmtree(directory, onerror=remove_readonly)
```

Archiving operations

New in version 3.2.

Changed in version 3.5: Added support for the *xztar* format.

High-level utilities to create and read compressed and archived files are also provided. They rely on the **zipfile** and **tarfile** modules.

shutil.make_archive(*base_name*, *format*[, *root_dir*[, *base_dir*[, *verbose*[, *dry_run*[, *owner*[, *group*[, *logger*]]]]]]])

Create an archive file (such as zip or tar) and return its name.

base_name is the name of the file to create, including the path, minus any format-specific extension. *format* is the archive format: one of “zip” (if the **zlib** module is available), “tar”, “gztar” (if the **zlib** module is available), “bztar” (if the **bz2**

module is available), or “xztar” (if the **lzma** module is available).

root_dir is a directory that will be the root directory of the archive, all paths in the archive will be relative to it; for example, we typically chdir into *root_dir* before creating the archive.

base_dir is the directory where we start archiving from; i.e. *base_dir* will be the common prefix of all files and directories in the archive. *base_dir* must be given relative to *root_dir*. See Archiving example with base_dir for how to use *base_dir* and *root_dir* together.

root_dir and *base_dir* both default to the current directory.

If *dry_run* is true, no archive is created, but the operations that would be executed are logged to *logger*.

owner and *group* are used when creating a tar archive. By default, uses the current owner and group.

logger must be an object compatible with **PEP 282** [https://peps.python.org/pep-0282/], usually an instance of **logging.Logger**.

The *verbose* argument is unused and deprecated.

Raises an auditing event `shutil.make_archive` with arguments `base_name`, `format`, `root_dir`, `base_dir`.

Note

This function is not thread-safe when custom archivers registered with **register_archive_format()** are used. In this case it temporarily changes the current working directory of the process to perform archiving.

Changed in version 3.8: The modern pax (POSIX.1-2001) format is now used instead of the legacy GNU format for archives created with `format="tar"`.

Changed in version 3.10.6: This function is now made thread-safe during creation of standard `.zip` and tar archives.

shutil.get_archive_formats()

Return a list of supported formats for archiving. Each element of the returned sequence is a tuple `(name, description)`.

By default **shutil** provides these formats:

- *zip*: ZIP file (if the **zlib** module is available).
- *tar*: Uncompressed tar file. Uses POSIX.1-2001 pax format for new archives.
- *gztar*: gzip'ed tar-file (if the **zlib** module is available).
- *bztar*: bzip2'ed tar-file (if the **bz2** module is available).
- *xztar*: xz'ed tar-file (if the **lzma** module is available).

You can register new formats or provide your own archiver for any existing formats, by using **register_archive_format()**.

shutil.register_archive_format(*name*, *function*[, *extra_args*[, *description*]])

Register an archiver for the format *name*.

function is the callable that will be used to unpack archives. The callable will receive the *base_name* of the file to create, followed by the *base_dir* (which defaults to **os.curdir**) to start archiving from. Further arguments are passed as keyword arguments: *owner*, *group*, *dry_run* and *logger* (as passed in **make_archive()**).

If given, *extra_args* is a sequence of `(name, value)` pairs that will be used as extra keywords arguments when the archiver callable is used.

description is used by **get_archive_formats()** which returns the list of archivers. Defaults to an empty string.

shutil.unregister_archive_format(*name*)

Remove the archive format *name* from the list of supported formats.

shutil.unpack_archive(*filename*[, *extract_dir*[, *format*]])

Unpack an archive. *filename* is the full path of the archive.

extract_dir is the name of the target directory where the archive is unpacked. If not provided, the current working directory is used.

format is the archive format: one of “zip”, “tar”, “gztar”, “bztar”, or “xztar”. Or any other format registered with **`register_unpack_format()`**. If not provided, **`unpack_archive()`** will use the archive file name extension and see if an unpacker was registered for that extension. In case none is found, a **`ValueError`** is raised.

Raises an auditing event `shutil.unpack_archive` with arguments `filename`, `extract_dir`, `format`.

Warning

Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of the path specified in the *extract_dir* argument, e.g. members that have absolute filenames starting with “/” or filenames with two dots “..”.

Changed in version 3.7: Accepts a path-like object for *filename* and *extract_dir*.

shutil.register_unpack_format(*name*, *extensions*, *function*[, *extra_args*[, *description*]])

Registers an unpack format. *name* is the name of the format and *extensions* is a list of extensions corresponding to the format, like `.zip` for Zip files.

function is the callable that will be used to unpack archives. The callable will receive the path of the archive, followed by

the directory the archive must be extracted to.

When provided, *extra_args* is a sequence of `(name, value)` tuples that will be passed as keywords arguments to the callable.

description can be provided to describe the format, and will be returned by the **`get_unpack_formats()`** function.

shutil.unregister_unpack_format(*name*)

Unregister an unpack format. *name* is the name of the format.

shutil.get_unpack_formats()

Return a list of all registered formats for unpacking. Each element of the returned sequence is a tuple `(name, extensions, description)`.

By default **`shutil`** provides these formats:

- *zip*: ZIP file (unpacking compressed files works only if the corresponding module is available).
- *tar*: uncompressed tar file.
- *gztar*: gzip'ed tar-file (if the **`zlib`** module is available).
- *bztar*: bzip2'ed tar-file (if the **`bz2`** module is available).
- *xztar*: xz'ed tar-file (if the **`lzma`** module is available).

You can register new formats or provide your own unpacker for any existing formats, by using **`register_unpack_format()`**.

Archiving example

In this example, we create a gzip'ed tar-file archive containing all files found in the `.ssh` directory of the user:

```
>>> from shutil import make_archive
>>> import os
>>> archive_name = os.path.expanduser(os.path.join('~',
>>> root_dir = os.path.expanduser(os.path.join('~', '.ss
```

```
>>> make_archive(archive_name, 'gztar', root_dir)
'/Users/tarek/myarchive.tar.gz'
```

The resulting archive contains:

```
$ tar -tzvf /Users/tarek/myarchive.tar.gz
drwx------ tarek/staff       0 2010-02-01 16:23:40 ./
-rw-r--r-- tarek/staff     609 2008-06-09 13:26:54 ./aut
-rwxr-xr-x tarek/staff      65 2008-06-09 13:26:54 ./cor
-rwx------ tarek/staff     668 2008-06-09 13:26:54 ./id_
-rwxr-xr-x tarek/staff     609 2008-06-09 13:26:54 ./id_
-rw------- tarek/staff    1675 2008-06-09 13:26:54 ./id_
-rw-r--r-- tarek/staff     397 2008-06-09 13:26:54 ./id_
-rw-r--r-- tarek/staff   37192 2010-02-06 18:23:10 ./kno
```

Archiving example with *base_dir*

In this example, similar to the one above, we show how to use **`make_archive()`**, but this time with the usage of *base_dir*. We now have the following directory structure:

```
$ tree tmp
tmp
    root
        structure
            content
                please_add.txt
            do_not_add.txt
```

In the final archive, `please_add.txt` should be included, but `do_not_add.txt` should not. Therefore we use the following:

```
>>> from shutil import make_archive
>>> import os
>>> archive_name = os.path.expanduser(os.path.join('~',
>>> make_archive(
...     archive_name,
...     'tar',
...     root_dir='tmp/root',
...     base_dir='structure/content',
```

```
... )
'/Users/tarek/my_archive.tar'
```

Listing the files in the resulting archive gives us:

```
$ python -m tarfile -l /Users/tarek/myarchive.tar
structure/content/
structure/content/please_add.txt
```

Querying the size of the output terminal

shutil.get_terminal_size(*fallback = (columns, lines)*)

Get the size of the terminal window.

For each of the two dimensions, the environment variable, `COLUMNS` and `LINES` respectively, is checked. If the variable is defined and the value is a positive integer, it is used.

When `COLUMNS` or `LINES` is not defined, which is the common case, the terminal connected to **`sys.__stdout__`** is queried by invoking **`os.get_terminal_size()`**.

If the terminal size cannot be successfully queried, either because the system doesn't support querying, or because we are not connected to a terminal, the value given in `fallback` parameter is used. `fallback` defaults to `(80, 24)` which is the default size used by many terminal emulators.

The value returned is a named tuple of type **`os.terminal_size`**.

See also: The Single UNIX Specification, Version 2, Other Environment Variables [https://pubs.opengroup.org/onlinepubs/7908799/xbd/envvar.html#tag_002_003].

New in version 3.3.

Changed in version 3.11: The `fallback` values are also used if **`os.get_terminal_size()`** returns zeroes.

Data Persistence

The modules described in this chapter support storing Python data in a persistent form on disk. The **pickle** and **marshal** modules can turn many Python data types into a stream of bytes and then recreate the objects from the bytes. The various DBM-related modules support a family of hash-based file formats that store a mapping of strings to other strings.

The list of modules described in this chapter is:

- **pickle** — Python object serialization
  - Relationship to other Python modules
    - Comparison with **marshal**
    - Comparison with **json**
  - Data stream format
  - Module Interface
  - What can be pickled and unpickled?
  - Pickling Class Instances
    - Persistence of External Objects
    - Dispatch Tables
    - Handling Stateful Objects
  - Custom Reduction for Types, Functions, and Other Objects
  - Out-of-band Buffers
    - Provider API
    - Consumer API
    - Example
  - Restricting Globals
  - Performance

    - Examples
- **copyreg** — Register **pickle** support functions
    - Example
- **shelve** — Python object persistence
    - Restrictions
    - Example
- **marshal** — Internal Python object serialization
- **dbm** — Interfaces to Unix “databases”
    - **dbm.gnu** — GNU’s reinterpretation of dbm
    - **dbm.ndbm** — Interface based on ndbm
    - **dbm.dumb** — Portable DBM implementation
- **sqlite3** — DB-API 2.0 interface for SQLite databases

`pickle` — Python object serialization

Source code: Lib/pickle.py [https://github.com/python/cpython/tree/3.11/Lib/pickle.py]

The `pickle` module implements binary protocols for serializing and de-serializing a Python object structure. *"Pickling"* is the process whereby a Python object hierarchy is converted into a byte stream, and *"unpickling"* is the inverse operation, whereby a byte stream (from a binary file or bytes-like object) is converted back into an object hierarchy. Pickling (and unpickling) is alternatively known as "serialization", "marshalling," 1 or "flattening"; however, to avoid confusion, the terms used here are "pickling" and "unpickling".

Warning

The `pickle` module **is not secure**. Only unpickle data you trust.

It is possible to construct malicious pickle data which will **execute arbitrary code during unpickling**. Never unpickle data that could have come from an untrusted source, or that could have been tampered with.

Consider signing data with `hmac` if you need to ensure that it has not been tampered with.

Safer serialization formats such as `json` may be more appropriate if you are processing untrusted data. See Comparison with json.

Relationship to other Python modules

Comparison with `marshal`

Python has a more primitive serialization module called **`marshal`**, but in general **`pickle`** should always be the preferred way to serialize Python objects. **`marshal`** exists primarily to support Python's `.pyc` files.

The **`pickle`** module differs from **`marshal`** in several significant ways:

- The **`pickle`** module keeps track of the objects it has already serialized, so that later references to the same object won't be serialized again. **`marshal`** doesn't do this.

  This has implications both for recursive objects and object sharing. Recursive objects are objects that contain references to themselves. These are not handled by marshal, and in fact, attempting to marshal recursive objects will crash your Python interpreter. Object sharing happens when there are multiple references to the same object in different places in the object hierarchy being serialized. **`pickle`** stores such objects only once, and ensures that all other references point to the master copy. Shared objects remain shared, which can be very important for mutable objects.

- **`marshal`** cannot be used to serialize user-defined classes and their instances. **`pickle`** can save and restore class instances transparently, however the class definition must be importable and live in the same module as when the object was stored.

- The **`marshal`** serialization format is not guaranteed to be portable across Python versions. Because its primary job in life is to support `.pyc` files, the Python implementers reserve the right to change the serialization format in non-backwards compatible ways should the need arise. The **`pickle`** serialization format is guaranteed to be backwards compatible across Python releases provided a compatible pickle protocol is chosen and pickling and unpickling code deals with Python 2 to Python 3 type differences if your data is crossing that unique breaking change language boundary.

Comparison with `json`

There are fundamental differences between the pickle protocols and JSON (JavaScript Object Notation) [https://json.org]:

- JSON is a text serialization format (it outputs unicode text, although most of the time it is then encoded to `utf-8`), while pickle is a binary serialization format;
- JSON is human-readable, while pickle is not;
- JSON is interoperable and widely used outside of the Python ecosystem, while pickle is Python-specific;
- JSON, by default, can only represent a subset of the Python built-in types, and no custom classes; pickle can represent an extremely large number of Python types (many of them automatically, by clever usage of Python's introspection facilities; complex cases can be tackled by implementing specific object APIs);
- Unlike pickle, deserializing untrusted JSON does not in itself create an arbitrary code execution vulnerability.

See also

The **`json`** module: a standard library module allowing JSON serialization and deserialization.

Data stream format

The data format used by **`pickle`** is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as JSON or XDR (which can't represent pointer sharing); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

By default, the **`pickle`** data format uses a relatively compact binary representation. If you need optimal size characteristics, you can efficiently compress pickled data.

The module **`pickletools`** contains tools for analyzing data streams generated by **`pickle`**. **`pickletools`** source code has

extensive comments about opcodes used by pickle protocols.

There are currently 6 different protocols which can be used for pickling. The higher the protocol used, the more recent the version of Python needed to read the pickle produced.

- Protocol version 0 is the original “human-readable” protocol and is backwards compatible with earlier versions of Python.
- Protocol version 1 is an old binary format which is also compatible with earlier versions of Python.
- Protocol version 2 was introduced in Python 2.3. It provides much more efficient pickling of new-style classes. Refer to **PEP 307** [https://peps.python.org/pep-0307/] for information about improvements brought by protocol 2.
- Protocol version 3 was added in Python 3.0. It has explicit support for **`bytes`** objects and cannot be unpickled by Python 2.x. This was the default protocol in Python 3.0–3.7.
- Protocol version 4 was added in Python 3.4. It adds support for very large objects, pickling more kinds of objects, and some data format optimizations. It is the default protocol starting with Python 3.8. Refer to **PEP 3154** [https://peps.python.org/pep-3154/] for information about improvements brought by protocol 4.
- Protocol version 5 was added in Python 3.8. It adds support for out-of-band data and speedup for in-band data. Refer to **PEP 574** [https://peps.python.org/pep-0574/] for information about improvements brought by protocol 5.

Note

Serialization is a more primitive notion than persistence; although **`pickle`** reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) issue of concurrent access to persistent objects. The **`pickle`** module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. Perhaps the most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The **`shelve`** module provides a simple interface to

pickle and unpickle objects on DBM-style database files.

Module Interface

To serialize an object hierarchy, you simply call the **dumps()** function. Similarly, to de-serialize a data stream, you call the **loads()** function. However, if you want more control over serialization and de-serialization, you can create a **Pickler** or an **Unpickler** object, respectively.

The **pickle** module provides the following constants:

pickle.HIGHEST_PROTOCOL

An integer, the highest protocol version available. This value can be passed as a *protocol* value to functions **dump()** and **dumps()** as well as the **Pickler** constructor.

pickle.DEFAULT_PROTOCOL

An integer, the default protocol version used for pickling. May be less than **HIGHEST_PROTOCOL**. Currently the default protocol is 4, first introduced in Python 3.4 and incompatible with previous versions.

Changed in version 3.0: The default protocol is 3.

Changed in version 3.8: The default protocol is 4.

The **pickle** module provides the following functions to make the pickling process more convenient:

pickle.dump(*obj*, *file*, *protocol*=*None*, ***, *fix_imports*=*True*, *buffer_callback*=*None*)

Write the pickled representation of the object *obj* to the open file object *file*. This is equivalent to `Pickler(file, protocol).dump(obj)`.

Arguments *file*, *protocol*, *fix_imports* and *buffer_callback* have the same meaning as in the **Pickler** constructor.

Changed in version 3.8: The *buffer_callback* argument was added.

pickle.dumps(*obj*, *protocol=None*, ***, *fix_imports=True*, *buffer_callback=None*)

Return the pickled representation of the object *obj* as a **bytes** object, instead of writing it to a file.

Arguments *protocol*, *fix_imports* and *buffer_callback* have the same meaning as in the **Pickler** constructor.

Changed in version 3.8: The *buffer_callback* argument was added.

pickle.load(*file*, ***, *fix_imports=True*, *encoding='ASCII'*, *errors='strict'*, *buffers=None*)

Read the pickled representation of an object from the open file object *file* and return the reconstituted object hierarchy specified therein. This is equivalent to `Unpickler(file).load()`.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled representation of the object are ignored.

Arguments *file*, *fix_imports*, *encoding*, *errors*, *strict* and *buffers* have the same meaning as in the **Unpickler** constructor.

Changed in version 3.8: The *buffers* argument was added.

pickle.loads(*data*, */*, ***, *fix_imports=True*, *encoding='ASCII'*, *errors='strict'*, *buffers=None*)

Return the reconstituted object hierarchy of the pickled representation *data* of an object. *data* must be a bytes-like object.

The protocol version of the pickle is detected automatically, so no protocol argument is needed. Bytes past the pickled representation of the object are ignored.

Arguments *fix_imports*, *encoding*, *errors*, *strict* and *buffers* have the same meaning as in the **Unpickler** constructor.

Changed in version 3.8: The *buffers* argument was added.

The **pickle** module defines three exceptions:

exception pickle.PickleError

Common base class for the other pickling exceptions. It inherits **Exception**.

exception pickle.PicklingError

Error raised when an unpicklable object is encountered by **Pickler**. It inherits **PickleError**.

Refer to What can be pickled and unpickled? to learn what kinds of objects can be pickled.

exception pickle.UnpicklingError

Error raised when there is a problem unpickling an object, such as a data corruption or a security violation. It inherits **PickleError**.

Note that other exceptions may also be raised during unpickling, including (but not necessarily limited to) AttributeError, EOFError, ImportError, and IndexError.

The **pickle** module exports three classes, **Pickler**, **Unpickler** and **PickleBuffer**:

class pickle.Pickler(*file*, *protocol*=*None*, *, *fix_imports*=*True*, *buffer_callback*=*None*)

This takes a binary file for writing a pickle data stream.

The optional *protocol* argument, an integer, tells the pickler to use the given protocol; supported protocols are 0 to **HIGHEST_PROTOCOL**. If not specified, the default is **DEFAULT_PROTOCOL**. If a negative number is specified, **HIGHEST_PROTOCOL** is selected.

The *file* argument must have a write() method that accepts a single bytes argument. It can thus be an on-disk file opened for binary writing, an **io.BytesIO** instance, or any other custom object that meets this interface.

If *fix_imports* is true and *protocol* is less than 3, pickle will try to map the new Python 3 names to the old module names used in Python 2, so that the pickle data stream is readable with Python 2.

If *buffer_callback* is None (the default), buffer views are serialized into *file* as part of the pickle stream.

If *buffer_callback* is not None, then it can be called any number of times with a buffer view. If the callback returns a false value (such as None), the given buffer is out-of-band; otherwise the buffer is serialized in-band, i.e. inside the pickle stream.

It is an error if *buffer_callback* is not None and *protocol* is None or smaller than 5.

Changed in version 3.8: The *buffer_callback* argument was added.

dump(*obj*)

Write the pickled representation of *obj* to the open file object given in the constructor.

persistent_id(*obj*)

Do nothing by default. This exists so a subclass can override it.

If **persistent_id()** returns `None`, *obj* is pickled as usual. Any other value causes **Pickler** to emit the returned value as a persistent ID for *obj*. The meaning of this persistent ID should be defined by **Unpickler.persistent_load()**. Note that the value returned by **persistent_id()** cannot itself have a persistent ID.

See Persistence of External Objects for details and examples of uses.

dispatch_table

A pickler object's dispatch table is a registry of *reduction functions* of the kind which can be declared using **copyreg.pickle()**. It is a mapping whose keys are classes and whose values are reduction functions. A reduction function takes a single argument of the associated class and should conform to the same interface as a **__reduce__()** method.

By default, a pickler object will not have a **dispatch_table** attribute, and it will instead use the global dispatch table managed by the **copyreg** module. However, to customize the pickling for a specific pickler object one can set the **dispatch_table** attribute to a dict-like object. Alternatively, if a subclass of **Pickler** has a **dispatch_table** attribute then this will be used as the default dispatch table for instances of that class.

See Dispatch Tables for usage examples.

New in version 3.3.

reducer_override(*obj*)

Special reducer that can be defined in **Pickler** subclasses. This method has priority over any reducer in the **dispatch_table**. It should conform to the same interface as a **__reduce__()** method, and can optionally return `NotImplemented` to fallback on **dispatch_table**-registered reducers to pickle `obj`.

For a detailed example, see Custom Reduction for Types, Functions, and Other Objects.

New in version 3.8.

fast

Deprecated. Enable fast mode if set to a true value. The fast mode disables the usage of memo, therefore speeding the pickling process by not generating superfluous PUT opcodes. It should not be used with self-referential objects, doing otherwise will cause **Pickler** to recurse infinitely.

Use **pickletools.optimize()** if you need more compact pickles.

class pickle.Unpickler(*file*, *, *fix_imports* = *True*, *encoding* = *'ASCII'*, *errors* = *'strict'*, *buffers* = *None*)

This takes a binary file for reading a pickle data stream.

The protocol version of the pickle is detected automatically, so no protocol argument is needed.

The argument *file* must have three methods, a read() method that takes an integer argument, a readinto() method that takes a buffer argument and a readline() method that requires no arguments, as in the **io.BufferedIOBase** interface. Thus *file* can be an on-disk file opened for binary reading, an **io.BytesIO** object, or any other custom object that meets this interface.

The optional arguments *fix_imports*, *encoding* and *errors* are used to control compatibility support for pickle stream generated by Python 2. If *fix_imports* is true, pickle will try to map the old Python 2 names to the new names used in Python 3. The *encoding* and *errors* tell pickle how to decode 8-bit string instances pickled by Python 2; these default to 'ASCII' and 'strict', respectively. The *encoding* can be 'bytes' to read these 8-bit string instances as bytes objects. Using `encoding='latin1'` is required for unpickling NumPy arrays and instances of **datetime**, **date** and **time** pickled by Python 2.

If *buffers* is None (the default), then all data necessary for deserialization must be contained in the pickle stream. This means that the *buffer_callback* argument was None when a

Pickler was instantiated (or when **dump()** or **dumps()** was called).

If *buffers* is not None, it should be an iterable of buffer-enabled objects that is consumed each time the pickle stream references an out-of-band buffer view. Such buffers have been given in order to the *buffer_callback* of a Pickler object.

Changed in version 3.8: The *buffers* argument was added.

load()

Read the pickled representation of an object from the open file object given in the constructor, and return the reconstituted object hierarchy specified therein. Bytes past the pickled representation of the object are ignored.

persistent_load(*pid*)

Raise an **UnpicklingError** by default.

If defined, **persistent_load()** should return the object specified by the persistent ID *pid*. If an invalid persistent ID is encountered, an **UnpicklingError** should be raised.

See Persistence of External Objects for details and examples of uses.

find_class(*module*, *name*)

Import *module* if necessary and return the object called *name* from it, where the *module* and *name* arguments are **str** objects. Note, unlike its name suggests, **find_class()** is also used for finding functions.

Subclasses may override this to gain control over what type of objects and how they can be loaded, potentially reducing security risks. Refer to Restricting Globals for details.

Raises an auditing event `pickle.find_class` with

arguments `module, name`.

class pickle.PickleBuffer(*buffer*)

A wrapper for a buffer representing picklable data. *buffer* must be a buffer-providing object, such as a bytes-like object or a N-dimensional array.

`PickleBuffer` is itself a buffer provider, therefore it is possible to pass it to other APIs expecting a buffer-providing object, such as **`memoryview`**.

`PickleBuffer` objects can only be serialized using pickle protocol 5 or higher. They are eligible for out-of-band serialization.

New in version 3.8.

raw()

Return a **`memoryview`** of the memory area underlying this buffer. The returned object is a one-dimensional, C-contiguous memoryview with format `B` (unsigned bytes). **`BufferError`** is raised if the buffer is neither C- nor Fortran-contiguous.

release()

Release the underlying buffer exposed by the PickleBuffer object.

What can be pickled and unpickled?

The following types can be pickled:

- `None`, `True`, and `False`;
- integers, floating-point numbers, complex numbers;
- strings, bytes, bytearrays;
- tuples, lists, sets, and dictionaries containing only picklable objects;
- functions (built-in and user-defined) accessible from the top level of a module (using **`def`**, not **`lambda`**);

- classes accessible from the top level of a module;
- instances of such classes whose the result of calling **`__getstate__()`** is picklable (see section Pickling Class Instances for details).

Attempts to pickle unpicklable objects will raise the **`PicklingError`** exception; when this happens, an unspecified number of bytes may have already been written to the underlying file. Trying to pickle a highly recursive data structure may exceed the maximum recursion depth, a **`RecursionError`** will be raised in this case. You can carefully raise this limit with **`sys.setrecursionlimit()`**.

Note that functions (built-in and user-defined) are pickled by fully qualified name, not by value. 2 This means that only the function name is pickled, along with the name of the containing module and classes. Neither the function's code, nor any of its function attributes are pickled. Thus the defining module must be importable in the unpickling environment, and the module must contain the named object, otherwise an exception will be raised. 3

Similarly, classes are pickled by fully qualified name, so the same restrictions in the unpickling environment apply. Note that none of the class's code or data is pickled, so in the following example the class attribute `attr` is not restored in the unpickling environment:

```
class Foo:
    attr = 'A class attribute'

picklestring = pickle.dumps(Foo)
```

These restrictions are why picklable functions and classes must be defined at the top level of a module.

Similarly, when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods to the class and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions

can be made by the class's **`__setstate__()`** method.

Pickling Class Instances

In this section, we describe the general mechanisms available to you to define, customize, and control how class instances are pickled and unpickled.

In most cases, no additional code is needed to make instances picklable. By default, pickle will retrieve the class and the attributes of an instance via introspection. When a class instance is unpickled, its **`__init__()`** method is usually *not* invoked. The default behaviour first creates an uninitialized instance and then restores the saved attributes. The following code shows an implementation of this behaviour:

```
def save(obj):
    return (obj.__class__, obj.__dict__)

def restore(cls, attributes):
    obj = cls.__new__(cls)
    obj.__dict__.update(attributes)
    return obj
```

Classes can alter the default behaviour by providing one or several special methods:

object._getnewargs_ex_()

In protocols 2 and newer, classes that implements the **`__getnewargs_ex__()`** method can dictate the values passed to the **`__new__()`** method upon unpickling. The method must return a pair `(args, kwargs)` where *args* is a tuple of positional arguments and *kwargs* a dictionary of named arguments for constructing the object. Those will be passed to the **`__new__()`** method upon unpickling.

You should implement this method if the **`__new__()`** method of your class requires keyword-only arguments. Otherwise, it is recommended for compatibility to implement

__getnewargs__().

Changed in version 3.6: **__getnewargs_ex__()** is now used in protocols 2 and 3.

object._getnewargs_()

This method serves a similar purpose as **__getnewargs_ex__()**, but supports only positional arguments. It must return a tuple of arguments `args` which will be passed to the **__new__()** method upon unpickling.

__getnewargs__() will not be called if **__getnewargs_ex__()** is defined.

Changed in version 3.6: Before Python 3.6, **__getnewargs__()** was called instead of **__getnewargs_ex__()** in protocols 2 and 3.

object._getstate_()

Classes can further influence how their instances are pickled by overriding the method **__getstate__()**. It is called and the returned object is pickled as the contents for the instance, instead of a default state. There are several cases:

- For a class that has no instance **__dict__** and no **__slots__**, the default state is `None`.
- For a class that has an instance **__dict__** and no **__slots__**, the default state is `self.__dict__`.
- For a class that has an instance **__dict__** and **__slots__**, the default state is a tuple consisting of two dictionaries: `self.__dict__`, and a dictionary mapping slot names to slot values. Only slots that have a value are included in the latter.
- For a class that has **__slots__** and no instance **__dict__**, the default state is a tuple whose first item is `None` and whose second item is a dictionary mapping slot names to slot values described in the previous bullet.

Changed in version 3.11: Added the default implementation of

the `__getstate__()` method in the **`object`** class.

object._setstate_(*state*)

Upon unpickling, if the class defines **`__setstate__()`**, it is called with the unpickled state. In that case, there is no requirement for the state object to be a dictionary. Otherwise, the pickled state must be a dictionary and its items are assigned to the new instance's dictionary.

Note

If **`__getstate__()`** returns a false value, the **`__setstate__()`** method will not be called upon unpickling.

Refer to the section Handling Stateful Objects for more information about how to use the methods **`__getstate__()`** and **`__setstate__()`**.

Note

At unpickling time, some methods like **`__getattr__()`**, **`__getattribute__()`**, or **`__setattr__()`** may be called upon the instance. In case those methods rely on some internal invariant being true, the type should implement **`__new__()`** to establish such an invariant, as **`__init__()`** is not called when unpickling an instance.

As we shall see, pickle does not use directly the methods described above. In fact, these methods are part of the copy protocol which implements the **`__reduce__()`** special method. The copy protocol provides a unified interface for retrieving the data necessary for pickling and copying objects. 4

Although powerful, implementing **`__reduce__()`** directly in your classes is error prone. For this reason, class designers should use the high-level interface (i.e., **`__getnewargs_ex__()`**, **`__getstate__()`** and **`__setstate__()`**) whenever possible. We

will show, however, cases where using **`__reduce__()`** is the only option or leads to more efficient pickling or both.

object._reduce_()

The interface is currently defined as follows. The **`__reduce__()`** method takes no argument and shall return either a string or preferably a tuple (the returned object is often referred to as the “reduce value”).

If a string is returned, the string should be interpreted as the name of a global variable. It should be the object’s local name relative to its module; the pickle module searches the module namespace to determine the object’s module. This behaviour is typically useful for singletons.

When a tuple is returned, it must be between two and six items long. Optional items can either be omitted, or `None` can be provided as their value. The semantics of each item are in order:

- A callable object that will be called to create the initial version of the object.
- A tuple of arguments for the callable object. An empty tuple must be given if the callable does not accept any argument.
- Optionally, the object’s state, which will be passed to the object’s **`__setstate__()`** method as previously described. If the object has no such method then, the value must be a dictionary and it will be added to the object’s **`__dict__`** attribute.
- Optionally, an iterator (and not a sequence) yielding successive items. These items will be appended to the object either using `obj.append(item)` or, in batch, using `obj.extend(list_of_items)`. This is primarily used for list subclasses, but may be used by other classes as long as they have **`append()`** and **`extend()`** methods with the appropriate signature. (Whether **`append()`** or **`extend()`** is used depends on

which pickle protocol version is used as well as the number of items to append, so both must be supported.)

- Optionally, an iterator (not a sequence) yielding successive key-value pairs. These items will be stored to the object using `obj[key] = value`. This is primarily used for dictionary subclasses, but may be used by other classes as long as they implement **`__setitem__()`**.

- Optionally, a callable with a `(obj, state)` signature. This callable allows the user to programmatically control the state-updating behavior of a specific object, instead of using `obj`'s static **`__setstate__()`** method. If not `None`, this callable will have priority over `obj`'s **`__setstate__()`**.

  New in version 3.8: The optional sixth tuple item, `(obj, state)`, was added.

object.__reduce_ex__(*protocol*)

Alternatively, a **`__reduce_ex__()`** method may be defined. The only difference is this method should take a single integer argument, the protocol version. When defined, pickle will prefer it over the **`__reduce__()`** method. In addition, **`__reduce__()`** automatically becomes a synonym for the extended version. The main use for this method is to provide backwards-compatible reduce values for older Python releases.

Persistence of External Objects

For the benefit of object persistence, the **`pickle`** module supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a persistent ID, which should be either a string of alphanumeric characters (for protocol 0) 5 or just an arbitrary object (for any newer protocol).

The resolution of such persistent IDs is not defined by the **`pickle`**

module; it will delegate this resolution to the user-defined methods on the pickler and unpickler, **`persistent_id()`** and **`persistent_load()`** respectively.

To pickle objects that have an external persistent ID, the pickler must have a custom **`persistent_id()`** method that takes an object as an argument and returns either `None` or the persistent ID for that object. When `None` is returned, the pickler simply pickles the object as normal. When a persistent ID string is returned, the pickler will pickle that object, along with a marker so that the unpickler will recognize it as a persistent ID.

To unpickle external objects, the unpickler must have a custom **`persistent_load()`** method that takes a persistent ID object and returns the referenced object.

Here is a comprehensive example presenting how persistent ID can be used to pickle external objects by reference.

```
# Simple example presenting how persistent ID can be use
# external objects by reference.

import pickle
import sqlite3
from collections import namedtuple

# Simple class representing a record in our database.
MemoRecord = namedtuple("MemoRecord", "key, task")

class DBPickler(pickle.Pickler):

    def persistent_id(self, obj):
        # Instead of pickling MemoRecord as a regular cl
        # persistent ID.
        if isinstance(obj, MemoRecord):
            # Here, our persistent ID is simply a tuple,
            # key, which refers to a specific record in
            return ("MemoRecord", obj.key)
        else:
            # If obj does not have a persistent ID, retu
```

```
            # needs to be pickled as usual.
            return None

class DBUnpickler(pickle.Unpickler):

if __name__ == '__main__':
    main()
```

Dispatch Tables

If one wants to customize pickling of some classes without disturbing any other code which depends on pickling, then one can create a pickler with a private dispatch table.

The global dispatch table managed by the **copyreg** module is available as **copyreg.dispatch_table**. Therefore, one may choose to use a modified copy of **copyreg.dispatch_table** as a private dispatch table.

For example

```
f = io.BytesIO()
p = pickle.Pickler(f)
p.dispatch_table = copyreg.dispatch_table.copy()
p.dispatch_table[SomeClass] = reduce_SomeClass
```

creates an instance of **pickle.Pickler** with a private dispatch table which handles the `SomeClass` class specially. Alternatively, the code

```
class MyPickler(pickle.Pickler):
    dispatch_table = copyreg.dispatch_table.copy()
    dispatch_table[SomeClass] = reduce_SomeClass
f = io.BytesIO()
p = MyPickler(f)
```

does the same but all instances of `MyPickler` will by default share the private dispatch table. On the other hand, the code

```
copyreg.pickle(SomeClass, reduce_SomeClass)
f = io.BytesIO()
p = pickle.Pickler(f)
```

modifies the global dispatch table shared by all users of the **copyreg** module.

Handling Stateful Objects

Here's an example that shows how to modify pickling behavior for a class. The **TextReader** class opens a text file, and returns the line number and line contents each time its **readline()** method is called. If a **TextReader** instance is pickled, all attributes *except* the file object member are saved. When the instance is unpickled, the file is reopened, and reading resumes from the last location. The **__setstate__()** and **__getstate__()** methods are used to implement this behavior.

```
class TextReader:
    """Print and number lines in a text file."""
```

```
    def __init__(self, filename):
        self.filename = filename
        self.file = open(filename)
        self.lineno = 0

    def readline(self):
        self.lineno += 1
        line = self.file.readline()
        if not line:
            return None
        if line.endswith('\n'):
            line = line[:-1]
        return "%i: %s" % (self.lineno, line)

    def __getstate__(self):
        # Copy the object's state from self.__dict__ whi
        # all our instance attributes. Always use the di
        # method to avoid modifying the original state.
        state = self.__dict__.copy()
        # Remove the unpicklable entries.
        del state['file']
        return state

    def __setstate__(self, state):
        # Restore instance attributes (i.e., filename ar
        self.__dict__.update(state)
        # Restore the previously opened file's state. To
        # reopen it and read from it until the line coun
        file = open(self.filename)
        for _ in range(self.lineno):
            file.readline()
        # Finally, save the file.
        self.file = file
```

A sample usage might be something like this:

```
>>> reader = TextReader("hello.txt")
>>> reader.readline()
```

```
'1: Hello world!'
>>> reader.readline()
'2: I am line number two.'
>>> new_reader = pickle.loads(pickle.dumps(reader))
>>> new_reader.readline()
'3: Goodbye!'
```

Custom Reduction for Types, Functions, and Other Objects

New in version 3.8.

Sometimes, **dispatch_table** may not be flexible enough. In particular we may want to customize pickling based on another criterion than the object's type, or we may want to customize the pickling of functions and classes.

For those cases, it is possible to subclass from the **Pickler** class and implement a **reducer_override()** method. This method can return an arbitrary reduction tuple (see **__reduce__()**). It can alternatively return `NotImplemented` to fallback to the traditional behavior.

If both the **dispatch_table** and **reducer_override()** are defined, then **reducer_override()** method takes priority.

Note

For performance reasons, **reducer_override()** may not be called for the following objects: `None`, `True`, `False`, and exact instances of **int**, **float**, **bytes**, **str**, **dict**, **set**, **frozenset**, **list** and **tuple**.

Here is a simple example where we allow pickling and reconstructing a given class:

```
import io
import pickle
```

```
class MyClass:
    my_attribute = 1

class MyPickler(pickle.Pickler):
    def reducer_override(self, obj):
        """Custom reducer for MyClass."""
        if getattr(obj, "__name__", None) == "MyClass":
            return type, (obj.__name__, obj.__bases__,
                          {'my_attribute': obj.my_attrib
        else:
            # For any other object, fallback to usual re
            return NotImplemented

f = io.BytesIO()
p = MyPickler(f)
p.dump(MyClass)

del MyClass

unpickled_class = pickle.loads(f.getvalue())

assert isinstance(unpickled_class, type)
assert unpickled_class.__name__ == "MyClass"
assert unpickled_class.my_attribute == 1
```

Out-of-band Buffers

New in version 3.8.

In some contexts, the **pickle** module is used to transfer massive amounts of data. Therefore, it can be important to minimize the number of memory copies, to preserve performance and resource consumption. However, normal operation of the **pickle** module, as it transforms a graph-like structure of objects into a sequential stream of bytes, intrinsically involves copying data to and from the pickle stream.

This constraint can be eschewed if both the *provider* (the implementation of the object types to be transferred) and the

consumer (the implementation of the communications system) support the out-of-band transfer facilities provided by pickle protocol 5 and higher.

Provider API

The large data objects to be pickled must implement a **`__reduce_ex__()`** method specialized for protocol 5 and higher, which returns a **`PickleBuffer`** instance (instead of e.g. a **`bytes`** object) for any large data.

A **`PickleBuffer`** object *signals* that the underlying buffer is eligible for out-of-band data transfer. Those objects remain compatible with normal usage of the **`pickle`** module. However, consumers can also opt-in to tell **`pickle`** that they will handle those buffers by themselves.

Consumer API

A communications system can enable custom handling of the **`PickleBuffer`** objects generated when serializing an object graph.

On the sending side, it needs to pass a *buffer_callback* argument to **`Pickler`** (or to the **`dump()`** or **`dumps()`** function), which will be called with each **`PickleBuffer`** generated while pickling the object graph. Buffers accumulated by the *buffer_callback* will not see their data copied into the pickle stream, only a cheap marker will be inserted.

On the receiving side, it needs to pass a *buffers* argument to **`Unpickler`** (or to the **`load()`** or **`loads()`** function), which is an iterable of the buffers which were passed to *buffer_callback*. That iterable should produce buffers in the same order as they were passed to *buffer_callback*. Those buffers will provide the data expected by the reconstructors of the objects whose pickling produced the original **`PickleBuffer`** objects.

Between the sending side and the receiving side, the communications system is free to implement its own transfer mechanism for out-of-band buffers. Potential optimizations include

the use of shared memory or datatype-dependent compression.

Example

Here is a trivial example where we implement a **bytearray** subclass able to participate in out-of-band buffer pickling:

```
class ZeroCopyByteArray(bytearray):

    def __reduce_ex__(self, protocol):
        if protocol >= 5:
            return type(self)._reconstruct, (PickleBuffe
        else:
            # PickleBuffer is forbidden with pickle prot
            return type(self)._reconstruct, (bytearray(s

    @classmethod
    def _reconstruct(cls, obj):
        with memoryview(obj) as m:
            # Get a handle over the original buffer obje
            obj = m.obj
            if type(obj) is cls:
                # Original buffer object is a ZeroCopyBy
                # as-is.
                return obj
            else:
                return cls(obj)
```

The reconstructor (the `_reconstruct` class method) returns the buffer's providing object if it has the right type. This is an easy way to simulate zero-copy behaviour on this toy example.

On the consumer side, we can pickle those objects the usual way, which when unserialized will give us a copy of the original object:

```
b = ZeroCopyByteArray(b"abc")
data = pickle.dumps(b, protocol=5)
new_b = pickle.loads(data)
print(b == new_b)  # True
```

```
print(b is new_b)  # False: a copy was made
```

But if we pass a *buffer_callback* and then give back the accumulated buffers when unserializing, we are able to get back the original object:

```
b = ZeroCopyByteArray(b"abc")
buffers = []
data = pickle.dumps(b, protocol=5, buffer_callback=buffe
new_b = pickle.loads(data, buffers=buffers)
print(b == new_b)  # True
print(b is new_b)  # True: no copy was made
```

This example is limited by the fact that **`bytearray`** allocates its own memory: you cannot create a **`bytearray`** instance that is backed by another object's memory. However, third-party datatypes such as NumPy arrays do not have this limitation, and allow use of zero-copy pickling (or making as few copies as possible) when transferring between distinct processes or systems.

PEP 574 [https://peps.python.org/pep-0574/] – Pickle protocol 5 with out-of-band data

Restricting Globals

By default, unpickling will import any class or function that it finds in the pickle data. For many applications, this behaviour is unacceptable as it permits the unpickler to import and invoke arbitrary code. Just consider what this hand-crafted pickle data stream does when loaded:

```
>>> import pickle
>>> pickle.loads(b"cos\nsystem\n(S'echo hello world'\ntR
hello world
0
```

In this example, the unpickler imports the **`os.system()`** function

and then apply the string argument “echo hello world”. Although this example is inoffensive, it is not difficult to imagine one that could damage your system.

For this reason, you may want to control what gets unpickled by customizing **`Unpickler.find_class()`**. Unlike its name suggests, **`Unpickler.find_class()`** is called whenever a global (i.e., a class or a function) is requested. Thus it is possible to either completely forbid globals or restrict them to a safe subset.

Here is an example of an unpickler allowing only few safe classes from the **`builtins`** module to be loaded:

```
import builtins
import io
import pickle

safe_builtins = {
    'range',
    'complex',
    'set',
    'frozenset',
    'slice',
}

class RestrictedUnpickler(pickle.Unpickler):

    def find_class(self, module, name):
        # Only allow safe classes from builtins.
        if module == "builtins" and name in safe_builtin
            return getattr(builtins, name)
        # Forbid everything else.
        raise pickle.UnpicklingError("global '%s.%s' is
                                     (module, name))

def restricted_loads(s):
    """Helper function analogous to pickle.loads()."""
    return RestrictedUnpickler(io.BytesIO(s)).load()
```

A sample usage of our unpickler working as intended:

```
>>> restricted_loads(pickle.dumps([1, 2, range(15)]))
[1, 2, range(0, 15)]
>>> restricted_loads(b"cos\nsystem\n(S'echo hello world'
Traceback (most recent call last):
  ...
pickle.UnpicklingError: global 'os.system' is forbidden
>>> restricted_loads(b'cbuiltins\neval\n'
...                  b'(S\'getattr(__import__("os"), "sy
...                  b'("echo hello world")\'\ntR.')
Traceback (most recent call last):
  ...
pickle.UnpicklingError: global 'builtins.eval' is forbic
```

As our examples shows, you have to be careful with what you allow to be unpickled. Therefore if security is a concern, you may want to consider alternatives such as the marshalling API in **`xmlrpc.client`** or third-party solutions.

Performance

Recent versions of the pickle protocol (from protocol 2 and upwards) feature efficient binary encodings for several common features and built-in types. Also, the **`pickle`** module has a transparent optimizer written in C.

Examples

For the simplest code, use the **`dump()`** and **`load()`** functions.

```
import pickle

# An arbitrary collection of objects supported by pickle
data = {
    'a': [1, 2.0, 3+4j],
    'b': ("character string", b"byte string"),
    'c': {None, True, False}
}
```

```
with open('data.pickle', 'wb') as f:
    # Pickle the 'data' dictionary using the highest pro
    pickle.dump(data, f, pickle.HIGHEST_PROTOCOL)
```

The following example reads the resulting pickled data.

```
import pickle

with open('data.pickle', 'rb') as f:
    # The protocol version used is detected automaticall
    # have to specify it.
    data = pickle.load(f)
```

Module **copyreg**
: Pickle interface constructor registration for extension types.

Module **pickletools**
: Tools for working with and analyzing pickled data.

Module **shelve**
: Indexed databases of objects; uses **pickle**.

Module **copy**
: Shallow and deep object copying.

Module **marshal**
: High-performance serialization of built-in types.

Footnotes

1
: Don't confuse this with the **marshal** module

2
: This is why **lambda** functions cannot be pickled: all **lambda**

functions share the same name: `<lambda>`.

3

The exception raised will likely be an **`ImportError`** or an **`AttributeError`** but it could be something else.

4

The **`copy`** module uses this protocol for shallow and deep copying operations.

5

The limitation on alphanumeric characters is due to the fact that persistent IDs in protocol 0 are delimited by the newline character. Therefore if any kind of newline characters occurs in persistent IDs, the resulting pickled data will become unreadable.

`copyreg` — Register `pickle` support functions

Source code: Lib/copyreg.py [https://github.com/python/cpython/tree/3.11/Lib/copyreg.py]

The `copyreg` module offers a way to define functions used while pickling specific objects. The `pickle` and `copy` modules use those functions when pickling/copying those objects. The module provides configuration information about object constructors which are not classes. Such constructors may be factory functions or class instances.

copyreg.constructor(*object*)

Declares *object* to be a valid constructor. If *object* is not callable (and hence not valid as a constructor), raises `TypeError`.

copyreg.pickle(*type*, *function*, *constructor_ob=None*)

Declares that *function* should be used as a "reduction" function for objects of type *type*. *function* should return either a string or a tuple containing two or three elements. See the `dispatch_table` for more details on the interface of *function*.

The *constructor_ob* parameter is a legacy feature and is now ignored, but if passed it must be a callable.

Note that the `dispatch_table` attribute of a pickler object or subclass of `pickle.Pickler` can also be used for declaring reduction functions.

Example

The example below would like to show how to register a pickle function and how it will be used:

```
>>> import copyreg, copy, pickle
>>> class C:
...     def __init__(self, a):
...         self.a = a
...
>>> def pickle_c(c):
...     print("pickling a C instance...")
...     return C, (c.a,)
...
>>> copyreg.pickle(C, pickle_c)
>>> c = C(1)
>>> d = copy.copy(c)
pickling a C instance...
>>> p = pickle.dumps(c)
pickling a C instance...
```

`shelve` — Python object persistence

Source code: Lib/shelve.py [https://github.com/python/cpython/tree/3.11/Lib/shelve.py]

A “shelf” is a persistent, dictionary-like object. The difference with “dbm” databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects — anything that the `pickle` module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

shelve.open(*filename*, *flag*='c', *protocol*=None, *writeback*=False)

Open a persistent dictionary. The filename specified is the base filename for the underlying database. As a side-effect, an extension may be added to the filename and more than one file may be created. By default, the underlying database file is opened for reading and writing. The optional *flag* parameter has the same interpretation as the *flag* parameter of `dbm.open()`.

By default, pickles created with `pickle.DEFAULT_PROTOCOL` are used to serialize values. The version of the pickle protocol can be specified with the *protocol* parameter.

Because of Python semantics, a shelf cannot know when a mutable persistent-dictionary entry is modified. By default modified objects are written *only* when assigned to the shelf (see Example). If the optional *writeback* parameter is set to `True`, all entries accessed are also cached in memory, and written back on `sync()` and `close()`; this can make it handier to mutate mutable entries in the persistent

dictionary, but, if many entries are accessed, it can consume vast amounts of memory for the cache, and it can make the close operation very slow since all accessed entries are written back (there is no way to determine which accessed entries are mutable, nor which ones were actually mutated).

Changed in version 3.10: **pickle.DEFAULT_PROTOCOL** is now used as the default pickle protocol.

Changed in version 3.11: Accepts path-like object for filename.

Note

Do not rely on the shelf being closed automatically; always call **close()** explicitly when you don't need it any more, or use **shelve.open()** as a context manager:

```
with shelve.open('spam') as db:
    db['eggs'] = 'eggs'
```

Warning

Because the **shelve** module is backed by **pickle**, it is insecure to load a shelf from an untrusted source. Like with pickle, loading a shelf can execute arbitrary code.

Shelf objects support most of methods and operations supported by dictionaries (except copying, constructors and operators | and |=). This eases the transition from dictionary based scripts to those requiring persistent storage.

Two additional methods are supported:

Shelf.sync()

Write back all entries in the cache if the shelf was opened with *writeback* set to **True**. Also empty the cache and synchronize the persistent dictionary on disk, if feasible. This is called automatically when the shelf is closed with

`close()`.

Shelf.close()

Synchronize and close the persistent *dict* object. Operations on a closed shelf will fail with a `ValueError`.

See also

Persistent dictionary recipe [https://code.activestate.com/recipes/576642/] with widely supported storage formats and having the speed of native dictionaries.

Restrictions

- The choice of which database package will be used (such as `dbm.ndbm` or `dbm.gnu`) depends on which interface is available. Therefore it is not safe to open the database directly using `dbm`. The database is also (unfortunately) subject to the limitations of `dbm`, if it is used — this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.
- The `shelve` module does not support *concurrent* read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. Unix file locking can be used to solve this, but this differs across Unix versions and requires knowledge about the database implementation used.

class shelve.Shelf(*dict*, *protocol=None*, *writeback=False*, *keyencoding='utf-8'*)

A subclass of `collections.abc.MutableMapping` which stores pickled values in the *dict* object.

By default, pickles created with `pickle.DEFAULT_PROTOCOL` are used to serialize values.

The version of the pickle protocol can be specified with the *protocol* parameter. See the **pickle** documentation for a discussion of the pickle protocols.

If the *writeback* parameter is `True`, the object will hold a cache of all entries accessed and write them back to the *dict* at sync and close times. This allows natural operations on mutable entries, but can consume much more memory and make sync and close take a long time.

The *keyencoding* parameter is the encoding used to encode keys before they are used with the underlying dict.

A **Shelf** object can also be used as a context manager, in which case it will be automatically closed when the **with** block ends.

Changed in version 3.2: Added the *keyencoding* parameter; previously, keys were always encoded in UTF-8.

Changed in version 3.4: Added context manager support.

Changed in version 3.10: **pickle.DEFAULT_PROTOCOL** is now used as the default pickle protocol.

class shelve.BsdDbShelf(*dict*, *protocol=None*, *writeback=False*, *keyencoding='utf-8'*)

A subclass of **Shelf** which exposes **first()**, **next()**, **previous()**, **last()** and **set_location()** which are available in the third-party **bsddb** module from pybsddb [https://www.jcea.es/programacion/pybsddb.htm] but not in other database modules. The *dict* object passed to the constructor must support those methods. This is generally accomplished by calling one of **bsddb.hashopen()**, **bsddb.btopen()** or **bsddb.rnopen()**. The optional *protocol*, *writeback*, and *keyencoding* parameters have the same interpretation as for the **Shelf** class.

class shelve.DbfilenameShelf(*filename*, *flag='c'*, *protocol=None*, *writeback=False*)

A subclass of **`Shelf`** which accepts a *filename* instead of a dict-like object. The underlying file will be opened using **`dbm.open()`**. By default, the file will be created and opened for both read and write. The optional *flag* parameter has the same interpretation as for the **`open()`** function. The optional *protocol* and *writeback* parameters have the same interpretation as for the **`Shelf`** class.

Example

To summarize the interface (`key` is a string, `data` is an arbitrary object):

```
import shelve

d = shelve.open(filename)  # open -- file may get suffix
                           # library

d[key] = data              # store data at key (overwrit
                           # using an existing key)
data = d[key]              # retrieve a COPY of data at
                           # if no such key)
del d[key]                 # delete data stored at key (
                           # if no such key)

flag = key in d            # true if the key exists
klist = list(d.keys())     # a list of all existing keys

# as d was opened WITHOUT writeback=True, beware:
d['xx'] = [0, 1, 2]        # this works as expected, but
d['xx'].append(3)          # *this doesn't!* -- d['xx']

# having opened d without writeback=True, you need to co
temp = d['xx']             # extracts the copy
temp.append(5)             # mutates the copy
d['xx'] = temp             # stores the copy right back,

# or, d=shelve.open(filename,writeback=True) would let y
```

```
# d['xx'].append(5) and have it work as expected, BUT it
# consume more memory and make the d.close() operation s

d.close()                   # close it
```

Module **dbm**
: Generic interface to dbm-style databases.

Module **pickle**
: Object serialization used by **shelve**.

`marshal` — Internal Python object serialization

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does). [1]

This is not a general "persistence" module. For general persistence and transfer of Python objects through RPC calls, see the modules `pickle` and `shelve`. The `marshal` module exists mainly to support reading and writing the "pseudo-compiled" code for Python modules of `.pyc` files. Therefore, the Python maintainers reserve the right to modify the marshal format in backward incompatible ways should the need arise. If you're serializing and de-serializing Python objects, use the `pickle` module instead – the performance is comparable, version independence is guaranteed, and pickle supports a substantially wider range of objects than marshal.

Warning

The `marshal` module is not intended to be secure against erroneous or maliciously constructed data. Never unmarshal data received from an untrusted or unauthenticated source.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: booleans, integers, floating point numbers, complex numbers, strings, bytes, bytearrays, tuples, lists, sets, frozensets, dictionaries, and code objects, where it should be understood that tuples, lists, sets, frozensets and dictionaries are only supported as

long as the values contained therein are themselves supported. The singletons **None**, **Ellipsis** and **StopIteration** can also be marshalled and unmarshalled. For format *version* lower than 3, recursive lists, sets and dictionaries cannot be written (see below).

There are functions that read/write files as well as functions operating on bytes-like objects.

The module defines these functions:

marshal.dump(*value*, *file*[, *version*])

Write the value on the open file. The value must be a supported type. The file must be a writeable binary file.

If the value has (or contains an object that has) an unsupported type, a **ValueError** exception is raised — but garbage data will also be written to the file. The object will not be properly read back by **load()**.

The *version* argument indicates the data format that `dump` should use (see below).

Raises an auditing event `marshal.dumps` with arguments `value, version`.

marshal.load(*file*)

Read one value from the open file and return it. If no valid value is read (e.g. because the data has a different Python version's incompatible marshal format), raise **EOFError**, **ValueError** or **TypeError**. The file must be a readable binary file.

Raises an auditing event `marshal.load` with no arguments.

Note

If an object containing an unsupported type was marshalled with **dump()**, **load()** will substitute `None` for the unmarshallable type.

Changed in version 3.10: This call used to raise a `code.__new__` audit event for each code object. Now it raises a single `marshal.load` event for the entire load operation.

marshal.dumps(*value*[, *version*])

Return the bytes object that would be written to a file by `dump(value, file)`. The value must be a supported type. Raise a **`ValueError`** exception if value has (or contains an object that has) an unsupported type.

The *version* argument indicates the data format that `dumps` should use (see below).

Raises an auditing event `marshal.dumps` with arguments `value, version`.

marshal.loads(*bytes*)

Convert the bytes-like object to a value. If no valid value is found, raise **`EOFError`**, **`ValueError`** or **`TypeError`**. Extra bytes in the input are ignored.

Raises an auditing event `marshal.loads` with argument `bytes`.

Changed in version 3.10: This call used to raise a `code.__new__` audit event for each code object. Now it raises a single `marshal.loads` event for the entire load operation.

In addition, the following constants are defined:

marshal.version

Indicates the format that the module uses. Version 0 is the historical format, version 1 shares interned strings and version 2 uses a binary format for floating point numbers. Version 3 adds support for object instancing and recursion. The current version is 4.

Footnotes

1

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term “marshalling” for shipping of data around in a self-contained form. Strictly speaking, “to marshal” means to convert some data from internal to external form (in an RPC buffer for instance) and “unmarshalling” for the reverse process.

dbm — Interfaces to Unix “databases”

Source code: Lib/dbm/__init__.py [https://github.com/python/cpython/tree/3.11/Lib/dbm/__init__.py]

---

dbm is a generic interface to variants of the DBM database — **dbm.gnu** or **dbm.ndbm**. If none of these modules is installed, the slow-but-simple implementation in module **dbm.dumb** will be used. There is a third party interface [https://www.jcea.es/programacion/pybsddb.htm] to the Oracle Berkeley DB.

exception dbm.error

A tuple containing the exceptions that can be raised by each of the supported modules, with a unique exception also named **dbm.error** as the first item — the latter is used when **dbm.error** is raised.

dbm.whichdb(*filename*)

This function attempts to guess which of the several simple database modules available — **dbm.gnu**, **dbm.ndbm** or **dbm.dumb** — should be used to open a given file.

Returns one of the following values: `None` if the file can’t be opened because it’s unreadable or doesn’t exist; the empty string (`''`) if the file’s format can’t be guessed; or a string containing the required module name, such as `'dbm.ndbm'` or `'dbm.gnu'`.

Changed in version 3.11: Accepts path-like object for filename.

dbm.open(*file*, *flag='r'*, *mode=0o666*)

Open the database file *file* and return a corresponding object.

If the database file already exists, the **whichdb()** function is used to determine its type and the appropriate module is used; if it does not exist, the first module listed above that can be imported is used.

The optional *flag* argument can be:

Value	Meaning
`'r'`	Open existing database for reading only (default)
`'w'`	Open existing database for reading and writing
`'c'`	Open database for reading and writing, creating it if it doesn't exist
`'n'`	Always create a new, empty database, open for reading and writing

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666` (and will be modified by the prevailing umask).

The object returned by **open()** supports the same basic functionality as dictionaries; keys and their corresponding values can be stored, retrieved, and deleted, and the **in** operator and the **keys()** method are available, as well as **get()** and **setdefault()**.

Changed in version 3.2: **get()** and **setdefault()** are now available in all database modules.

Changed in version 3.8: Deleting a key from a read-only database raises database module specific error instead of **KeyError**.

Changed in version 3.11: Accepts path-like object for file.

Key and values are always stored as bytes. This means that when strings are used they are implicitly converted to the default encoding before being stored.

These objects also support being used in a **with** statement, which will automatically close them when done.

Changed in version 3.4: Added native support for the context

management protocol to the objects returned by `open()`.

The following example records some hostnames and a corresponding title, and then prints out the contents of the database:

```
import dbm

# Open database, creating it if necessary.
with dbm.open('cache', 'c') as db:

    # Record some values
    db[b'hello'] = b'there'
    db['www.python.org'] = 'Python Website'
    db['www.cnn.com'] = 'Cable News Network'

    # Note that the keys are considered bytes now.
    assert db[b'www.python.org'] == b'Python Website'
    # Notice how the value is now in bytes.
    assert db['www.cnn.com'] == b'Cable News Network'

    # Often-used methods of the dict interface work too.
    print(db.get('python.org', b'not present'))

    # Storing a non-string key or value will raise an ex
    # likely a TypeError).
    db['www.yahoo.com'] = 4

# db is automatically closed when leaving the with state
```

Module `shelve`
: Persistence module which stores non-string data.

The individual submodules are described in the following sections.

`dbm.gnu` — GNU's reinterpretation of

dbm

Source code: Lib/dbm/gnu.py [https://github.com/python/cpython/tree/3.11/Lib/dbm/gnu.py]

This module is quite similar to the **dbm** module, but uses the GNU library `gdbm` instead to provide some additional functionality. Please note that the file formats created by **dbm.gnu** and **dbm.ndbm** are incompatible.

The **dbm.gnu** module provides an interface to the GNU DBM library. `dbm.gnu.gdbm` objects behave like mappings (dictionaries), except that keys and values are always converted to bytes before storing. Printing a `gdbm` object doesn't print the keys and values, and the **items()** and **values()** methods are not supported.

exception dbm.gnu.error

Raised on **dbm.gnu**-specific errors, such as I/O errors. **KeyError** is raised for general mapping errors like specifying an incorrect key.

dbm.gnu.open(*filename*[, *flag*[, *mode*]])

Open a `gdbm` database and return a **gdbm** object. The *filename* argument is the name of the database file.

The optional *flag* argument can be:

Value	Meaning
`'r'`	Open existing database for reading only (default)
`'w'`	Open existing database for reading and writing
`'c'`	Open database for reading and writing, creating it if it doesn't exist
`'n'`	Always create a new, empty database, open for reading and writing

The following additional characters may be appended to the flag to control how the database is opened:

Value	Meaning
`'f'`	Open the database in fast mode. Writes to the database will not be synchronized.
`'s'`	Synchronized mode. This will cause changes to the database to be immediately written to the file.
`'u'`	Do not lock database.

Not all flags are valid for all versions of `gdbm`. The module constant **`open_flags`** is a string of supported flag characters. The exception **`error`** is raised if an invalid flag is specified.

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666`.

In addition to the dictionary-like methods, `gdbm` objects have the following methods:

Changed in version 3.11: Accepts path-like object for filename.

gdbm.firstkey()

It's possible to loop over every key in the database using this method and the **`nextkey()`** method. The traversal is ordered by `gdbm`'s internal hash values, and won't be sorted by the key values. This method returns the starting key.

gdbm.nextkey(*key*)

Returns the key that follows *key* in the traversal. The following code prints every key in the database `db`, without having to create a list in memory that contains them all:

```
k = db.firstkey()
while k is not None:
    print(k)
    k = db.nextkey(k)
```

gdbm.reorganize()

If you have carried out a lot of deletions and would like to shrink the space used by the `gdbm` file, this routine will reorganize the database. `gdbm` objects will not shorten the length of a database file except by using this reorganization; otherwise, deleted file space will be kept and reused as new (key, value) pairs are added.

gdbm.sync()

When the database has been opened in fast mode, this method forces any unwritten data to be written to the disk.

gdbm.close()

Close the `gdbm` database.

`dbm.ndbm` — Interface based on ndbm

Source code: Lib/dbm/ndbm.py [https://github.com/python/cpython/tree/3.11/Lib/dbm/ndbm.py]

The **`dbm.ndbm`** module provides an interface to the Unix "(n)dbm" library. Dbm objects behave like mappings (dictionaries), except that keys and values are always stored as bytes. Printing a `dbm` object doesn't print the keys and values, and the **`items()`** and **`values()`** methods are not supported.

This module can be used with the "classic" ndbm interface or the GNU GDBM compatibility interface. On Unix, the **configure** script will attempt to locate the appropriate header file to simplify building this module.

exception dbm.ndbm.error

Raised on **`dbm.ndbm`**-specific errors, such as I/O errors. **`KeyError`** is raised for general mapping errors like specifying an incorrect key.

dbm.ndbm.library

Name of the `ndbm` implementation library used.

dbm.ndbm.open(*filename*[, *flag*[, *mode*]])

Open a dbm database and return a `ndbm` object. The *filename* argument is the name of the database file (without the `.dir` or `.pag` extensions).

The optional *flag* argument must be one of these values:

Value	Meaning
`'r'`	Open existing database for reading only (default)
`'w'`	Open existing database for reading and writing
`'c'`	Open database for reading and writing, creating it if it doesn't exist
`'n'`	Always create a new, empty database, open for reading and writing

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666` (and will be modified by the prevailing umask).

In addition to the dictionary-like methods, `ndbm` objects provide the following method:

Changed in version 3.11: Accepts path-like object for filename.

ndbm.close()

Close the `ndbm` database.

`dbm.dumb` — Portable DBM implementation

Source code: Lib/dbm/dumb.py [https://github.com/python/cpython/tree/3.11/Lib/dbm/dumb.py]

Note

The `dbm.dumb` module is intended as a last resort fallback for the `dbm` module when a more robust module is not available.

The **dbm.dumb** module is not written for speed and is not nearly as heavily used as the other database modules.

The **dbm.dumb** module provides a persistent dictionary-like interface which is written entirely in Python. Unlike other modules such as **dbm.gnu** no external library is required. As with other persistent mappings, the keys and values are always stored as bytes.

The module defines the following:

exception dbm.dumb.error

Raised on **dbm.dumb**-specific errors, such as I/O errors. **KeyError** is raised for general mapping errors like specifying an incorrect key.

dbm.dumb.open(*filename*[, *flag*[, *mode*]])

Open a `dumbdbm` database and return a dumbdbm object. The *filename* argument is the basename of the database file (without any specific extensions). When a dumbdbm database is created, files with `.dat` and `.dir` extensions are created.

The optional *flag* argument can be:

Value	Meaning
`'r'`	Open existing database for reading only (default)
`'w'`	Open existing database for reading and writing
`'c'`	Open database for reading and writing, creating it if it doesn't exist
`'n'`	Always create a new, empty database, open for reading and writing

The optional *mode* argument is the Unix mode of the file, used only when the database has to be created. It defaults to octal `0o666` (and will be modified by the prevailing umask).

Warning

It is possible to crash the Python interpreter when loading a database with a sufficiently large/complex entry due to

stack depth limitations in Python's AST compiler.

Changed in version 3.5: `open()` always creates a new database when the flag has the value `'n'`.

Changed in version 3.8: A database opened with flags `'r'` is now read-only. Opening with flags `'r'` and `'w'` no longer creates a database if it does not exist.

Changed in version 3.11: Accepts path-like object for filename.

In addition to the methods provided by the `collections.abc.MutableMapping` class, **dumbdbm** objects provide the following methods:

dumbdbm.sync()

Synchronize the on-disk directory and data files. This method is called by the `Shelve.sync()` method.

dumbdbm.close()

Close the `dumbdbm` database.

`sqlite3` — DB-API 2.0 interface for SQLite databases

Source code: Lib/sqlite3/ [https://github.com/python/cpython/tree/3.11/Lib/sqlite3/]

SQLite is a C library that provides a lightweight disk-based database that doesn't require a separate server process and allows accessing the database using a nonstandard variant of the SQL query language. Some applications can use SQLite for internal data storage. It's also possible to prototype an application using SQLite and then port the code to a larger database such as PostgreSQL or Oracle.

The `sqlite3` module was written by Gerhard Häring. It provides an SQL interface compliant with the DB-API 2.0 specification described by **PEP 249** [https://peps.python.org/pep-0249/], and requires SQLite 3.7.15 or newer.

This document includes four main sections:

- Tutorial teaches how to use the `sqlite3` module.
- Reference describes the classes and functions this module defines.
- How-to guides details how to handle specific tasks.
- Explanation provides in-depth background on transaction control.

PEP 249 [https://peps.python.org/pep-0249/] - Database API Specification 2.0
PEP written by Marc-André Lemburg.

Tutorial

In this tutorial, you will create a database of Monty Python movies using basic **`sqlite3`** functionality. It assumes a fundamental understanding of database concepts, including cursors [https://en.wikipedia.org/wiki/Cursor_(databases)] and transactions [https://en.wikipedia.org/wiki/Database_transaction].

First, we need to create a new database and open a database connection to allow **`sqlite3`** to work with it. Call **`sqlite3.connect()`** to to create a connection to the database `tutorial.db` in the current working directory, implicitly creating it if it does not exist:

```
import sqlite3
con = sqlite3.connect("tutorial.db")
```

The returned **`Connection`** object `con` represents the connection to the on-disk database.

In order to execute SQL statements and fetch results from SQL queries, we will need to use a database cursor. Call **`con.cursor()`** to create the **`Cursor`**:

```
cur = con.cursor()
```

Now that we've got a database connection and a cursor, we can create a database table `movie` with columns for title, release year, and review score. For simplicity, we can just use column names in the table declaration – thanks to the flexible typing [https://www.sqlite.org/flextypegood.html] feature of SQLite, specifying the data types is optional. Execute the `CREATE TABLE` statement by calling **`cur.execute(...)`**:

```
cur.execute("CREATE TABLE movie(title, year, score)")
```

We can verify that the new table has been created by querying the `sqlite_master` table built-in to SQLite, which should now contain an entry for the `movie` table definition (see The Schema Table [https://www.sqlite.org/schematab.html] for details). Execute that query by calling **`cur.execute(...)`**, assign the result to `res`, and call **`res.fetchone()`** to fetch the resulting row:

```
>>> res = cur.execute("SELECT name FROM sqlite_master")
>>> res.fetchone()
('movie',)
```

We can see that the table has been created, as the query returns a **`tuple`** containing the table's name. If we query `sqlite_master` for a non-existent table `spam`, **`res.fetchone()`** will return `None`:

```
>>> res = cur.execute("SELECT name FROM sqlite_master WH
>>> res.fetchone() is None
True
```

Now, add two rows of data supplied as SQL literals by executing an `INSERT` statement, once again by calling **`cur.execute(...)`**:

```
cur.execute("""
    INSERT INTO movie VALUES
        ('Monty Python and the Holy Grail', 1975, 8.2),
        ('And Now for Something Completely Different', 1
""")
```

The `INSERT` statement implicitly opens a transaction, which needs to be committed before changes are saved in the database (see Transaction control for details). Call **`con.commit()`** on the connection object to commit the transaction:

```
con.commit()
```

We can verify that the data was inserted correctly by executing a `SELECT` query. Use the now-familiar **`cur.execute(...)`** to assign the result to `res`, and call **`res.fetchall()`** to return all

resulting rows:

```
>>> res = cur.execute("SELECT score FROM movie")
>>> res.fetchall()
[(8.2,), (7.5,)]
```

The result is a **`list`** of two **`tuple`**s, one per row, each containing that row's `score` value.

Now, insert three more rows by calling **`cur.executemany(...)`**:

```
data = [
    ("Monty Python Live at the Hollywood Bowl", 1982, 7.
    ("Monty Python's The Meaning of Life", 1983, 7.5),
    ("Monty Python's Life of Brian", 1979, 8.0),
]
cur.executemany("INSERT INTO movie VALUES(?, ?, ?)", dat
con.commit()  # Remember to commit the transaction after
```

Notice that `?` placeholders are used to bind `data` to the query. Always use placeholders instead of string formatting to bind Python values to SQL statements, to avoid SQL injection attacks [https://en.wikipedia.org/wiki/SQL_injection] (see How to use placeholders to bind values in SQL queries for more details).

We can verify that the new rows were inserted by executing a `SELECT` query, this time iterating over the results of the query:

```
>>> for row in cur.execute("SELECT year, title FROM movi
...     print(row)
(1971, 'And Now for Something Completely Different')
(1975, 'Monty Python and the Holy Grail')
(1979, "Monty Python's Life of Brian")
(1982, 'Monty Python Live at the Hollywood Bowl')
(1983, "Monty Python's The Meaning of Life")
```

Each row is a two-item **`tuple`** of `(year, title)`, matching the columns selected in the query.

Finally, verify that the database has been written to disk by calling **`con.close()`** to close the existing connection, opening a new one,

creating a new cursor, then querying the database:

```
>>> con.close()
>>> new_con = sqlite3.connect("tutorial.db")
>>> new_cur = new_con.cursor()
>>> res = new_cur.execute("SELECT title, year FROM movie
>>> title, year = res.fetchone()
>>> print(f'The highest scoring Monty Python movie is {t
The highest scoring Monty Python movie is 'Monty Python
```

You've now created an SQLite database using the **sqlite3** module, inserted data and retrieved values from it in multiple ways.

Reference

Module functions

sqlite3.connect(*database*, *timeout=5.0*, *detect_types=0*, *isolation_level='DEFERRED'*, *check_same_thread=True*, *factory=sqlite3.Connection*, *cached_statements=128*, *uri=False*)

Open a connection to an SQLite database.

Parameters

- **database** (path-like object) – The path to the database file to be opened. Pass `":memory:"` to open a connection to a database that is in RAM instead of on disk.
- **timeout** (*float*) – How many seconds the connection should wait before raising an exception, if the database is locked by another connection. If another connection opens a transaction to modify the database, it will be locked until that transaction is committed. Default five seconds.
- **detect_types** (*int*) – Control whether and how data types not natively supported by SQLite are looked up to be converted to Python types, using the converters registered with **`register_converter()`**. Set it to any combination (using `|`, bitwise or) of **`PARSE_DECLTYPES`** and **`PARSE_COLNAMES`** to enable this. Column names takes precedence over declared types if both flags are set. Types cannot be detected for generated fields (for example `max(data)`), even when the *detect_types* parameter is set; **`str`** will be returned instead. By default (`0`), type detection is disabled.
- **isolation_level** (*str* | *None*) – The **`isolation_level`** of the connection, controlling whether and how transactions are implicitly opened. Can be `"DEFERRED"` (default), `"EXCLUSIVE"` or `"IMMEDIATE"`; or `None` to disable opening transactions implicitly. See Transaction control for more.
- **check_same_thread** (*bool*) – If `True`

(default), only the creating thread may use the connection. If `False`, the connection may be shared across multiple threads; if so, write operations should be serialized by the user to avoid data corruption.

- **factory** (*Connection*) – A custom subclass of **`Connection`** to create the connection with, if not the default **`Connection`** class.
- **cached_statements** (*int*) – The number of statements that **`sqlite3`** should internally cache for this connection, to avoid parsing overhead. By default, 128 statements.
- **uri** (*bool*) – If set to `True`, *database* is interpreted as a URI with a file path and an optional query string. The scheme part *must* be `"file:"`, and the path can be relative or absolute. The query string allows passing parameters to SQLite, enabling various How to work with SQLite URIs.

Return type

Connection

Raises an auditing event `sqlite3.connect` with argument `database`.

Raises an auditing event `sqlite3.connect/handle` with argument `connection_handle`.

New in version 3.4: The *uri* parameter.

Changed in version 3.7: database can now also be a path-like object, not only a string.

New in version 3.10: The `sqlite3.connect/handle` auditing event.

sqlite3.complete_statement(*statement*)

Return `True` if the string *statement* appears to contain one or more complete SQL statements. No syntactic verification or parsing of any kind is performed, other than checking that there are no unclosed string literals and the statement is terminated by a semicolon.

For example:

```
>>> sqlite3.complete_statement("SELECT foo FROM bar
True
>>> sqlite3.complete_statement("SELECT foo")
False
```

This function may be useful during command-line input to determine if the entered text seems to form a complete SQL statement, or if additional input is needed before calling **`execute()`**.

sqlite3.enable_callback_tracebacks(*flag*, */*)

Enable or disable callback tracebacks. By default you will not get any tracebacks in user-defined functions, aggregates, converters, authorizer callbacks etc. If you want to debug them, you can call this function with *flag* set to `True`. Afterwards, you will get tracebacks from callbacks on **`sys.stderr`**. Use `False` to disable the feature again.

Register an **`unraisable hook handler`** for an improved debug experience:

```
>>> sqlite3.enable_callback_tracebacks(True)
>>> con = sqlite3.connect(":memory:")
>>> def evil_trace(stmt):
...     5/0
>>> con.set_trace_callback(evil_trace)
>>> def debug(unraisable):
...     print(f"{unraisable.exc_value!r} in callbac
...     print(f"Error message: {unraisable.err_msg}
>>> import sys
```

```
>>> sys.unraisablehook = debug
>>> cur = con.execute("SELECT 1")
ZeroDivisionError('division by zero') in callback e
Error message: None
```

sqlite3.register_adapter(*type*, *adapter*, */*)

Register an *adapter* callable to adapt the Python type *type* into an SQLite type. The adapter is called with a Python object of type *type* as its sole argument, and must return a value of a type that SQLite natively understands.

sqlite3.register_converter(*typename*, *converter*, */*)

Register the *converter* callable to convert SQLite objects of type *typename* into a Python object of a specific type. The converter is invoked for all SQLite values of type *typename*; it is passed a **`bytes`** object and should return an object of the desired Python type. Consult the parameter *detect_types* of **`connect()`** for information regarding how type detection works.

Note: *typename* and the name of the type in your query are matched case-insensitively.

Module constants

sqlite3.PARSE_COLNAMES

Pass this flag value to the *detect_types* parameter of **`connect()`** to look up a converter function by using the type name, parsed from the query column name, as the converter dictionary key. The type name must be wrapped in square brackets (`[]`).

```
SELECT p as "p [point]" FROM test;  ! will look up
```

This flag may be combined with **`PARSE_DECLTYPES`** using the | (bitwise or) operator.

sqlite3.PARSE_DECLTYPES

Pass this flag value to the *detect_types* parameter of **connect()** to look up a converter function using the declared types for each column. The types are declared when the database table is created. **sqlite3** will look up a converter function using the first word of the declared type as the converter dictionary key. For example:

```
CREATE TABLE test(
   i integer primary key,   ! will look up a convert
   p point,                 ! will look up a convert
   n number(10)             ! will look up a convert
 )
```

This flag may be combined with **PARSE_COLNAMES** using the | (bitwise or) operator.

sqlite3.SQLITE_OK
sqlite3.SQLITE_DENY
sqlite3.SQLITE_IGNORE

Flags that should be returned by the *authorizer_callback* callable passed to **Connection.set_authorizer()**, to indicate whether:

- Access is allowed (**SQLITE_OK**),
- The SQL statement should be aborted with an error (**SQLITE_DENY**)
- The column should be treated as a `NULL` value (**SQLITE_IGNORE**)

sqlite3.apilevel

String constant stating the supported DB-API level. Required by the DB-API. Hard-coded to `"2.0"`.

sqlite3.paramstyle

String constant stating the type of parameter marker formatting expected by the **sqlite3** module. Required by the DB-API. Hard-coded to `"qmark"`.

Note

The **sqlite3** module supports `qmark`, `numeric`, and `named` DB-API parameter styles, because that is what the underlying SQLite library supports. However, the DB-API does not allow multiple values for the `paramstyle` attribute.

sqlite3.sqlite_version

Version number of the runtime SQLite library as a **string**.

sqlite3.sqlite_version_info

Version number of the runtime SQLite library as a **tuple** of **integers**.

sqlite3.threadsafety

Integer constant required by the DB-API 2.0, stating the level of thread safety the **sqlite3** module supports. This attribute is set based on the default threading mode [https://sqlite.org/threadsafe.html] the underlying SQLite library is compiled with. The SQLite threading modes are:

1. **Single-thread**: In this mode, all mutexes are disabled and SQLite is unsafe to use in more than a single thread at once.
2. **Multi-thread**: In this mode, SQLite can be safely used by multiple threads provided that no single database connection is used simultaneously in two or more threads.
3. **Serialized**: In serialized mode, SQLite can be safely used by multiple threads with no restriction.

The mappings from SQLite threading modes to DB-API 2.0 threadsafety levels are as follows:

DB-API 2.0 meaning	SQLite threading mode
Threads may not share the module	Single-thread

1	Threads may share the module, but not connections
3	Threads may share the module, connections and cursors

Changed in version 3.11: Set *threadsafety* dynamically instead of hard-coding it to `1`.

sqlite3.version

Version number of this module as a **`string`**. This is not the version of the SQLite library.

sqlite3.version_info

Version number of this module as a **`tuple`** of **`integers`**. This is not the version of the SQLite library.

Connection objects

class sqlite3.Connection

Each open SQLite database is represented by a `Connection` object, which is created using **`sqlite3.connect()`**. Their main purpose is creating **`Cursor`** objects, and Transaction control.

See also

- How to use connection shortcut methods
- How to use the connection context manager

An SQLite database connection has the following attributes and methods:

cursor(*factory* = *Cursor*)

Create and return a **`Cursor`** object. The cursor method accepts a single optional parameter *factory*. If supplied, this must be a callable returning an instance of **`Cursor`** or its subclasses.

blobopen(*table*, *column*, *row*, */*, ***, *readonly* = *False*, *name* = *'main'*)

Open a `Blob` handle to an existing BLOB.

Parameters

- **table** (*str*) – The name of the table where the blob is located.
- **column** (*str*) – The name of the column where the blob is located.
- **row** (*str*) – The name of the row where the blob is located.
- **readonly** (*bool*) – Set to `True` if the blob should be opened without write permissions. Defaults to `False`.
- **name** (*str*) – The name of the database where the blob is located. Defaults to `"main"`.

Raises

OperationalError – When trying to open a blob in a `WITHOUT ROWID` table.

Return type

Blob

Note

The blob size cannot be changed using the `Blob` class. Use the SQL function `zeroblob` to create a blob with a fixed size.

New in version 3.11.

commit()

Commit any pending transaction to the database. If there is no open transaction, this method is a no-op.

rollback()

Roll back to the start of any pending transaction. If there is no open transaction, this method is a no-op.

close()

Close the database connection. Any pending transaction is not committed implicitly; make sure to **commit()** before closing to avoid losing pending changes.

execute(*sql*, *parameters* = *()*, */*)

Create a new **Cursor** object and call **execute()** on it with the given *sql* and *parameters*. Return the new cursor object.

executemany(*sql*, *parameters*, */*)

Create a new **Cursor** object and call **executemany()** on it with the given *sql* and *parameters*. Return the new cursor object.

executescript(*sql_script*, */*)

Create a new **Cursor** object and call **executescript()** on it with the given *sql_script*. Return the new cursor object.

create_function(*name*, *narg*, *func*, ***, *deterministic* = *False*)

Create or remove a user-defined SQL function.

Parameters

- **name** (*str*) – The name of the SQL function.
- **narg** (*int*) – The number of arguments the SQL function can accept. If `-1`, it may take any number of arguments.
- **func** (callback | None) – A callable that is called when the SQL function is invoked. The callable must return a type natively supported by SQLite. Set to `None` to remove an existing SQL function.

- **deterministic** (*bool*) – If `True`, the created SQL function is marked as deterministic [https://sqlite.org/deterministic.html], which allows SQLite to perform additional optimizations.

Raises

NotSupportedError – If *deterministic* is used with SQLite versions older than 3.8.3.

New in version 3.8: The *deterministic* parameter.

Example:

```
>>> import hashlib
>>> def md5sum(t):
...     return hashlib.md5(t).hexdigest()
>>> con = sqlite3.connect(":memory:")
>>> con.create_function("md5", 1, md5sum)
>>> for row in con.execute("SELECT md5(?)", (b'
...     print(row)
('acbd18db4cc2f85cedef654fccc4a4d8',)
```

create_aggregate(*name*, */*, *n_arg*, *aggregate_class*)

Create or remove a user-defined SQL aggregate function.

Parameters

- **name** (*str*) – The name of the SQL aggregate function.
- **n_arg** (*int*) – The number of arguments the SQL aggregate function can accept. If `-1`, it may take any number of arguments.
- **aggregate_class** (class | None) – A class must implement the following methods:

- `step()`: Add a row to the aggregate.
- `finalize()`: Return the final result of the aggregate as a type natively supported by SQLite.

The number of arguments that the `step()` method must accept is controlled by *n_arg*.

Set to `None` to remove an existing SQL aggregate function.

Example:

```
class MySum:
    def __init__(self):
        self.count = 0

    def step(self, value):
        self.count += value

    def finalize(self):
        return self.count

con = sqlite3.connect(":memory:")
con.create_aggregate("mysum", 1, MySum)
cur = con.execute("CREATE TABLE test(i)")
cur.execute("INSERT INTO test(i) VALUES(1)")
cur.execute("INSERT INTO test(i) VALUES(2)")
cur.execute("SELECT mysum(i) FROM test")
print(cur.fetchone()[0])

con.close()
```

create_window_function(*name*, *num_params*, *aggregate_class*, */*)

Create or remove a user-defined aggregate window function.

Parameters

- **name** (*str*) – The name of the SQL aggregate window function to create or remove.
- **num_params** (*int*) – The number of arguments the SQL aggregate window function can accept. If `-1`, it may take any number of arguments.
- **aggregate_class** (class | None) – A class that must implement the following methods:
  - `step()`: Add a row to the current window.
  - `value()`: Return the current value of the aggregate.
  - `inverse()`: Remove a row from the current window.
  - `finalize()`: Return the final result of the aggregate as a type natively supported by SQLite.

  The number of arguments that the `step()` and `value()` methods must accept is controlled by *num_params*.
  Set to `None` to remove an existing SQL aggregate window function.

Raises

NotSupportedError – If used with a version of SQLite older than 3.25.0, which does not support aggregate window functions.

New in version 3.11.

Example:

```
# Example taken from https://www.sqlite.org/wir
class WindowSumInt:
```

```
        def __init__(self):
            self.count = 0

        def step(self, value):
            """Add a row to the current window."""
            self.count += value

        def value(self):
            """Return the current value of the aggr
            return self.count

        def inverse(self, value):
            """Remove a row from the current windov
            self.count -= value

        def finalize(self):
            """Return the final value of the aggreg

            Any clean-up actions should be placed h
            """
            return self.count

    con = sqlite3.connect(":memory:")
    cur = con.execute("CREATE TABLE test(x, y)")
    values = [
        ("a", 4),
        ("b", 5),
        ("c", 3),
        ("d", 8),
        ("e", 1),
    ]
    cur.executemany("INSERT INTO test VALUES(?, ?)"
    con.create_window_function("sumint", 1, WindowS
    cur.execute("""
        SELECT x, sumint(y) OVER (
            ORDER BY x ROWS BETWEEN 1 PRECEDING AND
        ) AS sum_y
```

```
    FROM test ORDER BY x
""")
print(cur.fetchall())
```

create_collation(*name*, *callable*)

Create a collation named *name* using the collating function *callable*. *callable* is passed two **string** arguments, and it should return an **integer**:

- `1` if the first is ordered higher than the second
- `-1` if the first is ordered lower than the second
- `0` if they are ordered equal

The following example shows a reverse sorting collation:

```
def collate_reverse(string1, string2):
    if string1 == string2:
        return 0
    elif string1 < string2:
        return 1
    else:
        return -1

con = sqlite3.connect(":memory:")
con.create_collation("reverse", collate_reverse

cur = con.execute("CREATE TABLE test(x)")
cur.executemany("INSERT INTO test(x) VALUES(?)"
cur.execute("SELECT x FROM test ORDER BY x COLL
for row in cur:
    print(row)
con.close()
```

Remove a collation function by setting *callable* to `None`.

Changed in version 3.11: The collation name can contain any Unicode character. Earlier, only ASCII characters

were allowed.

interrupt()

Call this method from a different thread to abort any queries that might be executing on the connection. Aborted queries will raise an exception.

set_authorizer(*authorizer_callback*)

Register callable *authorizer_callback* to be invoked for each attempt to access a column of a table in the database. The callback should return one of **SQLITE_OK**, **SQLITE_DENY**, or **SQLITE_IGNORE** to signal how access to the column should be handled by the underlying SQLite library.

The first argument to the callback signifies what kind of operation is to be authorized. The second and third argument will be arguments or `None` depending on the first argument. The 4th argument is the name of the database ("main", "temp", etc.) if applicable. The 5th argument is the name of the inner-most trigger or view that is responsible for the access attempt or `None` if this access attempt is directly from input SQL code.

Please consult the SQLite documentation about the possible values for the first argument and the meaning of the second and third argument depending on the first one. All necessary constants are available in the **sqlite3** module.

Passing `None` as *authorizer_callback* will disable the authorizer.

Changed in version 3.11: Added support for disabling the authorizer using `None`.

set_progress_handler(*progress_handler*, *n*)

Register callable *progress_handler* to be invoked for every *n* instructions of the SQLite virtual machine. This

is useful if you want to get called from SQLite during long-running operations, for example to update a GUI.

If you want to clear any previously installed progress handler, call the method with `None` for *progress_handler*.

Returning a non-zero value from the handler function will terminate the currently executing query and cause it to raise an **`OperationalError`** exception.

set_trace_callback(*trace_callback*)

Register callable *trace_callback* to be invoked for each SQL statement that is actually executed by the SQLite backend.

The only argument passed to the callback is the statement (as **`str`**) that is being executed. The return value of the callback is ignored. Note that the backend does not only run statements passed to the **`Cursor.execute()`** methods. Other sources include the transaction management of the **`sqlite3`** module and the execution of triggers defined in the current database.

Passing `None` as *trace_callback* will disable the trace callback.

Note

Exceptions raised in the trace callback are not propagated. As a development and debugging aid, use **`enable_callback_tracebacks()`** to enable printing tracebacks from exceptions raised in the trace callback.

New in version 3.3.

enable_load_extension(*enabled*, */*)

Enable the SQLite engine to load SQLite extensions from shared libraries if *enabled* is `True`; else, disallow loading SQLite extensions. SQLite extensions can define new functions, aggregates or whole new virtual table implementations. One well-known extension is the fulltext-search extension distributed with SQLite.

Note

The **sqlite3** module is not built with loadable extension support by default, because some platforms (notably macOS) have SQLite libraries which are compiled without this feature. To get loadable extension support, you must pass the **--enable-loadable-sqlite-extensions** option to **configure**.

Raises an auditing event `sqlite3.enable_load_extension` with arguments `connection, enabled`.

New in version 3.2.

Changed in version 3.10: Added the `sqlite3.enable_load_extension` auditing event.

```
con.enable_load_extension(True)

# Load the fulltext search extension
con.execute("select load_extension('./fts3.so')

# alternatively you can load the extension usir
# con.load_extension("./fts3.so")

# disable extension loading again
con.enable_load_extension(False)

# example from SQLite wiki
con.execute("CREATE VIRTUAL TABLE recipe USING
con.executescript("""
```

```
        INSERT INTO recipe (name, ingredients) VALU
        INSERT INTO recipe (name, ingredients) VALU
        INSERT INTO recipe (name, ingredients) VALU
        INSERT INTO recipe (name, ingredients) VALU
        """)
    for row in con.execute("SELECT rowid, name, ing
        print(row)

    con.close()
```

load_extension(*path*, */*)

Load an SQLite extension from a shared library located at *path*. Enable extension loading with **`enable_load_extension()`** before calling this method.

Raises an auditing event `sqlite3.load_extension` with arguments `connection, path`.

New in version 3.2.

Changed in version 3.10: Added the `sqlite3.load_extension` auditing event.

iterdump()

Return an iterator to dump the database as SQL source code. Useful when saving an in-memory database for later restoration. Similar to the `.dump` command in the **sqlite3** shell.

Example:

```
# Convert file example.db to SQL dump file dump
con = sqlite3.connect('example.db')
with open('dump.sql', 'w') as f:
    for line in con.iterdump():
        f.write('%s\n' % line)
con.close()
```

backup(*target*, ***, *pages=-1*, *progress=None*, *name='main'*, *sleep=0.250*)

Create a backup of an SQLite database.

Works even if the database is being accessed by other clients or concurrently by the same connection.

Parameters

- **target** (*Connection*) – The database connection to save the backup to.
- **pages** (*int*) – The number of pages to copy at a time. If equal to or less than `0`, the entire database is copied in a single step. Defaults to `-1`.
- **progress** (callback | None) – If set to a callable, it is invoked with three integer arguments for every backup iteration: the *status* of the last iteration, the *remaining* number of pages still to be copied, and the *total* number of pages. Defaults to `None`.
- **name** (*str*) – The name of the database to back up. Either `"main"` (the default) for the main database, `"temp"` for the temporary database, or the name of a custom database as attached using the `ATTACH DATABASE` SQL statement.
- **sleep** (*float*) – The number of seconds to sleep between successive attempts to back up remaining pages.

Example 1, copy an existing database into another:

```
def progress(status, remaining, total):
```

```
        print(f'Copied {total-remaining} of {total}
    src = sqlite3.connect('example.db')
    dst = sqlite3.connect('backup.db')
    with dst:
        src.backup(dst, pages=1, progress=progress)
    dst.close()
    src.close()
```

Example 2, copy an existing database into a transient copy:

```
src = sqlite3.connect('example.db')
dst = sqlite3.connect(':memory:')
src.backup(dst)
```

New in version 3.7.

getlimit(*category*, */*)

Get a connection runtime limit.

Parameters

category (*int*) – The SQLite limit category [https://www.sqlite.org/c3ref/c_limit_attached.html] to be queried.

Return type

int

Raises

ProgrammingError – If *category* is not recognised by the underlying SQLite library.

Example, query the maximum length of an SQL statement for `Connection con` (the default is 1000000000):

```
>>> con.getlimit(sqlite3.SQLITE_LIMIT_SQL_LENGT
1000000000
```

New in version 3.11.

setlimit(*category*, *limit*, */*)

Set a connection runtime limit. Attempts to increase a limit above its hard upper bound are silently truncated to the hard upper bound. Regardless of whether or not the limit was changed, the prior value of the limit is returned.

Parameters

- **category** (*int*) – The SQLite limit category [https://www.sqlite.org/c3ref/c_limit_attached.html] to be set.
- **limit** (*int*) – The value of the new limit. If negative, the current limit is unchanged.

Return type

int

Raises

ProgrammingError – If *category* is not recognised by the underlying SQLite library.

Example, limit the number of attached databases to 1 for `Connection` `con` (the default limit is 10):

```
>>> con.setlimit(sqlite3.SQLITE_LIMIT_ATTACHED,
10
>>> con.getlimit(sqlite3.SQLITE_LIMIT_ATTACHED)
1
```

New in version 3.11.

serialize(*, *name* = *'main'*)

Serialize a database into a `bytes` object. For an ordinary on-disk database file, the serialization is just a copy of the disk file. For an in-memory database or a “temp” database, the serialization is the same sequence of bytes which would be written to disk if that database were backed up to disk.

Parameters

name (*str*) – The database name to be serialized. Defaults to `"main"`.

Return type

bytes

Note

This method is only available if the underlying SQLite library has the serialize API.

New in version 3.11.

deserialize(*data*, */*, ***, *name='main'*)

Deserialize a **serialized** database into a **Connection**. This method causes the database connection to disconnect from database *name*, and reopen *name* as an in-memory database based on the serialization contained in *data*.

Parameters

- **data** (*bytes*) – A serialized database.
- **name** (*str*) – The database name to deserialize into. Defaults to `"main"`.

Raises

- **OperationalError** – If the database connection is currently involved in a read transaction or a backup operation.
- **DatabaseError** – If *data* does not contain a valid SQLite database.
- **OverflowError** – If **len(data)** is larger than `2**63 - 1`.

Note

This method is only available if the underlying

SQLite library has the deserialize API.

New in version 3.11.

in_transaction

This read-only attribute corresponds to the low-level SQLite autocommit mode [https://www.sqlite.org/lang_transaction.html#implicit_versus_explicit_transactions].

`True` if a transaction is active (there are uncommitted changes), `False` otherwise.

New in version 3.2.

isolation_level

This attribute controls the transaction handling performed by **`sqlite3`**. If set to `None`, transactions are never implicitly opened. If set to one of `"DEFERRED"`, `"IMMEDIATE"`, or `"EXCLUSIVE"`, corresponding to the underlying SQLite transaction behaviour [https://www.sqlite.org/lang_transaction.html#deferred_immediate_and_exclusive_transactions], implicit transaction management is performed.

If not overridden by the *isolation_level* parameter of **`connect()`**, the default is `""`, which is an alias for `"DEFERRED"`.

row_factory

The initial **`row_factory`** for **`Cursor`** objects created from this connection. Assigning to this attribute does not affect the **`row_factory`** of existing cursors belonging to this connection, only new ones. Is `None` by default, meaning each row is returned as a **`tuple`**.

See How to create and use row factories for more details.

text_factory

A callable that accepts a **bytes** parameter and returns a text representation of it. The callable is invoked for SQLite values with the `TEXT` data type. By default, this attribute is set to **str**. If you want to return `bytes` instead, set *text_factory* to `bytes`.

Example:

```
con = sqlite3.connect(":memory:")
cur = con.cursor()

AUSTRIA = "Österreich"

# by default, rows are returned as str
cur.execute("SELECT ?", (AUSTRIA,))
row = cur.fetchone()
assert row[0] == AUSTRIA

# but we can make sqlite3 always return bytestr
con.text_factory = bytes
cur.execute("SELECT ?", (AUSTRIA,))
row = cur.fetchone()
assert type(row[0]) is bytes
# the bytestrings will be encoded in UTF-8, unl
# database ...
assert row[0] == AUSTRIA.encode("utf-8")

# we can also implement a custom text_factory .
# here we implement one that appends "foo" to a
con.text_factory = lambda x: x.decode("utf-8")
cur.execute("SELECT ?", ("bar",))
row = cur.fetchone()
assert row[0] == "barfoo"

con.close()
```

total_changes

Return the total number of database rows that have been modified, inserted, or deleted since the database

connection was opened.

Cursor objects

A `Cursor` object represents a database cursor [https://en.wikipedia.org/wiki/Cursor_(databases)] which is used to execute SQL statements, and manage the context of a fetch operation. Cursors are created using **`Connection.cursor()`**, or by using any of the connection shortcut methods.

Cursor objects are iterators, meaning that if you **`execute()`** a `SELECT` query, you can simply iterate over the cursor to fetch the resulting rows:

```
for row in cur.execute("SELECT t FROM data"):
    print(row)
```

class sqlite3.Cursor

A **`Cursor`** instance has the following attributes and methods.

execute(*sql*, *parameters*=*()*, */*)

Execute SQL statement *sql*. Bind values to the statement using placeholders that map to the sequence or **`dict`** *parameters*.

`execute()` will only execute a single SQL statement. If you try to execute more than one statement with it, it will raise a **`ProgrammingError`**. Use **`executescript()`** if you want to execute multiple SQL statements with one call.

If **`isolation_level`** is not `None`, *sql* is an `INSERT`, `UPDATE`, `DELETE`, or `REPLACE` statement, and there is no open transaction, a transaction is implicitly opened before executing *sql*.

executemany(*sql*, *parameters*, */*)

Execute parameterized SQL statement *sql* against all parameter sequences or mappings found in the sequence *parameters*. It is also possible to use an iterator yielding parameters instead of a sequence. Uses the same implicit transaction handling as **`execute()`**.

Example:

```
rows = [
    ("row1",),
    ("row2",),
]
# cur is an sqlite3.Cursor object
cur.executemany("INSERT INTO data VALUES(?)", r
```

executescript(*sql_script*, */*)

Execute the SQL statements in *sql_script*. If there is a pending transaction, an implicit `COMMIT` statement is executed first. No other implicit transaction control is performed; any transaction control must be added to *sql_script*.

sql_script must be a **`string`**.

Example:

```
# cur is an sqlite3.Cursor object
cur.executescript("""
    BEGIN;
    CREATE TABLE person(firstname, lastname, ag
    CREATE TABLE book(title, author, published)
    CREATE TABLE publisher(name, address);
    COMMIT;
""")
```

fetchone()

If **`row_factory`** is `None`, return the next row query result set as a **`tuple`**. Else, pass it to the row factory and return its result. Return `None` if no more data is

available.

fetchmany(*size* = *cursor.arraysize*)

Return the next set of rows of a query result as a **list**. Return an empty list if no more rows are available.

The number of rows to fetch per call is specified by the *size* parameter. If *size* is not given, **arraysize** determines the number of rows to be fetched. If fewer than *size* rows are available, as many rows as are available are returned.

Note there are performance considerations involved with the *size* parameter. For optimal performance, it is usually best to use the arraysize attribute. If the *size* parameter is used, then it is best for it to retain the same value from one **fetchmany()** call to the next.

fetchall()

Return all (remaining) rows of a query result as a **list**. Return an empty list if no rows are available. Note that the **arraysize** attribute can affect the performance of this operation.

close()

Close the cursor now (rather than whenever `__del__` is called).

The cursor will be unusable from this point forward; a **ProgrammingError** exception will be raised if any operation is attempted with the cursor.

setinputsizes(*sizes*, */*)

Required by the DB-API. Does nothing in **sqlite3**.

setoutputsize(*size*, *column* = *None*, */*)

Required by the DB-API. Does nothing in **sqlite3**.

arraysize

Read/write attribute that controls the number of rows returned by **`fetchmany()`**. The default value is 1 which means a single row would be fetched per call.

connection

Read-only attribute that provides the SQLite database **`Connection`** belonging to the cursor. A **`Cursor`** object created by calling **`con.cursor()`** will have a **`connection`** attribute that refers to *con*:

```
>>> con = sqlite3.connect(":memory:")
>>> cur = con.cursor()
>>> cur.connection == con
True
```

description

Read-only attribute that provides the column names of the last query. To remain compatible with the Python DB API, it returns a 7-tuple for each column where the last six items of each tuple are `None`.

It is set for `SELECT` statements without any matching rows as well.

lastrowid

Read-only attribute that provides the row id of the last inserted row. It is only updated after successful `INSERT` or `REPLACE` statements using the **`execute()`** method. For other statements, after **`executemany()`** or **`executescript()`**, or if the insertion failed, the value of `lastrowid` is left unchanged. The initial value of `lastrowid` is `None`.

Note

Inserts into `WITHOUT ROWID` tables are not recorded.

Changed in version 3.6: Added support for the `REPLACE` statement.

rowcount

Read-only attribute that provides the number of modified rows for `INSERT`, `UPDATE`, `DELETE`, and `REPLACE` statements; is `-1` for other statements, including CTE queries. It is only updated by the **`execute()`** and **`executemany()`** methods.

row_factory

Control how a row fetched from this **`Cursor`** is represented. If `None`, a row is represented as a **`tuple`**. Can be set to the included **`sqlite3.Row`**; or a callable that accepts two arguments, a **`Cursor`** object and the **`tuple`** of row values, and returns a custom object representing an SQLite row.

Defaults to what **`Connection.row_factory`** was set to when the **`Cursor`** was created. Assigning to this attribute does not affect **`Connection.row_factory`** of the parent connection.

See How to create and use row factories for more details.

Row objects

class sqlite3.Row

A **`Row`** instance serves as a highly optimized **`row_factory`** for **`Connection`** objects. It supports iteration, equality testing, **`len()`**, and mapping access by column name and index.

Two **`Row`** objects compare equal if they have identical column names and values.

See How to create and use row factories for more details.

keys()

Return a `list` of column names as `strings`. Immediately after a query, it is the first member of each tuple in `Cursor.description`.

Changed in version 3.5: Added support of slicing.

Blob objects

New in version 3.11.

class sqlite3.Blob

A `Blob` instance is a file-like object that can read and write data in an SQLite BLOB. Call `len(blob)` to get the size (number of bytes) of the blob. Use indices and slices for direct access to the blob data.

Use the `Blob` as a context manager to ensure that the blob handle is closed after use.

```
con = sqlite3.connect(":memory:")
con.execute("CREATE TABLE test(blob_col blob)")
con.execute("INSERT INTO test(blob_col) VALUES(zero

# Write to our blob, using two write operations:
with con.blobopen("test", "blob_col", 1) as blob:
    blob.write(b"hello, ")
    blob.write(b"world.")
    # Modify the first and last bytes of our blob
    blob[0] = ord("H")
    blob[-1] = ord("!")

# Read the contents of our blob
with con.blobopen("test", "blob_col", 1) as blob:
    greeting = blob.read()

print(greeting)  # outputs "b'Hello, world!'"
```

close()

Close the blob.

The blob will be unusable from this point onward. An **Error** (or subclass) exception will be raised if any further operation is attempted with the blob.

read(*length* = -1, /)

Read *length* bytes of data from the blob at the current offset position. If the end of the blob is reached, the data up to EOF will be returned. When *length* is not specified, or is negative, **read()** will read until the end of the blob.

write(*data*, /)

Write *data* to the blob at the current offset. This function cannot change the blob length. Writing beyond the end of the blob will raise **ValueError**.

tell()

Return the current access position of the blob.

seek(*offset*, *origin* = *os.SEEK_SET*, /)

Set the current access position of the blob to *offset*. The *origin* argument defaults to **os.SEEK_SET** (absolute blob positioning). Other values for *origin* are **os.SEEK_CUR** (seek relative to the current position) and **os.SEEK_END** (seek relative to the blob's end).

PrepareProtocol objects

class sqlite3.PrepareProtocol

The PrepareProtocol type's single purpose is to act as a **PEP 246** [https://peps.python.org/pep-0246/] style adaption protocol for objects that can adapt themselves to native SQLite types.

Exceptions

The exception hierarchy is defined by the DB-API 2.0 (**PEP 249** [https://peps.python.org/pep-0249/]).

exception sqlite3.Warning

This exception is not currently raised by the **sqlite3** module, but may be raised by applications using **sqlite3**, for example if a user-defined function truncates data while inserting. `Warning` is a subclass of **Exception**.

exception sqlite3.Error

The base class of the other exceptions in this module. Use this to catch all errors with one single **except** statement. `Error` is a subclass of **Exception**.

If the exception originated from within the SQLite library, the following two attributes are added to the exception:

sqlite_errorcode

The numeric error code from the SQLite API [https://sqlite.org/rescode.html]

New in version 3.11.

sqlite_errorname

The symbolic name of the numeric error code from the SQLite API [https://sqlite.org/rescode.html]

New in version 3.11.

exception sqlite3.InterfaceError

Exception raised for misuse of the low-level SQLite C API. In other words, if this exception is raised, it probably indicates a bug in the **sqlite3** module. `InterfaceError` is a subclass of **Error**.

exception sqlite3.DatabaseError

Exception raised for errors that are related to the database. This serves as the base exception for several types of database errors. It is only raised implicitly through the specialised

subclasses. `DatabaseError` is a subclass of **`Error`**.

exception sqlite3.DataError

Exception raised for errors caused by problems with the processed data, like numeric values out of range, and strings which are too long. `DataError` is a subclass of **`DatabaseError`**.

exception sqlite3.OperationalError

Exception raised for errors that are related to the database's operation, and not necessarily under the control of the programmer. For example, the database path is not found, or a transaction could not be processed. `OperationalError` is a subclass of **`DatabaseError`**.

exception sqlite3.IntegrityError

Exception raised when the relational integrity of the database is affected, e.g. a foreign key check fails. It is a subclass of **`DatabaseError`**.

exception sqlite3.InternalError

Exception raised when SQLite encounters an internal error. If this is raised, it may indicate that there is a problem with the runtime SQLite library. `InternalError` is a subclass of **`DatabaseError`**.

exception sqlite3.ProgrammingError

Exception raised for **`sqlite3`** API programming errors, for example supplying the wrong number of bindings to a query, or trying to operate on a closed **`Connection`**. `ProgrammingError` is a subclass of **`DatabaseError`**.

exception sqlite3.NotSupportedError

Exception raised in case a method or database API is not supported by the underlying SQLite library. For example, setting *deterministic* to `True` in **`create_function()`**, if the underlying SQLite library does not support deterministic functions. `NotSupportedError` is a subclass of

DatabaseError.

SQLite and Python types

SQLite natively supports the following types: `NULL`, `INTEGER`, `REAL`, `TEXT`, `BLOB`.

The following Python types can thus be sent to SQLite without any problem:

Python type	SQLite type
`None`	`NULL`
`int`	`INTEGER`
`float`	`REAL`
`str`	`TEXT`
`bytes`	`BLOB`

This is how SQLite types are converted to Python types by default:

SQLite type	Python type
`NULL`	`None`
`INTEGER`	`int`
`REAL`	`float`
`TEXT`	depends on **text_factory**, **str** by default
`BLOB`	`bytes`

The type system of the **sqlite3** module is extensible in two ways: you can store additional Python types in an SQLite database via object adapters, and you can let the **sqlite3** module convert SQLite types to Python types via converters.

Default adapters and converters

There are default adapters for the date and datetime types in the datetime module. They will be sent as ISO dates/ISO timestamps to SQLite.

The default converters are registered under the name “date” for **datetime.date** and under the name “timestamp” for **datetime.datetime**.

This way, you can use date/timestamps from Python without any additional fiddling in most cases. The format of the adapters is also compatible with the experimental SQLite date/time functions.

The following example demonstrates this.

```
import sqlite3
import datetime

con = sqlite3.connect(":memory:", detect_types=sqlite3.P
cur = con.cursor()
cur.execute("create table test(d date, ts timestamp)")

today = datetime.date.today()
now = datetime.datetime.now()

cur.execute("insert into test(d, ts) values (?, ?)", (to
cur.execute("select d, ts from test")
row = cur.fetchone()
print(today, "=>", row[0], type(row[0]))
print(now, "=>", row[1], type(row[1]))

cur.execute('select current_date as "d [date]", current_
row = cur.fetchone()
print("current_date", row[0], type(row[0]))
print("current_timestamp", row[1], type(row[1]))

con.close()
```

If a timestamp stored in SQLite has a fractional part longer than 6 numbers, its value will be truncated to microsecond precision by the timestamp converter.

Note

The default “timestamp” converter ignores UTC offsets in the database and always returns a naive `datetime.datetime` object. To preserve UTC offsets in timestamps, either leave converters disabled, or register an offset-aware converter with

register_converter().

How-to guides

How to use placeholders to bind values in SQL queries

SQL operations usually need to use values from Python variables. However, beware of using Python's string operations to assemble queries, as they are vulnerable to SQL injection attacks [https://en.wikipedia.org/wiki/SQL_injection]. For example, an attacker can simply close the single quote and inject `OR TRUE` to select all rows:

```
>>> # Never do this -- insecure!
>>> symbol = input()
' OR TRUE; --
>>> sql = "SELECT * FROM stocks WHERE symbol = '%s'" % s
>>> print(sql)
SELECT * FROM stocks WHERE symbol = '' OR TRUE; --'
>>> cur.execute(sql)
```

Instead, use the DB-API's parameter substitution. To insert a variable into a query string, use a placeholder in the string, and substitute the actual values into the query by providing them as a **tuple** of values to the second argument of the cursor's **execute()** method. An SQL statement may use one of two kinds of placeholders: question marks (qmark style) or named placeholders (named style). For the qmark style, `parameters` must be a sequence. For the named style, it can be either a sequence or **dict** instance. The length of the sequence must match the number of placeholders, or a **ProgrammingError** is raised. If a **dict** is given, it must contain keys for all named parameters. Any extra items are ignored. Here's an example of both styles:

```
con = sqlite3.connect(":memory:")
cur = con.execute("CREATE TABLE lang(name, first_appeare

# This is the qmark style:
cur.execute("INSERT INTO lang VALUES(?, ?)", ("C", 1972)
```

```
# The qmark style used with executemany():
lang_list = [
    ("Fortran", 1957),
    ("Python", 1991),
    ("Go", 2009),
]
cur.executemany("INSERT INTO lang VALUES(?, ?)", lang_li

# And this is the named style:
cur.execute("SELECT * FROM lang WHERE first_appeared = :
print(cur.fetchall())
```

How to adapt custom Python types to SQLite values

SQLite supports only a limited set of data types natively. To store custom Python types in SQLite databases, *adapt* them to one of the Python types SQLite natively understands.

There are two ways to adapt Python objects to SQLite types: letting your object adapt itself, or using an *adapter callable*. The latter will take precedence above the former. For a library that exports a custom type, it may make sense to enable that type to adapt itself. As an application developer, it may make more sense to take direct control by registering custom adapter functions.

How to write adaptable objects

Suppose we have a **`Point`** class that represents a pair of coordinates, `x` and `y`, in a Cartesian coordinate system. The coordinate pair will be stored as a text string in the database, using a semicolon to separate the coordinates. This can be implemented by adding a `__conform__(self, protocol)` method which returns the adapted value. The object passed to *protocol* will be of type **`PrepareProtocol`**.

```
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y
```

```
    def __conform__(self, protocol):
        if protocol is sqlite3.PrepareProtocol:
            return f"{self.x};{self.y}"

con = sqlite3.connect(":memory:")
cur = con.cursor()

cur.execute("SELECT ?", (Point(4.0, -3.2),))
print(cur.fetchone()[0])
```

How to register adapter callables

The other possibility is to create a function that converts the Python object to an SQLite-compatible type. This function can then be registered using `register_adapter()`.

```
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

def adapt_point(point):
    return f"{point.x};{point.y}"

sqlite3.register_adapter(Point, adapt_point)

con = sqlite3.connect(":memory:")
cur = con.cursor()

cur.execute("SELECT ?", (Point(1.0, 2.5),))
print(cur.fetchone()[0])
```

How to convert SQLite values to custom Python types

Writing an adapter lets you convert *from* custom Python types *to* SQLite values. To be able to convert *from* SQLite values *to* custom Python types, we use *converters*.

Let's go back to the `Point` class. We stored the x and y coordinates separated via semicolons as strings in SQLite.

First, we'll define a converter function that accepts the string as a parameter and constructs a **`Point`** object from it.

Note

Converter functions are **always** passed a **`bytes`** object, no matter the underlying SQLite data type.

```
def convert_point(s):
    x, y = map(float, s.split(b";"))
    return Point(x, y)
```

We now need to tell **`sqlite3`** when it should convert a given SQLite value. This is done when connecting to a database, using the *detect_types* parameter of **`connect()`**. There are three options:

- Implicit: set *detect_types* to **`PARSE_DECLTYPES`**
- Explicit: set *detect_types* to **`PARSE_COLNAMES`**
- Both: set *detect_types* to `sqlite3.PARSE_DECLTYPES | sqlite3.PARSE_COLNAMES`. Column names take precedence over declared types.

The following example illustrates the implicit and explicit approaches:

```
class Point:
    def __init__(self, x, y):
        self.x, self.y = x, y

    def __repr__(self):
        return f"Point({self.x}, {self.y})"

def adapt_point(point):
    return f"{point.x};{point.y}"

def convert_point(s):
    x, y = list(map(float, s.split(b";")))
    return Point(x, y)
```

```
# Register the adapter and converter
sqlite3.register_adapter(Point, adapt_point)
sqlite3.register_converter("point", convert_point)

# 1) Parse using declared types
p = Point(4.0, -3.2)
con = sqlite3.connect(":memory:", detect_types=sqlite3.P
cur = con.execute("CREATE TABLE test(p point)")

cur.execute("INSERT INTO test(p) VALUES(?)", (p,))
cur.execute("SELECT p FROM test")
print("with declared types:", cur.fetchone()[0])
cur.close()
con.close()

# 2) Parse using column names
con = sqlite3.connect(":memory:", detect_types=sqlite3.P
cur = con.execute("CREATE TABLE test(p)")

cur.execute("INSERT INTO test(p) VALUES(?)", (p,))
cur.execute('SELECT p AS "p [point]" FROM test')
print("with column names:", cur.fetchone()[0])
```

Adapter and converter recipes

This section shows recipes for common adapters and converters.

```
import datetime
import sqlite3

def adapt_date_iso(val):
    """Adapt datetime.date to ISO 8601 date."""
    return val.isoformat()

def adapt_datetime_iso(val):
    """Adapt datetime.datetime to timezone-naive ISO 860
    return val.isoformat()

def adapt_datetime_epoch(val):
```

```
    """Adapt datetime.datetime to Unix timestamp."""
    return int(val.timestamp())

sqlite3.register_adapter(datetime.date, adapt_date_iso)
sqlite3.register_adapter(datetime.datetime, adapt_dateti
sqlite3.register_adapter(datetime.datetime, adapt_dateti

def convert_date(val):
    """Convert ISO 8601 date to datetime.date object."""
    return datetime.date.fromisoformat(val.decode())

def convert_datetime(val):
    """Convert ISO 8601 datetime to datetime.datetime ob
    return datetime.datetime.fromisoformat(val.decode())

def convert_timestamp(val):
    """Convert Unix epoch timestamp to datetime.datetime
    return datetime.datetime.fromtimestamp(int(val))

sqlite3.register_converter("date", convert_date)
sqlite3.register_converter("datetime", convert_datetime)
sqlite3.register_converter("timestamp", convert_timestam
```

How to use connection shortcut methods

Using the **`execute()`**, **`executemany()`**, and **`executescript()`** methods of the **`Connection`** class, your code can be written more concisely because you don't have to create the (often superfluous) **`Cursor`** objects explicitly. Instead, the **`Cursor`** objects are created implicitly and these shortcut methods return the cursor objects. This way, you can execute a `SELECT` statement and iterate over it directly using only a single call on the **`Connection`** object.

```
# Create and fill the table.
con = sqlite3.connect(":memory:")
con.execute("CREATE TABLE lang(name, first_appeared)")
data = [
    ("C++", 1985),
```

```
    ("Objective-C", 1984),
]
con.executemany("INSERT INTO lang(name, first_appeared)

# Print the table contents
for row in con.execute("SELECT name, first_appeared FROM
    print(row)

print("I just deleted", con.execute("DELETE FROM lang").

# close() is not a shortcut method and it's not called a
# the connection object should be closed manually
con.close()
```

How to use the connection context manager

A **`Connection`** object can be used as a context manager that automatically commits or rolls back open transactions when leaving the body of the context manager. If the body of the **`with`** statement finishes without exceptions, the transaction is committed. If this commit fails, or if the body of the `with` statement raises an uncaught exception, the transaction is rolled back.

If there is no open transaction upon leaving the body of the `with` statement, the context manager is a no-op.

Note

The context manager neither implicitly opens a new transaction nor closes the connection.

```
con = sqlite3.connect(":memory:")
con.execute("CREATE TABLE lang(id INTEGER PRIMARY KEY, n

# Successful, con.commit() is called automatically after
with con:
    con.execute("INSERT INTO lang(name) VALUES(?)", ("Py

# con.rollback() is called after the with block finishes
```

```
# the exception is still raised and must be caught
try:
    with con:
        con.execute("INSERT INTO lang(name) VALUES(?)",
except sqlite3.IntegrityError:
    print("couldn't add Python twice")

# Connection object used as context manager only commits
# so the connection object should be closed manually
con.close()
```

How to work with SQLite URIs

Some useful URI tricks include:

- Open a database in read-only mode:

```
>>> con = sqlite3.connect("file:tutorial.db?mode=ro", ur
>>> con.execute("CREATE TABLE readonly(data)")
Traceback (most recent call last):
OperationalError: attempt to write a readonly database
```

- Do not implicitly create a new database file if it does not already exist; will raise **`OperationalError`** if unable to create a new file:

```
>>> con = sqlite3.connect("file:nosuchdb.db?mode=rw", ur
Traceback (most recent call last):
OperationalError: unable to open database file
```

- Create a shared named in-memory database:

```
db = "file:mem1?mode=memory&cache=shared"
con1 = sqlite3.connect(db, uri=True)
con2 = sqlite3.connect(db, uri=True)
with con1:
    con1.execute("CREATE TABLE shared(data)")
    con1.execute("INSERT INTO shared VALUES(28)")
res = con2.execute("SELECT data FROM shared")
assert res.fetchone() == (28,)
```

More information about this feature, including a list of parameters, can be found in the SQLite URI documentation [https://www.sqlite.org/uri.html].

How to create and use row factories

By default, **sqlite3** represents each row as a **tuple**. If a **tuple** does not suit your needs, you can use the **sqlite3.Row** class or a custom **row_factory**.

While **row_factory** exists as an attribute both on the **Cursor** and the **Connection**, it is recommended to set **Connection.row_factory**, so all cursors created from the connection will use the same row factory.

Row provides indexed and case-insensitive named access to columns, with minimal memory overhead and performance impact over a **tuple**. To use **Row** as a row factory, assign it to the **row_factory** attribute:

```
>>> con = sqlite3.connect(":memory:")
>>> con.row_factory = sqlite3.Row
```

Queries now return **Row** objects:

```
>>> res = con.execute("SELECT 'Earth' AS name, 6378 AS r
>>> row = res.fetchone()
>>> row.keys()
['name', 'radius']
>>> row[0]          # Access by index.
'Earth'
>>> row["name"]     # Access by name.
'Earth'
>>> row["RADIUS"]   # Column names are case-insensitive.
6378
```

You can create a custom **row_factory** that returns each row as a **dict**, with column names mapped to values:

```
def dict_factory(cursor, row):
```

```
    fields = [column[0] for column in cursor.description
    return {key: value for key, value in zip(fields, row
```

Using it, queries now return a **`dict`** instead of a **`tuple`**:

```
>>> con = sqlite3.connect(":memory:")
>>> con.row_factory = dict_factory
>>> for row in con.execute("SELECT 1 AS a, 2 AS b"):
...     print(row)
{'a': 1, 'b': 2}
```

The following row factory returns a named tuple:

```
from collections import namedtuple

def namedtuple_factory(cursor, row):
    fields = [column[0] for column in cursor.description
    cls = namedtuple("Row", fields)
    return cls._make(row)
```

`namedtuple_factory()` can be used as follows:

```
>>> con = sqlite3.connect(":memory:")
>>> con.row_factory = namedtuple_factory
>>> cur = con.execute("SELECT 1 AS a, 2 AS b")
>>> row = cur.fetchone()
>>> row
Row(a=1, b=2)
>>> row[0]  # Indexed access.
1
>>> row.b   # Attribute access.
2
```

With some adjustments, the above recipe can be adapted to use a **`dataclass`**, or any other custom class, instead of a **`namedtuple`**.

Explanation

Transaction control

The **sqlite3** module does not adhere to the transaction handling recommended by **PEP 249** [https://peps.python.org/pep-0249/].

If the connection attribute **isolation_level** is not `None`, new transactions are implicitly opened before **execute()** and **executemany()** executes `INSERT`, `UPDATE`, `DELETE`, or `REPLACE` statements; for other statements, no implicit transaction handling is performed. Use the **commit()** and **rollback()** methods to respectively commit and roll back pending transactions. You can choose the underlying SQLite transaction behaviour [https://www.sqlite.org/lang_transaction.html#deferred_immediate_and_exclusive_transactions] — that is, whether and what type of `BEGIN` statements **sqlite3** implicitly executes – via the **isolation_level** attribute.

If **isolation_level** is set to `None`, no transactions are implicitly opened at all. This leaves the underlying SQLite library in autocommit mode [https://www.sqlite.org/lang_transaction.html#implicit_versus_explicit_transactions], but also allows the user to perform their own transaction handling using explicit SQL statements. The underlying SQLite library autocommit mode can be queried using the **in_transaction** attribute.

The **executescript()** method implicitly commits any pending transaction before execution of the given SQL script, regardless of the value of **isolation_level**.

Changed in version 3.6: **sqlite3** used to implicitly commit an open transaction before DDL statements. This is no longer the case.

Data Compression and Archiving

The modules described in this chapter support data compression with the zlib, gzip, bzip2 and lzma algorithms, and the creation of ZIP- and tar-format archives. See also Archiving operations provided by the `shutil` module.

- `zlib` — Compression compatible with **gzip**
- `gzip` — Support for **gzip** files
  - Examples of usage
  - Command Line Interface
    - Command line options
- `bz2` — Support for **bzip2** compression
  - (De)compression of files
  - Incremental (de)compression
  - One-shot (de)compression
  - Examples of usage
- `lzma` — Compression using the LZMA algorithm
  - Reading and writing compressed files
  - Compressing and decompressing data in memory
  - Miscellaneous
  - Specifying custom filter chains
  - Examples
- `zipfile` — Work with ZIP archives
  - ZipFile Objects
  - Path Objects
  - PyZipFile Objects

    - ZipInfo Objects
    - Command-Line Interface
        - Command-line options
    - Decompression pitfalls
        - From file itself
        - File System limitations
        - Resources limitations
        - Interruption
        - Default behaviors of extraction

- **`tarfile`** — Read and write tar archive files
    - TarFile Objects
    - TarInfo Objects
    - Command-Line Interface
        - Command-line options
    - Examples
    - Supported tar formats
    - Unicode issues

`zlib` — Compression compatible with gzip

For applications that require data compression, the functions in this module allow compression and decompression, using the zlib library. The zlib library has its own home page at https://www.zlib.net. There are known incompatibilities between the Python module and versions of the zlib library earlier than 1.1.3; 1.1.3 has a security vulnerability [https://zlib.net/zlib_faq.html#faq33], so we recommend using 1.1.4 or later.

zlib's functions have many options and often need to be used in a particular order. This documentation doesn't attempt to cover all of the permutations; consult the zlib manual at http://www.zlib.net/manual.html for authoritative information.

For reading and writing `.gz` files see the **`gzip`** module.

The available exception and functions in this module are:

exception zlib.error

Exception raised on compression and decompression errors.

zlib.adler32(*data*[, *value*])

Computes an Adler-32 checksum of *data*. (An Adler-32 checksum is almost as reliable as a CRC32 but can be computed much more quickly.) The result is an unsigned 32-bit integer. If *value* is present, it is used as the starting value of the checksum; otherwise, a default value of 1 is used. Passing in *value* allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable

for use as a general hash algorithm.

Changed in version 3.0: The result is always unsigned.

zlib.compress(*data*, */*, *level=-1*, *wbits=MAX_WBITS*)

Compresses the bytes in *data*, returning a bytes object containing compressed data. *level* is an integer from `0` to `9` or `-1` controlling the level of compression; `1` (Z_BEST_SPEED) is fastest and produces the least compression, `9` (Z_BEST_COMPRESSION) is slowest and produces the most. `0` (Z_NO_COMPRESSION) is no compression. The default value is `-1` (Z_DEFAULT_COMPRESSION). Z_DEFAULT_COMPRESSION represents a default compromise between speed and compression (currently equivalent to level 6).

The *wbits* argument controls the size of the history buffer (or the "window size") used when compressing data, and whether a header and trailer is included in the output. It can take several ranges of values, defaulting to `15` (MAX_WBITS):

- +9 to +15: The base-two logarithm of the window size, which therefore ranges between 512 and 32768. Larger values produce better compression at the expense of greater memory usage. The resulting output will include a zlib-specific header and trailer.
- −9 to −15: Uses the absolute value of *wbits* as the window size logarithm, while producing a raw output stream with no header or trailing checksum.
- +25 to +31 = 16 + (9 to 15): Uses the low 4 bits of the value as the window size logarithm, while including a basic **gzip** header and trailing checksum in the output.

Raises the **`error`** exception if any error occurs.

Changed in version 3.6: level can now be used as a keyword parameter.

Changed in version 3.11: The *wbits* parameter is now available

to set window bits and compression type.

zlib.compressobj(*level=-1*, *method=DEFLATED*, *wbits=MAX_WBITS*, *memLevel=DEF_MEM_LEVEL*, *strategy=Z_DEFAULT_STRATEGY*[, *zdict*])

Returns a compression object, to be used for compressing data streams that won't fit into memory at once.

level is the compression level – an integer from `0` to `9` or `-1`. A value of `1` (Z_BEST_SPEED) is fastest and produces the least compression, while a value of `9` (Z_BEST_COMPRESSION) is slowest and produces the most. `0` (Z_NO_COMPRESSION) is no compression. The default value is `-1` (Z_DEFAULT_COMPRESSION). Z_DEFAULT_COMPRESSION represents a default compromise between speed and compression (currently equivalent to level 6).

method is the compression algorithm. Currently, the only supported value is **`DEFLATED`**.

The *wbits* parameter controls the size of the history buffer (or the "window size"), and what header and trailer format will be used. It has the same meaning as described for compress().

The *memLevel* argument controls the amount of memory used for the internal compression state. Valid values range from `1` to `9`. Higher values use more memory, but are faster and produce smaller output.

strategy is used to tune the compression algorithm. Possible values are **`Z_DEFAULT_STRATEGY`**, **`Z_FILTERED`**, **`Z_HUFFMAN_ONLY`**, **`Z_RLE`** (zlib 1.2.0.1) and **`Z_FIXED`** (zlib 1.2.2.2).

zdict is a predefined compression dictionary. This is a sequence of bytes (such as a **`bytes`** object) containing subsequences that are expected to occur frequently in the data that is to be compressed. Those subsequences that are expected to be most common should come at the end of the dictionary.

Changed in version 3.3: Added the *zdict* parameter and keyword argument support.

zlib.crc32(*data*[, *value*])

Computes a CRC (Cyclic Redundancy Check) checksum of *data*. The result is an unsigned 32-bit integer. If *value* is present, it is used as the starting value of the checksum; otherwise, a default value of 0 is used. Passing in *value* allows computing a running checksum over the concatenation of several inputs. The algorithm is not cryptographically strong, and should not be used for authentication or digital signatures. Since the algorithm is designed for use as a checksum algorithm, it is not suitable for use as a general hash algorithm.

Changed in version 3.0: The result is always unsigned.

zlib.decompress(*data*, */*, *wbits*=*MAX_WBITS*, *bufsize*=*DEF_BUF_SIZE*)

Decompresses the bytes in *data*, returning a bytes object containing the uncompressed data. The *wbits* parameter depends on the format of *data*, and is discussed further below. If *bufsize* is given, it is used as the initial size of the output buffer. Raises the **error** exception if any error occurs.

The *wbits* parameter controls the size of the history buffer (or "window size"), and what header and trailer format is expected. It is similar to the parameter for **compressobj()**, but accepts more ranges of values:

- +8 to +15: The base-two logarithm of the window size. The input must include a zlib header and trailer.
- 0: Automatically determine the window size from the zlib header. Only supported since zlib 1.2.3.5.
- −8 to −15: Uses the absolute value of *wbits* as the window size logarithm. The input must be a raw stream with no header or trailer.
- +24 to +31 = 16 + (8 to 15): Uses the low 4 bits of the value as the window size logarithm. The input must

include a gzip header and trailer.

- +40 to +47 = 32 + (8 to 15): Uses the low 4 bits of the value as the window size logarithm, and automatically accepts either the zlib or gzip format.

When decompressing a stream, the window size must not be smaller than the size originally used to compress the stream; using a too-small value may result in an **error** exception. The default *wbits* value corresponds to the largest window size and requires a zlib header and trailer to be included.

bufsize is the initial size of the buffer used to hold decompressed data. If more space is required, the buffer size will be increased as needed, so you don't have to get this value exactly right; tuning it will only save a few calls to **malloc()**.

Changed in version 3.6: wbits and *bufsize* can be used as keyword arguments.

zlib.decompressobj(*wbits*=*MAX_WBITS*[, *zdict*])

Returns a decompression object, to be used for decompressing data streams that won't fit into memory at once.

The *wbits* parameter controls the size of the history buffer (or the "window size"), and what header and trailer format is expected. It has the same meaning as described for decompress().

The *zdict* parameter specifies a predefined compression dictionary. If provided, this must be the same dictionary as was used by the compressor that produced the data that is to be decompressed.

Note

If *zdict* is a mutable object (such as a **bytearray**), you must not modify its contents between the call to **decompressobj()** and the first call to the decompressor's `decompress()` method.

Changed in version 3.3: Added the *zdict* parameter.

Compression objects support the following methods:

Compress.compress(*data*)

Compress *data*, returning a bytes object containing compressed data for at least part of the data in *data*. This data should be concatenated to the output produced by any preceding calls to the **compress()** method. Some input may be kept in internal buffers for later processing.

Compress.flush([*mode*])

All pending input is processed, and a bytes object containing the remaining compressed output is returned. *mode* can be selected from the constants **Z_NO_FLUSH**, **Z_PARTIAL_FLUSH**, **Z_SYNC_FLUSH**, **Z_FULL_FLUSH**, **Z_BLOCK** (zlib 1.2.3.4), or **Z_FINISH**, defaulting to **Z_FINISH**. Except **Z_FINISH**, all constants allow compressing further bytestrings of data, while **Z_FINISH** finishes the compressed stream and prevents compressing any more data. After calling **flush()** with *mode* set to **Z_FINISH**, the **compress()** method cannot be called again; the only realistic action is to delete the object.

Compress.copy()

Returns a copy of the compression object. This can be used to efficiently compress a set of data that share a common initial prefix.

Changed in version 3.8: Added **copy.copy()** and **copy.deepcopy()** support to compression objects.

Decompression objects support the following methods and attributes:

Decompress.unused_data

A bytes object which contains any bytes past the end of the compressed data. That is, this remains `b""` until the last byte

that contains compression data is available. If the whole bytestring turned out to contain compressed data, this is `b""`, an empty bytes object.

Decompress.unconsumed_tail

A bytes object that contains any data that was not consumed by the last **`decompress()`** call because it exceeded the limit for the uncompressed data buffer. This data has not yet been seen by the zlib machinery, so you must feed it (possibly with further data concatenated to it) back to a subsequent **`decompress()`** method call in order to get correct output.

Decompress.eof

A boolean indicating whether the end of the compressed data stream has been reached.

This makes it possible to distinguish between a properly formed compressed stream, and an incomplete or truncated one.

New in version 3.3.

Decompress.decompress(*data*, *max_length*=*0*)

Decompress *data*, returning a bytes object containing the uncompressed data corresponding to at least part of the data in *string*. This data should be concatenated to the output produced by any preceding calls to the **`decompress()`** method. Some of the input data may be preserved in internal buffers for later processing.

If the optional parameter *max_length* is non-zero then the return value will be no longer than *max_length*. This may mean that not all of the compressed input can be processed; and unconsumed data will be stored in the attribute **`unconsumed_tail`**. This bytestring must be passed to a subsequent call to **`decompress()`** if decompression is to continue. If *max_length* is zero then the whole input is decompressed, and **`unconsumed_tail`** is empty.

Changed in version 3.6: max_length can be used as a keyword argument.

Decompress.flush([*length*])

All pending input is processed, and a bytes object containing the remaining uncompressed output is returned. After calling `flush()`, the `decompress()` method cannot be called again; the only realistic action is to delete the object.

The optional parameter *length* sets the initial size of the output buffer.

Decompress.copy()

Returns a copy of the decompression object. This can be used to save the state of the decompressor midway through the data stream in order to speed up random seeks into the stream at a future point.

Changed in version 3.8: Added `copy.copy()` and `copy.deepcopy()` support to decompression objects.

Information about the version of the zlib library in use is available through the following constants:

zlib.ZLIB_VERSION

The version string of the zlib library that was used for building the module. This may be different from the zlib library actually used at runtime, which is available as `ZLIB_RUNTIME_VERSION`.

zlib.ZLIB_RUNTIME_VERSION

The version string of the zlib library actually loaded by the interpreter.

New in version 3.3.

`gzip` — Support for gzip files

Source code: Lib/gzip.py [https://github.com/python/cpython/tree/3.11/Lib/gzip.py]

This module provides a simple interface to compress and decompress files just like the GNU programs **gzip** and **gunzip** would.

The data compression is provided by the `zlib` module.

The `gzip` module provides the `GzipFile` class, as well as the `open()`, `compress()` and `decompress()` convenience functions. The `GzipFile` class reads and writes **gzip**-format files, automatically compressing or decompressing the data so that it looks like an ordinary file object.

Note that additional file formats which can be decompressed by the **gzip** and **gunzip** programs, such as those produced by **compress** and **pack**, are not supported by this module.

The module defines the following items:

gzip.open(*filename*, *mode*='rb', *compresslevel*=9, *encoding*=None, *errors*=None, *newline*=None)

Open a gzip-compressed file in binary or text mode, returning a file object.

The *filename* argument can be an actual filename (a `str` or `bytes` object), or an existing file object to read from or write to.

The *mode* argument can be any of `'r'`, `'rb'`, `'a'`, `'ab'`, `'w'`, `'wb'`, `'x'` or `'xb'` for binary mode, or `'rt'`, `'at'`, `'wt'`, or `'xt'` for text mode. The default is `'rb'`.

The *compresslevel* argument is an integer from 0 to 9, as for the **GzipFile** constructor.

For binary mode, this function is equivalent to the **GzipFile** constructor: `GzipFile(filename, mode, compresslevel)`. In this case, the *encoding*, *errors* and *newline* arguments must not be provided.

For text mode, a **GzipFile** object is created, and wrapped in an **io.TextIOWrapper** instance with the specified encoding, error handling behavior, and line ending(s).

Changed in version 3.3: Added support for *filename* being a file object, support for text mode, and the *encoding*, *errors* and *newline* arguments.

Changed in version 3.4: Added support for the `'x'`, `'xb'` and `'xt'` modes.

Changed in version 3.6: Accepts a path-like object.

exception gzip.BadGzipFile

An exception raised for invalid gzip files. It inherits **OSError**. **EOFError** and **zlib.error** can also be raised for invalid gzip files.

New in version 3.8.

class gzip.GzipFile(*filename=None*, *mode=None*, *compresslevel=9*, *fileobj=None*, *mtime=None*)

Constructor for the **GzipFile** class, which simulates most of the methods of a file object, with the exception of the **truncate()** method. At least one of *fileobj* and *filename* must be given a non-trivial value.

The new class instance is based on *fileobj*, which can be a regular file, an **io.BytesIO** object, or any other object which simulates a file. It defaults to `None`, in which case *filename* is opened to provide a file object.

When *fileobj* is not `None`, the *filename* argument is only used to be included in the **gzip** file header, which may include the original filename of the uncompressed file. It defaults to the filename of *fileobj*, if discernible; otherwise, it defaults to the empty string, and in this case the original filename is not included in the header.

The *mode* argument can be any of `'r'`, `'rb'`, `'a'`, `'ab'`, `'w'`, `'wb'`, `'x'`, or `'xb'`, depending on whether the file will be read or written. The default is the mode of *fileobj* if discernible; otherwise, the default is `'rb'`. In future Python releases the mode of *fileobj* will not be used. It is better to always specify *mode* for writing.

Note that the file is always opened in binary mode. To open a compressed file in text mode, use **`open()`** (or wrap your **`GzipFile`** with an **`io.TextIOWrapper`**).

The *compresslevel* argument is an integer from `0` to `9` controlling the level of compression; `1` is fastest and produces the least compression, and `9` is slowest and produces the most compression. `0` is no compression. The default is `9`.

The *mtime* argument is an optional numeric timestamp to be written to the last modification time field in the stream when compressing. It should only be provided in compression mode. If omitted or `None`, the current time is used. See the **`mtime`** attribute for more details.

Calling a **`GzipFile`** object's **`close()`** method does not close *fileobj*, since you might wish to append more material after the compressed data. This also allows you to pass an **`io.BytesIO`** object opened for writing as *fileobj*, and retrieve the resulting memory buffer using the **`io.BytesIO`** object's **`getvalue()`** method.

`GzipFile` supports the **`io.BufferedIOBase`** interface, including iteration and the **`with`** statement. Only the **`truncate()`** method isn't implemented.

GzipFile also provides the following method and attribute:

peek(*n*)

Read *n* uncompressed bytes without advancing the file position. At most one single read on the compressed stream is done to satisfy the call. The number of bytes returned may be more or less than requested.

Note

While calling **peek()** does not change the file position of the **GzipFile**, it may change the position of the underlying file object (e.g. if the **GzipFile** was constructed with the *fileobj* parameter).

New in version 3.2.

mtime

When decompressing, the value of the last modification time field in the most recently read header may be read from this attribute, as an integer. The initial value before reading any headers is `None`.

All **gzip** compressed streams are required to contain this timestamp field. Some programs, such as **gunzip**, make use of the timestamp. The format is the same as the return value of **time.time()** and the **st_mtime** attribute of the object returned by **os.stat()**.

Changed in version 3.1: Support for the **with** statement was added, along with the *mtime* constructor argument and **mtime** attribute.

Changed in version 3.2: Support for zero-padded and unseekable files was added.

Changed in version 3.3: The **io.BufferedIOBase.read1()** method is now implemented.

Changed in version 3.4: Added support for the `'x'` and `'xb'` modes.

Changed in version 3.5: Added support for writing arbitrary bytes-like objects. The **`read()`** method now accepts an argument of `None`.

Changed in version 3.6: Accepts a path-like object.

Deprecated since version 3.9: Opening **`GzipFile`** for writing without specifying the *mode* argument is deprecated.

gzip.compress(*data*, *compresslevel*=*9*, ***, *mtime*=*None*)

Compress the *data*, returning a **`bytes`** object containing the compressed data. *compresslevel* and *mtime* have the same meaning as in the **`GzipFile`** constructor above. When *mtime* is set to `0`, this function is equivalent to **`zlib.compress()`** with *wbits* set to `31`. The zlib function is faster.

New in version 3.2.

Changed in version 3.8: Added the *mtime* parameter for reproducible output.

Changed in version 3.11: Speed is improved by compressing all data at once instead of in a streamed fashion. Calls with *mtime* set to `0` are delegated to **`zlib.compress()`** for better speed.

gzip.decompress(*data*)

Decompress the *data*, returning a **`bytes`** object containing the uncompressed data. This function is capable of decompressing multi-member gzip data (multiple gzip blocks concatenated together). When the data is certain to contain only one member the **`zlib.decompress()`** function with *wbits* set to 31 is faster.

New in version 3.2.

Changed in version 3.11: Speed is improved by decompressing

members at once in memory instead of in a streamed fashion.

Examples of usage

Example of how to read a compressed file:

```
import gzip
with gzip.open('/home/joe/file.txt.gz', 'rb') as f:
    file_content = f.read()
```

Example of how to create a compressed GZIP file:

```
import gzip
content = b"Lots of content here"
with gzip.open('/home/joe/file.txt.gz', 'wb') as f:
    f.write(content)
```

Example of how to GZIP compress an existing file:

```
import gzip
import shutil
with open('/home/joe/file.txt', 'rb') as f_in:
    with gzip.open('/home/joe/file.txt.gz', 'wb') as f_o
        shutil.copyfileobj(f_in, f_out)
```

Example of how to GZIP compress a binary string:

```
import gzip
s_in = b"Lots of content here"
s_out = gzip.compress(s_in)
```

See also

Module `zlib`
: The basic data compression module needed to support the **gzip** file format.

Command Line Interface

The `gzip` module provides a simple command line interface to compress or decompress files.

Once executed the `gzip` module keeps the input file(s).

Changed in version 3.8: Add a new command line interface with a usage. By default, when you will execute the CLI, the default compression level is 6.

Command line options

file
: If *file* is not specified, read from `sys.stdin`.

--fast
: Indicates the fastest compression method (less compression).

--best
: Indicates the slowest compression method (best compression).

-d, --decompress
: Decompress the given file.

-h, --help
: Show the help message.

`bz2` — Support for bzip2 compression

Source code: Lib/bz2.py [https://github.com/python/cpython/tree/3.11/Lib/bz2.py]

This module provides a comprehensive interface for compressing and decompressing data using the bzip2 compression algorithm.

The `bz2` module contains:

- The `open()` function and `BZ2File` class for reading and writing compressed files.
- The `BZ2Compressor` and `BZ2Decompressor` classes for incremental (de)compression.
- The `compress()` and `decompress()` functions for one-shot (de)compression.

(De)compression of files

bz2.open(*filename*, *mode='rb'*, *compresslevel=9*, *encoding=None*, *errors=None*, *newline=None*)

Open a bzip2-compressed file in binary or text mode, returning a file object.

As with the constructor for `BZ2File`, the *filename* argument can be an actual filename (a `str` or `bytes` object), or an existing file object to read from or write to.

The *mode* argument can be any of `'r'`, `'rb'`, `'w'`, `'wb'`, `'x'`, `'xb'`, `'a'` or `'ab'` for binary mode, or `'rt'`, `'wt'`, `'xt'`, or `'at'` for text mode. The default is `'rb'`.

The *compresslevel* argument is an integer from 1 to 9, as for

the **BZ2File** constructor.

For binary mode, this function is equivalent to the **BZ2File** constructor: `BZ2File(filename, mode, compresslevel=compresslevel)`. In this case, the *encoding*, *errors* and *newline* arguments must not be provided.

For text mode, a **BZ2File** object is created, and wrapped in an **io.TextIOWrapper** instance with the specified encoding, error handling behavior, and line ending(s).

New in version 3.3.

Changed in version 3.4: The `'x'` (exclusive creation) mode was added.

Changed in version 3.6: Accepts a path-like object.

class bz2.BZ2File(*filename*, *mode*=*'r'*, ***, *compresslevel*=*9*)

Open a bzip2-compressed file in binary mode.

If *filename* is a **str** or **bytes** object, open the named file directly. Otherwise, *filename* should be a file object, which will be used to read or write the compressed data.

The *mode* argument can be either `'r'` for reading (default), `'w'` for overwriting, `'x'` for exclusive creation, or `'a'` for appending. These can equivalently be given as `'rb'`, `'wb'`, `'xb'` and `'ab'` respectively.

If *filename* is a file object (rather than an actual file name), a mode of `'w'` does not truncate the file, and is instead equivalent to `'a'`.

If *mode* is `'w'` or `'a'`, *compresslevel* can be an integer between `1` and `9` specifying the level of compression: `1` produces the least compression, and `9` (default) produces the most compression.

If *mode* is `'r'`, the input file may be the concatenation of multiple compressed streams.

BZ2File provides all of the members specified by the **io.BufferedIOBase**, except for **detach()** and **truncate()**. Iteration and the **with** statement are supported.

BZ2File also provides the following method:

peek([*n*])

Return buffered data without advancing the file position. At least one byte of data will be returned (unless at EOF). The exact number of bytes returned is unspecified.

Note

While calling **peek()** does not change the file position of the **BZ2File**, it may change the position of the underlying file object (e.g. if the **BZ2File** was constructed by passing a file object for *filename*).

New in version 3.3.

Changed in version 3.1: Support for the **with** statement was added.

Changed in version 3.3: The **fileno()**, **readable()**, **seekable()**, **writable()**, **read1()** and **readinto()** methods were added.

Changed in version 3.3: Support was added for *filename* being a file object instead of an actual filename.

Changed in version 3.3: The `'a'` (append) mode was added, along with support for reading multi-stream files.

Changed in version 3.4: The `'x'` (exclusive creation) mode was added.

Changed in version 3.5: The **read()** method now accepts an argument of `None`.

Changed in version 3.6: Accepts a path-like object.

Changed in version 3.9: The *buffering* parameter has been removed. It was ignored and deprecated since Python 3.0. Pass an open file object to control how the file is opened.

The *compresslevel* parameter became keyword-only.

Changed in version 3.10: This class is thread unsafe in the face of multiple simultaneous readers or writers, just like its equivalent classes in **gzip** and **lzma** have always been.

Incremental (de)compression

class bz2.BZ2Compressor(*compresslevel=9*)

Create a new compressor object. This object may be used to compress data incrementally. For one-shot compression, use the **compress()** function instead.

compresslevel, if given, must be an integer between `1` and `9`. The default is `9`.

compress(*data*)

Provide data to the compressor object. Returns a chunk of compressed data if possible, or an empty byte string otherwise.

When you have finished providing data to the compressor, call the **flush()** method to finish the compression process.

flush()

Finish the compression process. Returns the compressed data left in internal buffers.

The compressor object may not be used after this method has been called.

class bz2.BZ2Decompressor

Create a new decompressor object. This object may be used to decompress data incrementally. For one-shot compression, use the **`decompress()`** function instead.

Note

This class does not transparently handle inputs containing multiple compressed streams, unlike **`decompress()`** and **`BZ2File`**. If you need to decompress a multi-stream input with **`BZ2Decompressor`**, you must use a new decompressor for each stream.

decompress(*data*, *max_length*=-1)

Decompress *data* (a bytes-like object), returning uncompressed data as bytes. Some of *data* may be buffered internally, for use in later calls to **`decompress()`**. The returned data should be concatenated with the output of any previous calls to **`decompress()`**.

If *max_length* is nonnegative, returns at most *max_length* bytes of decompressed data. If this limit is reached and further output can be produced, the **`needs_input`** attribute will be set to `False`. In this case, the next call to **`decompress()`** may provide *data* as `b''` to obtain more of the output.

If all of the input data was decompressed and returned (either because this was less than *max_length* bytes, or because *max_length* was negative), the **`needs_input`** attribute will be set to `True`.

Attempting to decompress data after the end of stream is reached raises an **`EOFError`**. Any data found after the end of the stream is ignored and saved in the **`unused_data`** attribute.

Changed in version 3.5: Added the *max_length* parameter.

eof

`True` if the end-of-stream marker has been reached.

New in version 3.3.

unused_data
: Data found after the end of the compressed stream.

  If this attribute is accessed before the end of the stream has been reached, its value will be `b''`.

needs_input
: `False` if the **`decompress()`** method can provide more decompressed data before requiring new uncompressed input.

  New in version 3.5.

One-shot (de)compression

bz2.compress(*data*, *compresslevel*=*9*)
: Compress *data*, a bytes-like object.

  compresslevel, if given, must be an integer between `1` and `9`. The default is `9`.

  For incremental compression, use a **`BZ2Compressor`** instead.

bz2.decompress(*data*)
: Decompress *data*, a bytes-like object.

  If *data* is the concatenation of multiple compressed streams, decompress all of the streams.

  For incremental decompression, use a **`BZ2Decompressor`** instead.

  Changed in version 3.3: Support for multi-stream inputs was added.

Examples of usage

Below are some examples of typical usage of the **bz2** module.

Using **compress()** and **decompress()** to demonstrate round-trip compression:

```
>>> import bz2
>>> data = b"""\
... Donec rhoncus quis sapien sit amet molestie. Fusce s
... nec ullamcorper. Nam rutrum pretium placerat. Aliqua
... sit amet cursus ante. In interdum laoreet mi, sit am
... pulvinar a. Nam gravida euismod magna, non varius ju
... Aliquam pharetra lacus non risus vehicula rutrum. Ma
... felis. Pellentesque semper nunc sit amet nibh ullamc
... dolor luctus. Curabitur lacinia mi ornare consectetu
>>> c = bz2.compress(data)
>>> len(data) / len(c)  # Data compression ratio
1.513595166163142
>>> d = bz2.decompress(c)
>>> data == d  # Check equality to original object after
True
```

Using **BZ2Compressor** for incremental compression:

```
>>> import bz2
>>> def gen_data(chunks=10, chunksize=1000):
...     """Yield incremental blocks of chunksize bytes."
...     for _ in range(chunks):
...         yield b"z" * chunksize
...
>>> comp = bz2.BZ2Compressor()
>>> out = b""
>>> for chunk in gen_data():
...     # Provide data to the compressor object
...     out = out + comp.compress(chunk)
...
>>> # Finish the compression process.  Call this once yo
>>> # finished providing data to the compressor.
```

```
>>> out = out + comp.flush()
```

The example above uses a very “nonrandom” stream of data (a stream of `b"z"` chunks). Random data tends to compress poorly, while ordered, repetitive data usually yields a high compression ratio.

Writing and reading a bzip2-compressed file in binary mode:

```
>>> import bz2
>>> data = b"""\
... Donec rhoncus quis sapien sit amet molestie. Fusce s
... nec ullamcorper. Nam rutrum pretium placerat. Aliqua
... sit amet cursus ante. In interdum laoreet mi, sit am
... pulvinar a. Nam gravida euismod magna, non varius ju
... Aliquam pharetra lacus non risus vehicula rutrum. Ma
... felis. Pellentesque semper nunc sit amet nibh ullamc
... dolor luctus. Curabitur lacinia mi ornare consectetu
>>> with bz2.open("myfile.bz2", "wb") as f:
...     # Write compressed data to file
...     unused = f.write(data)
>>> with bz2.open("myfile.bz2", "rb") as f:
...     # Decompress data from file
...     content = f.read()
>>> content == data  # Check equality to original object
True
```

`lzma` — Compression using the LZMA algorithm

New in version 3.3.

Source code: Lib/lzma.py [https://github.com/python/cpython/tree/3.11/Lib/lzma.py]

This module provides classes and convenience functions for compressing and decompressing data using the LZMA compression algorithm. Also included is a file interface supporting the `.xz` and legacy `.lzma` file formats used by the **xz** utility, as well as raw compressed streams.

The interface provided by this module is very similar to that of the `bz2` module. Note that `LZMAFile` and `bz2.BZ2File` are *not* thread-safe, so if you need to use a single `LZMAFile` instance from multiple threads, it is necessary to protect it with a lock.

exception lzma.LZMAError

This exception is raised when an error occurs during compression or decompression, or while initializing the compressor/decompressor state.

Reading and writing compressed files

lzma.open(*filename*, *mode*='rb', *, *format*=None, *check*=-1, *preset*=None, *filters*=None, *encoding*=None, *errors*=None, *newline*=None)

Open an LZMA-compressed file in binary or text mode, returning a file object.

The *filename* argument can be either an actual file name

(given as a **str**, **bytes** or path-like object), in which case the named file is opened, or it can be an existing file object to read from or write to.

The *mode* argument can be any of `"r"`, `"rb"`, `"w"`, `"wb"`, `"x"`, `"xb"`, `"a"` or `"ab"` for binary mode, or `"rt"`, `"wt"`, `"xt"`, or `"at"` for text mode. The default is `"rb"`.

When opening a file for reading, the *format* and *filters* arguments have the same meanings as for **LZMADecompressor**. In this case, the *check* and *preset* arguments should not be used.

When opening a file for writing, the *format*, *check*, *preset* and *filters* arguments have the same meanings as for **LZMACompressor**.

For binary mode, this function is equivalent to the **LZMAFile** constructor: `LZMAFile(filename, mode, ...)`. In this case, the *encoding*, *errors* and *newline* arguments must not be provided.

For text mode, a **LZMAFile** object is created, and wrapped in an **io.TextIOWrapper** instance with the specified encoding, error handling behavior, and line ending(s).

Changed in version 3.4: Added support for the `"x"`, `"xb"` and `"xt"` modes.

Changed in version 3.6: Accepts a path-like object.

class lzma.LZMAFile(*filename=None*, *mode='r'*, ***, *format=None*, *check=-1*, *preset=None*, *filters=None*)

Open an LZMA-compressed file in binary mode.

An **LZMAFile** can wrap an already-open file object, or operate directly on a named file. The *filename* argument specifies either the file object to wrap, or the name of the file to open (as a **str**, **bytes** or path-like object). When wrapping an existing file object, the wrapped file will not be closed when the **LZMAFile** is closed.

The *mode* argument can be either `"r"` for reading (default), `"w"` for overwriting, `"x"` for exclusive creation, or `"a"` for appending. These can equivalently be given as `"rb"`, `"wb"`, `"xb"` and `"ab"` respectively.

If *filename* is a file object (rather than an actual file name), a mode of `"w"` does not truncate the file, and is instead equivalent to `"a"`.

When opening a file for reading, the input file may be the concatenation of multiple separate compressed streams. These are transparently decoded as a single logical stream.

When opening a file for reading, the *format* and *filters* arguments have the same meanings as for **`LZMADecompressor`**. In this case, the *check* and *preset* arguments should not be used.

When opening a file for writing, the *format*, *check*, *preset* and *filters* arguments have the same meanings as for **`LZMACompressor`**.

`LZMAFile` supports all the members specified by **`io.BufferedIOBase`**, except for **`detach()`** and **`truncate()`**. Iteration and the **`with`** statement are supported.

The following method is also provided:

peek(*size* = *-1*)

Return buffered data without advancing the file position. At least one byte of data will be returned, unless EOF has been reached. The exact number of bytes returned is unspecified (the *size* argument is ignored).

Note

While calling **`peek()`** does not change the file position of the **`LZMAFile`**, it may change the position of the underlying file object (e.g. if the

LZMAFile was constructed by passing a file object for *filename*).

Changed in version 3.4: Added support for the `"x"` and `"xb"` modes.

Changed in version 3.5: The **read()** method now accepts an argument of `None`.

Changed in version 3.6: Accepts a path-like object.

Compressing and decompressing data in memory

class lzma.LZMACompressor(*format=FORMAT_XZ*, *check=-1*, *preset=None*, *filters=None*)

Create a compressor object, which can be used to compress data incrementally.

For a more convenient way of compressing a single chunk of data, see **compress()**.

The *format* argument specifies what container format should be used. Possible values are:

- **FORMAT_XZ**: The `.xz` container format.
  This is the default format.

- **FORMAT_ALONE**: The legacy `.lzma` container format.
  This format is more limited than `.xz` – it does not support integrity checks or multiple filters.

- **FORMAT_RAW**: A raw data stream, not using any container format.
  This format specifier does not support integrity checks, and requires that you always specify a custom filter chain (for both compression and

decompression). Additionally, data compressed in this manner cannot be decompressed using **FORMAT_AUTO** (see **LZMADecompressor**).

The *check* argument specifies the type of integrity check to include in the compressed data. This check is used when decompressing, to ensure that the data has not been corrupted. Possible values are:

- **CHECK_NONE**: No integrity check. This is the default (and the only acceptable value) for **FORMAT_ALONE** and **FORMAT_RAW**.
- **CHECK_CRC32**: 32-bit Cyclic Redundancy Check.
- **CHECK_CRC64**: 64-bit Cyclic Redundancy Check. This is the default for **FORMAT_XZ**.
- **CHECK_SHA256**: 256-bit Secure Hash Algorithm.

If the specified check is not supported, an **LZMAError** is raised.

The compression settings can be specified either as a preset compression level (with the *preset* argument), or in detail as a custom filter chain (with the *filters* argument).

The *preset* argument (if provided) should be an integer between `0` and `9` (inclusive), optionally OR-ed with the constant **PRESET_EXTREME**. If neither *preset* nor *filters* are given, the default behavior is to use **PRESET_DEFAULT** (preset level `6`). Higher presets produce smaller output, but make the compression process slower.

Note

In addition to being more CPU-intensive, compression with higher presets also requires much more memory (and produces output that needs more memory to decompress). With preset `9` for example, the overhead for an **LZMACompressor** object can be as high as 800 MiB. For this reason, it is generally best to stick with the default preset.

The *filters* argument (if provided) should be a filter chain specifier. See Specifying custom filter chains for details.

compress(*data*)

Compress *data* (a **bytes** object), returning a **bytes** object containing compressed data for at least part of the input. Some of *data* may be buffered internally, for use in later calls to **compress()** and **flush()**. The returned data should be concatenated with the output of any previous calls to **compress()**.

flush()

Finish the compression process, returning a **bytes** object containing any data stored in the compressor's internal buffers.

The compressor cannot be used after this method has been called.

class lzma.LZMADecompressor(*format=FORMAT_AUTO*, *memlimit=None*, *filters=None*)

Create a decompressor object, which can be used to decompress data incrementally.

For a more convenient way of decompressing an entire compressed stream at once, see **decompress()**.

The *format* argument specifies the container format that should be used. The default is **FORMAT_AUTO**, which can decompress both `.xz` and `.lzma` files. Other possible values are **FORMAT_XZ**, **FORMAT_ALONE**, and **FORMAT_RAW**.

The *memlimit* argument specifies a limit (in bytes) on the amount of memory that the decompressor can use. When this argument is used, decompression will fail with an **LZMAError** if it is not possible to decompress the input within the given memory limit.

The *filters* argument specifies the filter chain that was used to

create the stream being decompressed. This argument is required if *format* is **FORMAT_RAW**, but should not be used for other formats. See Specifying custom filter chains for more information about filter chains.

Note

This class does not transparently handle inputs containing multiple compressed streams, unlike **decompress()** and **LZMAFile**. To decompress a multi-stream input with **LZMADecompressor**, you must create a new decompressor for each stream.

decompress(*data*, *max_length*=-1)

Decompress *data* (a bytes-like object), returning uncompressed data as bytes. Some of *data* may be buffered internally, for use in later calls to **decompress()**. The returned data should be concatenated with the output of any previous calls to **decompress()**.

If *max_length* is nonnegative, returns at most *max_length* bytes of decompressed data. If this limit is reached and further output can be produced, the **needs_input** attribute will be set to `False`. In this case, the next call to **decompress()** may provide *data* as `b''` to obtain more of the output.

If all of the input data was decompressed and returned (either because this was less than *max_length* bytes, or because *max_length* was negative), the **needs_input** attribute will be set to `True`.

Attempting to decompress data after the end of stream is reached raises an **EOFError**. Any data found after the end of the stream is ignored and saved in the **unused_data** attribute.

Changed in version 3.5: Added the *max_length* parameter.

check

The ID of the integrity check used by the input stream. This may be **CHECK_UNKNOWN** until enough of the input has been decoded to determine what integrity check it uses.

eof

`True` if the end-of-stream marker has been reached.

unused_data

Data found after the end of the compressed stream.

Before the end of the stream is reached, this will be `b""`.

needs_input

`False` if the **decompress()** method can provide more decompressed data before requiring new uncompressed input.

New in version 3.5.

lzma.compress(*data*, *format*=*FORMAT_XZ*, *check*=*-1*, *preset*=*None*, *filters*=*None*)

Compress *data* (a **bytes** object), returning the compressed data as a **bytes** object.

See **LZMACompressor** above for a description of the *format*, *check*, *preset* and *filters* arguments.

lzma.decompress(*data*, *format*=*FORMAT_AUTO*, *memlimit*=*None*, *filters*=*None*)

Decompress *data* (a **bytes** object), returning the uncompressed data as a **bytes** object.

If *data* is the concatenation of multiple distinct compressed streams, decompress all of these streams, and return the concatenation of the results.

See **LZMADecompressor** above for a description of the *format*, *memlimit* and *filters* arguments.

Miscellaneous

lzma.is_check_supported(*check*)

Return `True` if the given integrity check is supported on this system.

CHECK_NONE and **CHECK_CRC32** are always supported. **CHECK_CRC64** and **CHECK_SHA256** may be unavailable if you are using a version of **liblzma** that was compiled with a limited feature set.

Specifying custom filter chains

A filter chain specifier is a sequence of dictionaries, where each dictionary contains the ID and options for a single filter. Each dictionary must contain the key `"id"`, and may contain additional keys to specify filter-dependent options. Valid filter IDs are as follows:

- Compression filters:
  - **FILTER_LZMA1** (for use with **FORMAT_ALONE**)
  - **FILTER_LZMA2** (for use with **FORMAT_XZ** and **FORMAT_RAW**)
- Delta filter:
  - **FILTER_DELTA**
- Branch-Call-Jump (BCJ) filters:
  - **FILTER_X86**
  - **FILTER_IA64**
  - **FILTER_ARM**
  - **FILTER_ARMTHUMB**
  - **FILTER_POWERPC**
  - **FILTER_SPARC**

A filter chain can consist of up to 4 filters, and cannot be empty. The last filter in the chain must be a compression filter, and any other filters must be delta or BCJ filters.

Compression filters support the following options (specified as additional entries in the dictionary representing the filter):

- `preset`: A compression preset to use as a source of default values for options that are not specified explicitly.
- `dict_size`: Dictionary size in bytes. This should be between 4 KiB and 1.5 GiB (inclusive).
- `lc`: Number of literal context bits.
- `lp`: Number of literal position bits. The sum `lc + lp` must be at most 4.
- `pb`: Number of position bits; must be at most 4.
- `mode`: **`MODE_FAST`** or **`MODE_NORMAL`**.
- `nice_len`: What should be considered a "nice length" for a match. This should be 273 or less.
- `mf`: What match finder to use – **`MF_HC3`**, **`MF_HC4`**, **`MF_BT2`**, **`MF_BT3`**, or **`MF_BT4`**.
- `depth`: Maximum search depth used by match finder. 0 (default) means to select automatically based on other filter options.

The delta filter stores the differences between bytes, producing more repetitive input for the compressor in certain circumstances. It supports one option, `dist`. This indicates the distance between bytes to be subtracted. The default is 1, i.e. take the differences between adjacent bytes.

The BCJ filters are intended to be applied to machine code. They convert relative branches, calls and jumps in the code to use absolute addressing, with the aim of increasing the redundancy that can be exploited by the compressor. These filters support one option, `start_offset`. This specifies the address that should be mapped to the beginning of the input data. The default is 0.

Examples

Reading in a compressed file:

```
import lzma
with lzma.open("file.xz") as f:
    file_content = f.read()
```

Creating a compressed file:

```
import lzma
data = b"Insert Data Here"
with lzma.open("file.xz", "w") as f:
    f.write(data)
```

Compressing data in memory:

```
import lzma
data_in = b"Insert Data Here"
data_out = lzma.compress(data_in)
```

Incremental compression:

```
import lzma
lzc = lzma.LZMACompressor()
out1 = lzc.compress(b"Some data\n")
out2 = lzc.compress(b"Another piece of data\n")
out3 = lzc.compress(b"Even more data\n")
out4 = lzc.flush()
# Concatenate all the partial results:
result = b"".join([out1, out2, out3, out4])
```

Writing compressed data to an already-open file:

```
import lzma
with open("file.xz", "wb") as f:
    f.write(b"This data will not be compressed\n")
    with lzma.open(f, "w") as lzf:
        lzf.write(b"This *will* be compressed\n")
    f.write(b"Not compressed\n")
```

Creating a compressed file using a custom filter chain:

```
import lzma
my_filters = [
    {"id": lzma.FILTER_DELTA, "dist": 5},
    {"id": lzma.FILTER_LZMA2, "preset": 7 | lzma.PRESET_
]
with lzma.open("file.xz", "w", filters=my_filters) as f:
    f.write(b"blah blah blah")
```

`zipfile` — Work with ZIP archives

Source code: Lib/zipfile.py [https://github.com/python/cpython/tree/3.11/Lib/zipfile.py]

The ZIP file format is a common archive and compression standard. This module provides tools to create, read, write, append, and list a ZIP file. Any advanced use of this module will require an understanding of the format, as defined in PKZIP Application Note [https://pkware.cachefly.net/webdocs/casestudies/APPNOTE.TXT].

This module does not currently handle multi-disk ZIP files. It can handle ZIP files that use the ZIP64 extensions (that is ZIP files that are more than 4 GiB in size). It supports decryption of encrypted files in ZIP archives, but it currently cannot create an encrypted file. Decryption is extremely slow as it is implemented in native Python rather than C.

The module defines the following items:

exception zipfile.BadZipFile

The error raised for bad ZIP files.

New in version 3.2.

exception zipfile.BadZipfile

Alias of `BadZipFile`, for compatibility with older Python versions.

Deprecated since version 3.2.

exception zipfile.LargeZipFile

The error raised when a ZIP file would require ZIP64

functionality but that has not been enabled.

class zipfile.ZipFile

The class for reading and writing ZIP files. See section ZipFile Objects for constructor details.

class zipfile.Path

A pathlib-compatible wrapper for zip files. See section Path Objects for details.

New in version 3.8.

class zipfile.PyZipFile

Class for creating ZIP archives containing Python libraries.

class zipfile.ZipInfo(*filename='NoName', date_time=(1980, 1, 1, 0, 0, 0)*)

Class used to represent information about a member of an archive. Instances of this class are returned by the **`getinfo()`** and **`infolist()`** methods of **`ZipFile`** objects. Most users of the **`zipfile`** module will not need to create these, but only use those created by this module. *filename* should be the full name of the archive member, and *date_time* should be a tuple containing six fields which describe the time of the last modification to the file; the fields are described in section ZipInfo Objects.

zipfile.is_zipfile(*filename*)

Returns `True` if *filename* is a valid ZIP file based on its magic number, otherwise returns `False`. *filename* may be a file or file-like object too.

Changed in version 3.1: Support for file and file-like objects.

zipfile.ZIP_STORED

The numeric constant for an uncompressed archive member.

zipfile.ZIP_DEFLATED

The numeric constant for the usual ZIP compression method. This requires the **zlib** module.

zipfile.ZIP_BZIP2

The numeric constant for the BZIP2 compression method. This requires the **bz2** module.

New in version 3.3.

zipfile.ZIP_LZMA

The numeric constant for the LZMA compression method. This requires the **lzma** module.

New in version 3.3.

Note

The ZIP file format specification has included support for bzip2 compression since 2001, and for LZMA compression since 2006. However, some tools (including older Python releases) do not support these compression methods, and may either refuse to process the ZIP file altogether, or fail to extract individual files.

Information about the Info-ZIP project's ZIP archive programs and development libraries.

ZipFile Objects

class zipfile.ZipFile(*file*, *mode='r'*, *compression=ZIP_STORED*, *allowZip64=True*, *compresslevel=None*, ***, *strict_timestamps=True*, *metadata_encoding=None*)

Open a ZIP file, where *file* can be a path to a file (a string), a file-like object or a path-like object.

The *mode* parameter should be `'r'` to read an existing file, `'w'` to truncate and write a new file, `'a'` to append to an existing file, or `'x'` to exclusively create and write a new file. If *mode* is `'x'` and *file* refers to an existing file, a **`FileExistsError`** will be raised. If *mode* is `'a'` and *file* refers to an existing ZIP file, then additional files are added to it. If *file* does not refer to a ZIP file, then a new ZIP archive is appended to the file. This is meant for adding a ZIP archive to another file (such as `python.exe`). If *mode* is `'a'` and the file does not exist at all, it is created. If *mode* is `'r'` or `'a'`, the file should be seekable.

compression is the ZIP compression method to use when writing the archive, and should be **`ZIP_STORED`**, **`ZIP_DEFLATED`**, **`ZIP_BZIP2`** or **`ZIP_LZMA`**; unrecognized values will cause **`NotImplementedError`** to be raised. If **`ZIP_DEFLATED`**, **`ZIP_BZIP2`** or **`ZIP_LZMA`** is specified but the corresponding module (**`zlib`**, **`bz2`** or **`lzma`**) is not available, **`RuntimeError`** is raised. The default is **`ZIP_STORED`**.

If *allowZip64* is `True` (the default) zipfile will create ZIP files that use the ZIP64 extensions when the zipfile is larger than 4 GiB. If it is `false` **`zipfile`** will raise an exception when the ZIP file would require ZIP64 extensions.

The *compresslevel* parameter controls the compression level to use when writing files to the archive. When using **`ZIP_STORED`** or **`ZIP_LZMA`** it has no effect. When using **`ZIP_DEFLATED`** integers `0` through `9` are accepted (see **`zlib`** for more information). When using **`ZIP_BZIP2`** integers `1` through `9` are accepted (see **`bz2`** for more information).

The *strict_timestamps* argument, when set to `False`, allows to zip files older than 1980-01-01 at the cost of setting the timestamp to 1980-01-01. Similar behavior occurs with files newer than 2107-12-31, the timestamp is also set to the limit.

When mode is `'r'`, *metadata_encoding* may be set to the name of a codec, which will be used to decode metadata such as the names of members and ZIP comments.

If the file is created with mode `'w'`, `'x'` or `'a'` and then **`closed`** without adding any files to the archive, the appropriate ZIP structures for an empty archive will be written to the file.

ZipFile is also a context manager and therefore supports the **`with`** statement. In the example, *myzip* is closed after the **`with`** statement's suite is finished—even if an exception occurs:

```
with ZipFile('spam.zip', 'w') as myzip:
    myzip.write('eggs.txt')
```

Note

metadata_encoding is an instance-wide setting for the ZipFile. It is not currently possible to set this on a per-member basis.

This attribute is a workaround for legacy implementations which produce archives with names in the current locale encoding or code page (mostly on Windows). According to the .ZIP standard, the encoding of metadata may be specified to be either IBM code page (default) or UTF-8 by a flag in the archive header. That flag takes precedence over *metadata_encoding*, which is a Python-specific extension.

New in version 3.2: Added the ability to use **`ZipFile`** as a context manager.

Changed in version 3.3: Added support for **`bzip2`** and **`lzma`**

compression.

Changed in version 3.4: ZIP64 extensions are enabled by default.

Changed in version 3.5: Added support for writing to unseekable streams. Added support for the `'x'` mode.

Changed in version 3.6: Previously, a plain **`RuntimeError`** was raised for unrecognized compression values.

Changed in version 3.6.2: The *file* parameter accepts a path-like object.

Changed in version 3.7: Add the *compresslevel* parameter.

New in version 3.8: The *strict_timestamps* keyword-only argument

Changed in version 3.11: Added support for specifying member name encoding for reading metadata in the zipfile's directory and file headers.

ZipFile.close()

Close the archive file. You must call **`close()`** before exiting your program or essential records will not be written.

ZipFile.getinfo(*name*)

Return a **`ZipInfo`** object with information about the archive member *name*. Calling **`getinfo()`** for a name not currently contained in the archive will raise a **`KeyError`**.

ZipFile.infolist()

Return a list containing a **`ZipInfo`** object for each member of the archive. The objects are in the same order as their entries in the actual ZIP file on disk if an existing archive was opened.

ZipFile.namelist()

Return a list of archive members by name.

ZipFile.open(*name*, *mode='r'*, *pwd=None*, ***, *force_zip64=False*)

Access a member of the archive as a binary file-like object. *name* can be either the name of a file within the archive or a **ZipInfo** object. The *mode* parameter, if included, must be `'r'` (the default) or `'w'`. *pwd* is the password used to decrypt encrypted ZIP files.

open() is also a context manager and therefore supports the **with** statement:

```
with ZipFile('spam.zip') as myzip:
    with myzip.open('eggs.txt') as myfile:
        print(myfile.read())
```

With *mode* `'r'` the file-like object (`ZipExtFile`) is read-only and provides the following methods: **read()**, **readline()**, **readlines()**, **seek()**, **tell()**, **__iter__()**, **__next__()**. These objects can operate independently of the ZipFile.

With `mode='w'`, a writable file handle is returned, which supports the **write()** method. While a writable file handle is open, attempting to read or write other files in the ZIP file will raise a **ValueError**.

When writing a file, if the file size is not known in advance but may exceed 2 GiB, pass `force_zip64=True` to ensure that the header format is capable of supporting large files. If the file size is known in advance, construct a **ZipInfo** object with **file_size** set, and use that as the *name* parameter.

Note

The **open()**, **read()** and **extract()** methods can take a filename or a **ZipInfo** object. You will appreciate this when trying to read a ZIP file that contains members with duplicate names.

Changed in version 3.6: Removed support of `mode='U'`. Use **`io.TextIOWrapper`** for reading compressed text files in universal newlines mode.

Changed in version 3.6: **`ZipFile.open()`** can now be used to write files into the archive with the `mode='w'` option.

Changed in version 3.6: Calling **`open()`** on a closed ZipFile will raise a **`ValueError`**. Previously, a **`RuntimeError`** was raised.

ZipFile.extract(*member*, *path*=*None*, *pwd*=*None*)

Extract a member from the archive to the current working directory; *member* must be its full name or a **`ZipInfo`** object. Its file information is extracted as accurately as possible. *path* specifies a different directory to extract to. *member* can be a filename or a **`ZipInfo`** object. *pwd* is the password used for encrypted files.

Returns the normalized path created (a directory or new file).

Note

If a member filename is an absolute path, a drive/UNC sharepoint and leading (back)slashes will be stripped, e.g.: `///foo/bar` becomes `foo/bar` on Unix, and `C:\foo\bar` becomes `foo\bar` on Windows. And all `".."` components in a member filename will be removed, e.g.: `../../foo../../ba..r` becomes `foo../ba..r`. On Windows illegal characters (`:`, `<`, `>`, `|`, `"`, `?`, and `*`) replaced by underscore (`_`).

Changed in version 3.6: Calling **`extract()`** on a closed ZipFile will raise a **`ValueError`**. Previously, a **`RuntimeError`** was raised.

Changed in version 3.6.2: The *path* parameter accepts a path-like object.

ZipFile.extractall(*path*=*None*, *members*=*None*, *pwd*=*None*)

Extract all members from the archive to the current working directory. *path* specifies a different directory to extract to. *members* is optional and must be a subset of the list returned by `namelist()`. *pwd* is the password used for encrypted files.

Warning

Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with `"/"` or filenames with two dots `".."`. This module attempts to prevent that. See `extract()` note.

Changed in version 3.6: Calling `extractall()` on a closed ZipFile will raise a `ValueError`. Previously, a `RuntimeError` was raised.

Changed in version 3.6.2: The *path* parameter accepts a path-like object.

ZipFile.printdir()

Print a table of contents for the archive to `sys.stdout`.

ZipFile.setpassword(*pwd*)

Set *pwd* as default password to extract encrypted files.

ZipFile.read(*name*, *pwd=None*)

Return the bytes of the file *name* in the archive. *name* is the name of the file in the archive, or a `ZipInfo` object. The archive must be open for read or append. *pwd* is the password used for encrypted files and, if specified, it will override the default password set with `setpassword()`. Calling `read()` on a ZipFile that uses a compression method other than `ZIP_STORED`, `ZIP_DEFLATED`, `ZIP_BZIP2` or `ZIP_LZMA` will raise a `NotImplementedError`. An error will also be raised if the corresponding compression module is not available.

Changed in version 3.6: Calling `read()` on a closed ZipFile will raise a `ValueError`. Previously, a `RuntimeError` was raised.

ZipFile.testzip()

Read all the files in the archive and check their CRC's and file headers. Return the name of the first bad file, or else return `None`.

Changed in version 3.6: Calling `testzip()` on a closed ZipFile will raise a `ValueError`. Previously, a `RuntimeError` was raised.

ZipFile.write(*filename*, *arcname*=*None*, *compress_type*=*None*, *compresslevel*=*None*)

Write the file named *filename* to the archive, giving it the archive name *arcname* (by default, this will be the same as *filename*, but without a drive letter and with leading path separators removed). If given, *compress_type* overrides the value given for the *compression* parameter to the constructor for the new entry. Similarly, *compresslevel* will override the constructor if given. The archive must be open with mode `'w'`, `'x'` or `'a'`.

Note

The ZIP file standard historically did not specify a metadata encoding, but strongly recommended CP437 (the original IBM PC encoding) for interoperability. Recent versions allow use of UTF-8 (only). In this module, UTF-8 will automatically be used to write the member names if they contain any non-ASCII characters. It is not possible to write member names in any encoding other than ASCII or UTF-8.

Note

Archive names should be relative to the archive root, that is, they should not start with a path separator.

Note

If `arcname` (or `filename`, if `arcname` is not given) contains a null byte, the name of the file in the archive will be truncated at the null byte.

Note

A leading slash in the filename may lead to the archive being impossible to open in some zip programs on Windows systems.

Changed in version 3.6: Calling **`write()`** on a ZipFile created with mode `'r'` or a closed ZipFile will raise a **`ValueError`**. Previously, a **`RuntimeError`** was raised.

ZipFile.writestr(*zinfo_or_arcname*, *data*, *compress_type=None*, *compresslevel=None*)

Write a file into the archive. The contents is *data*, which may be either a **`str`** or a **`bytes`** instance; if it is a **`str`**, it is encoded as UTF-8 first. *zinfo_or_arcname* is either the file name it will be given in the archive, or a **`ZipInfo`** instance. If it's an instance, at least the filename, date, and time must be given. If it's a name, the date and time is set to the current date and time. The archive must be opened with mode `'w'`, `'x'` or `'a'`.

If given, *compress_type* overrides the value given for the *compression* parameter to the constructor for the new entry, or in the *zinfo_or_arcname* (if that is a **`ZipInfo`** instance). Similarly, *compresslevel* will override the constructor if given.

Note

When passing a **`ZipInfo`** instance as the *zinfo_or_arcname* parameter, the compression method used will be that specified in the *compress_type* member of the given **`ZipInfo`** instance. By default, the **`ZipInfo`** constructor sets this member to **`ZIP_STORED`**.

Changed in version 3.2: The *compress_type* argument.

Changed in version 3.6: Calling `writestr()` on a ZipFile created with mode `'r'` or a closed ZipFile will raise a `ValueError`. Previously, a `RuntimeError` was raised.

ZipFile.mkdir(*zinfo_or_directory*, *mode*=*511*)

Create a directory inside the archive. If *zinfo_or_directory* is a string, a directory is created inside the archive with the mode that is specified in the *mode* argument. If, however, *zinfo_or_directory* is a `ZipInfo` instance then the *mode* argument is ignored.

The archive must be opened with mode `'w'`, `'x'` or `'a'`.

New in version 3.11.

The following data attributes are also available:

ZipFile.filename

Name of the ZIP file.

ZipFile.debug

The level of debug output to use. This may be set from `0` (the default, no output) to `3` (the most output). Debugging information is written to `sys.stdout`.

ZipFile.comment

The comment associated with the ZIP file as a `bytes` object. If assigning a comment to a `ZipFile` instance created with mode `'w'`, `'x'` or `'a'`, it should be no longer than 65535 bytes. Comments longer than this will be truncated.

Path Objects

class zipfile.Path(*root*, *at*=*''*)

Construct a Path object from a `root` zipfile (which may be a `ZipFile` instance or `file` suitable for passing to the

ZipFile constructor).

`at` specifies the location of this Path within the zipfile, e.g. 'dir/file.txt', 'dir/', or ''. Defaults to the empty string, indicating the root.

Path objects expose the following features of **pathlib.Path** objects:

Path objects are traversable using the `/` operator or `joinpath`.

Path.name

The final path component.

Path.open(*mode='r'*, ***, *pwd*, ****)

Invoke **ZipFile.open()** on the current path. Allows opening for read or write, text or binary through supported modes: 'r', 'w', 'rb', 'wb'. Positional and keyword arguments are passed through to **io.TextIOWrapper** when opened as text and ignored otherwise. `pwd` is the `pwd` parameter to **ZipFile.open()**.

Changed in version 3.9: Added support for text and binary modes for open. Default mode is now text.

Path.iterdir()

Enumerate the children of the current directory.

Path.is_dir()

Return `True` if the current context references a directory.

Path.is_file()

Return `True` if the current context references a file.

Path.exists()

Return `True` if the current context references a file or directory in the zip file.

Path.suffix

The file extension of the final component.

New in version 3.11: Added **Path.suffix** property.

Path.stem

The final path component, without its suffix.

New in version 3.11: Added **Path.stem** property.

Path.suffixes

A list of the path's file extensions.

New in version 3.11: Added **Path.suffixes** property.

Path.read_text(*, **)

Read the current file as unicode text. Positional and keyword arguments are passed through to **io.TextIOWrapper** (except `buffer`, which is implied by the context).

Path.read_bytes()

Read the current file as bytes.

Path.joinpath(**other*)

Return a new Path object with each of the *other* arguments joined. The following are equivalent:

```
>>> Path(...).joinpath('child').joinpath('grandchil
>>> Path(...).joinpath('child', 'grandchild')
>>> Path(...) / 'child' / 'grandchild'
```

Changed in version 3.10: Prior to 3.10, `joinpath` was undocumented and accepted exactly one parameter.

The zipp [https://pypi.org/project/zipp] project provides backports of the latest path object functionality to older Pythons. Use `zipp.Path` in place of `zipfile.Path` for early access to changes.

PyZipFile Objects

The **PyZipFile** constructor takes the same parameters as the **ZipFile** constructor, and one additional parameter, *optimize*.

class zipfile.PyZipFile(*file*, *mode='r'*, *compression=ZIP_STORED*, *allowZip64=True*, *optimize=-1*)

New in version 3.2: The *optimize* parameter.

Changed in version 3.4: ZIP64 extensions are enabled by default.

Instances have one method in addition to those of **ZipFile** objects:

writepy(*pathname*, *basename=''*, *filterfunc=None*)

Search for files `*.py` and add the corresponding file to the archive.

If the *optimize* parameter to **PyZipFile** was not given or `-1`, the corresponding file is a `*.pyc` file, compiling if necessary.

If the *optimize* parameter to **PyZipFile** was `0`, `1` or `2`, only files with that optimization level (see **compile()**) are added to the archive, compiling if necessary.

If *pathname* is a file, the filename must end with `.py`, and just the (corresponding `*.pyc`) file is added at the top level (no path information). If *pathname* is a file that does not end with `.py`, a **RuntimeError** will be raised. If it is a directory, and the directory is not a package directory, then all the files `*.pyc` are added at the top level. If the directory is a package directory, then all `*.pyc` are added under the package name as a file path, and if any subdirectories are package directories, all of these are added recursively in sorted order.

basename is intended for internal use only.

filterfunc, if given, must be a function taking a single string argument. It will be passed each path (including each individual full file path) before it is added to the archive. If *filterfunc* returns a false value, the path will not be added, and if it is a directory its contents will be ignored. For example, if our test files are all either in `test` directories or start with the string `test_`, we can use a *filterfunc* to exclude them:

```
>>> zf = PyZipFile('myprog.zip')
>>> def notests(s):
...     fn = os.path.basename(s)
...     return (not (fn == 'test' or fn.startsw
>>> zf.writepy('myprog', filterfunc=notests)
```

The **`writepy()`** method makes archives with file names like this:

```
string.pyc                    # Top level name
test/__init__.pyc             # Package director
test/testall.pyc              # Module test.test
test/bogus/__init__.pyc       # Subpackage direc
test/bogus/myfile.pyc         # Submodule test.b
```

New in version 3.4: The *filterfunc* parameter.

Changed in version 3.6.2: The *pathname* parameter accepts a path-like object.

Changed in version 3.7: Recursion sorts directory entries.

ZipInfo Objects

Instances of the **`ZipInfo`** class are returned by the **`getinfo()`** and **`infolist()`** methods of **`ZipFile`** objects. Each object stores information about a single member of the ZIP archive.

There is one classmethod to make a **`ZipInfo`** instance for a

filesystem file:

classmethod ZipInfo.from_file(*filename*, *arcname=None*, *, *strict_timestamps=True*)

Construct a **ZipInfo** instance for a file on the filesystem, in preparation for adding it to a zip file.

filename should be the path to a file or directory on the filesystem.

If *arcname* is specified, it is used as the name within the archive. If *arcname* is not specified, the name will be the same as *filename*, but with any drive letter and leading path separators removed.

The *strict_timestamps* argument, when set to `False`, allows to zip files older than 1980-01-01 at the cost of setting the timestamp to 1980-01-01. Similar behavior occurs with files newer than 2107-12-31, the timestamp is also set to the limit.

New in version 3.6.

Changed in version 3.6.2: The *filename* parameter accepts a path-like object.

New in version 3.8: The *strict_timestamps* keyword-only argument

Instances have the following methods and attributes:

ZipInfo.is_dir()

Return `True` if this archive member is a directory.

This uses the entry's name: directories should always end with `/`.

New in version 3.6.

ZipInfo.filename

Name of the file in the archive.

ZipInfo.date_time

The time and date of the last modification to the archive member. This is a tuple of six values:

Index	Value
0	Year (>= 1980)
1	Month (one-based)
2	Day of month (one-based)
3	Hours (zero-based)
4	Minutes (zero-based)
5	Seconds (zero-based)

Note

The ZIP file format does not support timestamps before 1980.

ZipInfo.compress_type

Type of compression for the archive member.

ZipInfo.comment

Comment for the individual archive member as a `bytes` object.

ZipInfo.extra

Expansion field data. The PKZIP Application Note [https://pkware.cachefly.net/webdocs/casestudies/APPNOTE.TXT] contains some comments on the internal structure of the data contained in this `bytes` object.

ZipInfo.create_system

System which created ZIP archive.

ZipInfo.create_version

PKZIP version which created ZIP archive.

ZipInfo.extract_version

PKZIP version needed to extract archive.

ZipInfo.reserved
: Must be zero.

ZipInfo.flag_bits
: ZIP flag bits.

ZipInfo.volume
: Volume number of file header.

ZipInfo.internal_attr
: Internal attributes.

ZipInfo.external_attr
: External file attributes.

ZipInfo.header_offset
: Byte offset to the file header.

ZipInfo.CRC
: CRC-32 of the uncompressed file.

ZipInfo.compress_size
: Size of the compressed data.

ZipInfo.file_size
: Size of the uncompressed file.

Command-Line Interface

The **`zipfile`** module provides a simple command-line interface to interact with ZIP archives.

If you want to create a new ZIP archive, specify its name after the **`-c`** option and then list the filename(s) that should be included:

```
$ python -m zipfile -c monty.zip spam.txt eggs.txt
```

Passing a directory is also acceptable:

```
$ python -m zipfile -c monty.zip life-of-brian_1979/
```

If you want to extract a ZIP archive into the specified directory, use the **-e** option:

```
$ python -m zipfile -e monty.zip target-dir/
```

For a list of the files in a ZIP archive, use the **-l** option:

```
$ python -m zipfile -l monty.zip
```

Command-line options

-l <zipfile>
--list <zipfile>
: List files in a zipfile.

-c <zipfile> <source1> ... <sourceN>
--create <zipfile> <source1> ... <sourceN>
: Create zipfile from source files.

-e <zipfile> <output_dir>
--extract <zipfile> <output_dir>
: Extract zipfile into target directory.

-t <zipfile>
--test <zipfile>
: Test whether the zipfile is valid or not.

--metadata-encoding <encoding>
: Specify encoding of member names for **-l**, **-e** and **-t**.

  New in version 3.11.

Decompression pitfalls

The extraction in zipfile module might fail due to some pitfalls listed below.

From file itself

Decompression may fail due to incorrect password / CRC checksum / ZIP format or unsupported compression method / decryption.

File System limitations

Exceeding limitations on different file systems can cause decompression failed. Such as allowable characters in the directory entries, length of the file name, length of the pathname, size of a single file, and number of files, etc.

Resources limitations

The lack of memory or disk volume would lead to decompression failed. For example, decompression bombs (aka ZIP bomb [https://en.wikipedia.org/wiki/Zip_bomb]) apply to zipfile library that can cause disk volume exhaustion.

Interruption

Interruption during the decompression, such as pressing control-C or killing the decompression process may result in incomplete decompression of the archive.

Default behaviors of extraction

Not knowing the default extraction behaviors can cause unexpected decompression results. For example, when extracting the same archive twice, it overwrites files without asking.

`tarfile` — Read and write tar archive files

Source code: Lib/tarfile.py [https://github.com/python/cpython/tree/3.11/Lib/tarfile.py]

The `tarfile` module makes it possible to read and write tar archives, including those using gzip, bz2 and lzma compression. Use the `zipfile` module to read or write `.zip` files, or the higher-level functions in shutil.

Some facts and figures:

- reads and writes `gzip`, `bz2` and `lzma` compressed archives if the respective modules are available.
- read/write support for the POSIX.1-1988 (ustar) format.
- read/write support for the GNU tar format including *longname* and *longlink* extensions, read-only support for all variants of the *sparse* extension including restoration of sparse files.
- read/write support for the POSIX.1-2001 (pax) format.
- handles directories, regular files, hardlinks, symbolic links, fifos, character devices and block devices and is able to acquire and restore file information like timestamp, access permissions and owner.

Changed in version 3.3: Added support for `lzma` compression.

tarfile.open(*name=None*, *mode='r'*, *fileobj=None*, *bufsize=10240*, ***kwargs*)

Return a `TarFile` object for the pathname *name*. For detailed information on `TarFile` objects and the keyword arguments that are allowed, see TarFile Objects.

mode has to be a string of the form

`'filemode[:compression]'`, it defaults to `'r'`. Here is a full list of mode combinations:

mode	action
`'r'` or `'r:*'`	Open for reading with transparent compression (recommended).
`'r:'`	Open for reading exclusively without compression.
`'r:gz'`	Open for reading with gzip compression.
`'r:bz2'`	Open for reading with bzip2 compression.
`'r:xz'`	Open for reading with lzma compression.
`'x'` or `'x:'`	Create a tarfile exclusively without compression. Raise a **`FileExistsError`** exception if it already exists.
`'x:gz'`	Create a tarfile with gzip compression. Raise a **`FileExistsError`** exception if it already exists.
`'x:bz2'`	Create a tarfile with bzip2 compression. Raise a **`FileExistsError`** exception if it already exists.
`'x:xz'`	Create a tarfile with lzma compression. Raise a **`FileExistsError`** exception if it already exists.
`'a'` or `'a:'`	Open for appending with no compression. The file is created if it does not exist.
`'w'` or `'w:'`	Open for uncompressed writing.
`'w:gz'`	Open for gzip compressed writing.
`'w:bz2'`	Open for bzip2 compressed writing.
`'w:xz'`	Open for lzma compressed writing.

Note that `'a:gz'`, `'a:bz2'` or `'a:xz'` is not possible. If *mode* is not suitable to open a certain (compressed) file for reading, **`ReadError`** is raised. Use *mode* `'r'` to avoid this. If a compression method is not supported, **`CompressionError`** is raised.

If *fileobj* is specified, it is used as an alternative to a file object opened in binary mode for *name*. It is supposed to be at position 0.

For modes `'w:gz'`, `'r:gz'`, `'w:bz2'`, `'r:bz2'`, `'x:gz'`, `'x:bz2'`, **`tarfile.open()`** accepts the keyword argument *compresslevel* (default `9`) to specify the compression level of the file.

For modes `'w:xz'` and `'x:xz'`, **`tarfile.open()`**

accepts the keyword argument *preset* to specify the compression level of the file.

For special purposes, there is a second format for *mode*: `'filemode|[compression]'`. **`tarfile.open()`** will return a **`TarFile`** object that processes its data as a stream of blocks. No random seeking will be done on the file. If given, *fileobj* may be any object that has a **`read()`** or **`write()`** method (depending on the *mode*). *bufsize* specifies the blocksize and defaults to `20 * 512` bytes. Use this variant in combination with e.g. `sys.stdin`, a socket file object or a tape device. However, such a **`TarFile`** object is limited in that it does not allow random access, see Examples. The currently possible modes:

Mode	Action
`'r'`	Open a *stream* of tar blocks for reading with transparent compression.
`'r:'`	Open a *stream* of uncompressed tar blocks for reading.
`'r:gz'`	Open a gzip compressed *stream* for reading.
`'r:bz2'`	Open a bzip2 compressed *stream* for reading.
`'r:xz'`	Open an lzma compressed *stream* for reading.
`'w'` or `'w:'`	Open an uncompressed *stream* for writing.
`'w:gz'`	Open a gzip compressed *stream* for writing.
`'w:bz2'`	Open a bzip2 compressed *stream* for writing.
`'w:xz'`	Open an lzma compressed *stream* for writing.

Changed in version 3.5: The `'x'` (exclusive creation) mode was added.

Changed in version 3.6: The *name* parameter accepts a path-like object.

class tarfile.TarFile

Class for reading and writing tar archives. Do not use this class directly: use **`tarfile.open()`** instead. See TarFile Objects.

tarfile.is_tarfile(*name*)

Return **`True`** if *name* is a tar archive file, that the **`tarfile`**

module can read. *name* may be a **str**, file, or file-like object.

Changed in version 3.9: Support for file and file-like objects.

The **tarfile** module defines the following exceptions:

exception tarfile.TarError

Base class for all **tarfile** exceptions.

exception tarfile.ReadError

Is raised when a tar archive is opened, that either cannot be handled by the **tarfile** module or is somehow invalid.

exception tarfile.CompressionError

Is raised when a compression method is not supported or when the data cannot be decoded properly.

exception tarfile.StreamError

Is raised for the limitations that are typical for stream-like **TarFile** objects.

exception tarfile.ExtractError

Is raised for *non-fatal* errors when using **TarFile.extract()**, but only if **TarFile.errorlevel**== 2.

exception tarfile.HeaderError

Is raised by **TarInfo.frombuf()** if the buffer it gets is invalid.

The following constants are available at the module level:

tarfile.ENCODING

The default character encoding: `'utf-8'` on Windows, the value returned by **sys.getfilesystemencoding()** otherwise.

Each of the following constants defines a tar archive format that the

tarfile module is able to create. See section Supported tar formats for details.

tarfile.USTAR_FORMAT
: POSIX.1-1988 (ustar) format.

tarfile.GNU_FORMAT
: GNU tar format.

tarfile.PAX_FORMAT
: POSIX.1-2001 (pax) format.

tarfile.DEFAULT_FORMAT
: The default format for creating archives. This is currently **PAX_FORMAT**.

  Changed in version 3.8: The default format for new archives was changed to **PAX_FORMAT** from **GNU_FORMAT**.

See also

Module zipfile
: Documentation of the **zipfile** standard module.

Archiving operations
: Documentation of the higher-level archiving facilities provided by the standard **shutil** module.

GNU tar manual, Basic Tar Format **[https://www.gnu.org/software/tar/manual/html_node/Standard.html]**
: Documentation for tar archive files, including GNU tar extensions.

TarFile Objects

The **TarFile** object provides an interface to a tar archive. A tar archive is a sequence of blocks. An archive member (a stored file) is made up of a header block followed by data blocks. It is possible to

store a file in a tar archive several times. Each archive member is represented by a **TarInfo** object, see TarInfo Objects for details.

A **TarFile** object can be used as a context manager in a **with** statement. It will automatically be closed when the block is completed. Please note that in the event of an exception an archive opened for writing will not be finalized; only the internally used file object will be closed. See the Examples section for a use case.

New in version 3.2: Added support for the context management protocol.

class tarfile.TarFile(*name=None*, *mode='r'*, *fileobj=None*, *format=DEFAULT_FORMAT*, *tarinfo=TarInfo*, *dereference=False*, *ignore_zeros=False*, *encoding=ENCODING*, *errors='surrogateescape'*, *pax_headers=None*, *debug=0*, *errorlevel=0*)

All following arguments are optional and can be accessed as instance attributes as well.

name is the pathname of the archive. *name* may be a path-like object. It can be omitted if *fileobj* is given. In this case, the file object's **name** attribute is used if it exists.

mode is either `'r'` to read from an existing archive, `'a'` to append data to an existing file, `'w'` to create a new file overwriting an existing one, or `'x'` to create a new file only if it does not already exist.

If *fileobj* is given, it is used for reading or writing data. If it can be determined, *mode* is overridden by *fileobj*'s mode. *fileobj* will be used from position 0.

Note

fileobj is not closed, when **TarFile** is closed.

format controls the archive format for writing. It must be one of the constants **USTAR_FORMAT**, **GNU_FORMAT** or **PAX_FORMAT** that are defined at module level. When reading, format will be automatically detected, even if different

formats are present in a single archive.

The *tarinfo* argument can be used to replace the default **`TarInfo`** class with a different one.

If *dereference* is **`False`**, add symbolic and hard links to the archive. If it is **`True`**, add the content of the target files to the archive. This has no effect on systems that do not support symbolic links.

If *ignore_zeros* is **`False`**, treat an empty block as the end of the archive. If it is **`True`**, skip empty (and invalid) blocks and try to get as many members as possible. This is only useful for reading concatenated or damaged archives.

debug can be set from `0` (no debug messages) up to `3` (all debug messages). The messages are written to `sys.stderr`.

If *errorlevel* is `0`, all errors are ignored when using **`TarFile.extract()`**. Nevertheless, they appear as error messages in the debug output, when debugging is enabled. If `1`, all *fatal* errors are raised as **`OSError`** exceptions. If `2`, all *non-fatal* errors are raised as **`TarError`** exceptions as well.

The *encoding* and *errors* arguments define the character encoding to be used for reading or writing the archive and how conversion errors are going to be handled. The default settings will work for most users. See section Unicode issues for in-depth information.

The *pax_headers* argument is an optional dictionary of strings which will be added as a pax global header if *format* is **`PAX_FORMAT`**.

Changed in version 3.2: Use `'surrogateescape'` as the default for the *errors* argument.

Changed in version 3.5: The `'x'` (exclusive creation) mode was added.

Changed in version 3.6: The *name* parameter accepts a path-like object.

classmethod TarFile.open(...)

Alternative constructor. The `tarfile.open()` function is actually a shortcut to this classmethod.

TarFile.getmember(*name*)

Return a `TarInfo` object for member *name*. If *name* can not be found in the archive, `KeyError` is raised.

Note

If a member occurs more than once in the archive, its last occurrence is assumed to be the most up-to-date version.

TarFile.getmembers()

Return the members of the archive as a list of `TarInfo` objects. The list has the same order as the members in the archive.

TarFile.getnames()

Return the members as a list of their names. It has the same order as the list returned by `getmembers()`.

TarFile.list(*verbose=True*, *, *members=None*)

Print a table of contents to `sys.stdout`. If *verbose* is `False`, only the names of the members are printed. If it is `True`, output similar to that of **ls -l** is produced. If optional *members* is given, it must be a subset of the list returned by `getmembers()`.

Changed in version 3.5: Added the *members* parameter.

TarFile.next()

Return the next member of the archive as a `TarInfo` object, when `TarFile` is opened for reading. Return `None` if there is no more available.

TarFile.extractall(*path='.', members=None, *, numeric_owner=False*)

Extract all members from the archive to the current working directory or directory *path*. If optional *members* is given, it must be a subset of the list returned by `getmembers()`. Directory information like owner, modification time and permissions are set after all members have been extracted. This is done to work around two problems: A directory's modification time is reset each time a file is created in it. And, if a directory's permissions do not allow writing, extracting files to it will fail.

If *numeric_owner* is `True`, the uid and gid numbers from the tarfile are used to set the owner/group for the extracted files. Otherwise, the named values from the tarfile are used.

Warning

Never extract archives from untrusted sources without prior inspection. It is possible that files are created outside of *path*, e.g. members that have absolute filenames starting with `"/"` or filenames with two dots `".."`.

Changed in version 3.5: Added the *numeric_owner* parameter.

Changed in version 3.6: The *path* parameter accepts a path-like object.

TarFile.extract(*member, path='', set_attrs=True, *, numeric_owner=False*)

Extract a member from the archive to the current working directory, using its full name. Its file information is extracted as accurately as possible. *member* may be a filename or a `TarInfo` object. You can specify a different directory using *path*. *path* may be a path-like object. File attributes (owner, mtime, mode) are set unless *set_attrs* is false.

If *numeric_owner* is `True`, the uid and gid numbers from the tarfile are used to set the owner/group for the extracted files. Otherwise, the named values from the tarfile are used.

Note

The `extract()` method does not take care of several extraction issues. In most cases you should consider using the `extractall()` method.

Warning

See the warning for `extractall()`.

Changed in version 3.2: Added the *set_attrs* parameter.

Changed in version 3.5: Added the *numeric_owner* parameter.

Changed in version 3.6: The *path* parameter accepts a path-like object.

TarFile.extractfile(*member*)

Extract a member from the archive as a file object. *member* may be a filename or a `TarInfo` object. If *member* is a regular file or a link, an `io.BufferedReader` object is returned. For all other existing members, `None` is returned. If *member* does not appear in the archive, `KeyError` is raised.

Changed in version 3.3: Return an `io.BufferedReader` object.

TarFile.add(*name*, *arcname*=*None*, *recursive*=*True*, *, *filter*=*None*)

Add the file *name* to the archive. *name* may be any type of file (directory, fifo, symbolic link, etc.). If given, *arcname* specifies an alternative name for the file in the archive. Directories are added recursively by default. This can be avoided by setting *recursive* to `False`. Recursion adds entries in sorted order. If *filter* is given, it should be a function that takes a `TarInfo` object argument and returns the changed `TarInfo` object. If it instead returns `None` the `TarInfo` object will be excluded from the archive. See Examples for an example.

Changed in version 3.2: Added the *filter* parameter.

Changed in version 3.7: Recursion adds entries in sorted order.

TarFile.addfile(*tarinfo*, *fileobj*=*None*)

Add the **TarInfo** object *tarinfo* to the archive. If *fileobj* is given, it should be a binary file, and `tarinfo.size` bytes are read from it and added to the archive. You can create **TarInfo** objects directly, or by using **gettarinfo()**.

TarFile.gettarinfo(*name*=*None*, *arcname*=*None*, *fileobj*=*None*)

Create a **TarInfo** object from the result of **os.stat()** or equivalent on an existing file. The file is either named by *name*, or specified as a file object *fileobj* with a file descriptor. *name* may be a path-like object. If given, *arcname* specifies an alternative name for the file in the archive, otherwise, the name is taken from *fileobj*'s **name** attribute, or the *name* argument. The name should be a text string.

You can modify some of the **TarInfo**'s attributes before you add it using **addfile()**. If the file object is not an ordinary file object positioned at the beginning of the file, attributes such as **size** may need modifying. This is the case for objects such as **GzipFile**. The **name** may also be modified, in which case *arcname* could be a dummy string.

Changed in version 3.6: The *name* parameter accepts a path-like object.

TarFile.close()

Close the **TarFile**. In write mode, two finishing zero blocks are appended to the archive.

TarFile.pax_headers

A dictionary containing key-value pairs of pax global headers.

TarInfo Objects

A **TarInfo** object represents one member in a **TarFile**. Aside from storing all required attributes of a file (like file type, size,

time, permissions, owner etc.), it provides some useful methods to determine its type. It does *not* contain the file's data itself.

TarInfo objects are returned by **TarFile**'s methods **getmember()**, **getmembers()** and **gettarinfo()**.

class tarfile.TarInfo(*name*='')

Create a **TarInfo** object.

classmethod TarInfo.frombuf(*buf*, *encoding*, *errors*)

Create and return a **TarInfo** object from string buffer *buf*.

Raises **HeaderError** if the buffer is invalid.

classmethod TarInfo.fromtarfile(*tarfile*)

Read the next member from the **TarFile** object *tarfile* and return it as a **TarInfo** object.

TarInfo.tobuf(*format*=*DEFAULT_FORMAT*, *encoding*=*ENCODING*, *errors*='*surrogateescape*')

Create a string buffer from a **TarInfo** object. For information on the arguments see the constructor of the **TarFile** class.

Changed in version 3.2: Use `'surrogateescape'` as the default for the *errors* argument.

A `TarInfo` object has the following public data attributes:

TarInfo.name

Name of the archive member.

TarInfo.size

Size in bytes.

TarInfo.mtime

Time of last modification.

TarInfo.mode

Permission bits.

TarInfo.type

File type. *type* is usually one of these constants: **REGTYPE**, **AREGTYPE**, **LNKTYPE**, **SYMTYPE**, **DIRTYPE**, **FIFOTYPE**, **CONTTYPE**, **CHRTYPE**, **BLKTYPE**, **GNUTYPE_SPARSE**. To determine the type of a **TarInfo** object more conveniently, use the `is*()` methods below.

TarInfo.linkname

Name of the target file name, which is only present in **TarInfo** objects of type **LNKTYPE** and **SYMTYPE**.

TarInfo.uid

User ID of the user who originally stored this member.

TarInfo.gid

Group ID of the user who originally stored this member.

TarInfo.uname

User name.

TarInfo.gname

Group name.

TarInfo.pax_headers

A dictionary containing key-value pairs of an associated pax extended header.

A **TarInfo** object also provides some convenient query methods:

TarInfo.isfile()

Return **True** if the **Tarinfo** object is a regular file.

TarInfo.isreg()

Same as `isfile()`.

TarInfo.isdir()
: Return `True` if it is a directory.

TarInfo.issym()
: Return `True` if it is a symbolic link.

TarInfo.islnk()
: Return `True` if it is a hard link.

TarInfo.ischr()
: Return `True` if it is a character device.

TarInfo.isblk()
: Return `True` if it is a block device.

TarInfo.isfifo()
: Return `True` if it is a FIFO.

TarInfo.isdev()
: Return `True` if it is one of character device, block device or FIFO.

Command-Line Interface

New in version 3.4.

The `tarfile` module provides a simple command-line interface to interact with tar archives.

If you want to create a new tar archive, specify its name after the `-c` option and then list the filename(s) that should be included:

```
$ python -m tarfile -c monty.tar  spam.txt eggs.txt
```

Passing a directory is also acceptable:

```
$ python -m tarfile -c monty.tar life-of-brian_1979/
```

If you want to extract a tar archive into the current directory, use the `-e` option:

```
$ python -m tarfile -e monty.tar
```

You can also extract a tar archive into a different directory by passing the directory's name:

```
$ python -m tarfile -e monty.tar  other-dir/
```

For a list of the files in a tar archive, use the `-l` option:

```
$ python -m tarfile -l monty.tar
```

Command-line options

-l <tarfile>
--list <tarfile>

List files in a tarfile.

-c <tarfile> <source1> ... <sourceN>
--create <tarfile> <source1> ... <sourceN>

Create tarfile from source files.

-e <tarfile> [<output_dir>]
--extract <tarfile> [<output_dir>]

Extract tarfile into the current directory if *output_dir* is not specified.

-t <tarfile>
--test <tarfile>

Test whether the tarfile is valid or not.

-v, --verbose

Verbose output.

Examples

How to extract an entire tar archive to the current working directory:

```
import tarfile
tar = tarfile.open("sample.tar.gz")
tar.extractall()
tar.close()
```

How to extract a subset of a tar archive with `TarFile.extractall()` using a generator function instead of a list:

```
import os
import tarfile

def py_files(members):
    for tarinfo in members:
        if os.path.splitext(tarinfo.name)[1] == ".py":
            yield tarinfo

tar = tarfile.open("sample.tar.gz")
tar.extractall(members=py_files(tar))
tar.close()
```

How to create an uncompressed tar archive from a list of filenames:

```
import tarfile
tar = tarfile.open("sample.tar", "w")
for name in ["foo", "bar", "quux"]:
    tar.add(name)
tar.close()
```

The same example using the `with` statement:

```
import tarfile
with tarfile.open("sample.tar", "w") as tar:
    for name in ["foo", "bar", "quux"]:
        tar.add(name)
```

How to read a gzip compressed tar archive and display some member information:

```
import tarfile
tar = tarfile.open("sample.tar.gz", "r:gz")
for tarinfo in tar:
    print(tarinfo.name, "is", tarinfo.size, "bytes in si
    if tarinfo.isreg():
        print("a regular file.")
    elif tarinfo.isdir():
        print("a directory.")
    else:
        print("something else.")
tar.close()
```

How to create an archive and reset the user information using the *filter* parameter in **`TarFile.add()`**:

```
import tarfile
def reset(tarinfo):
    tarinfo.uid = tarinfo.gid = 0
    tarinfo.uname = tarinfo.gname = "root"
    return tarinfo
tar = tarfile.open("sample.tar.gz", "w:gz")
tar.add("foo", filter=reset)
tar.close()
```

Supported tar formats

There are three tar formats that can be created with the **`tarfile`** module:

- The POSIX.1-1988 ustar format (**`USTAR_FORMAT`**). It supports filenames up to a length of at best 256 characters and linknames up to 100 characters. The maximum file size is 8 GiB. This is an old and limited but widely supported format.
- The GNU tar format (**`GNU_FORMAT`**). It supports long filenames and linknames, files bigger than 8 GiB and sparse

files. It is the de facto standard on GNU/Linux systems. **`tarfile`** fully supports the GNU tar extensions for long names, sparse file support is read-only.

- The POSIX.1-2001 pax format (**`PAX_FORMAT`**). It is the most flexible format with virtually no limits. It supports long filenames and linknames, large files and stores pathnames in a portable way. Modern tar implementations, including GNU tar, bsdtar/libarchive and star, fully support extended *pax* features; some old or unmaintained libraries may not, but should treat *pax* archives as if they were in the universally supported *ustar* format. It is the current default format for new archives.

  It extends the existing *ustar* format with extra headers for information that cannot be stored otherwise. There are two flavours of pax headers: Extended headers only affect the subsequent file header, global headers are valid for the complete archive and affect all following files. All the data in a pax header is encoded in *UTF-8* for portability reasons.

There are some more variants of the tar format which can be read, but not created:

- The ancient V7 format. This is the first tar format from Unix Seventh Edition, storing only regular files and directories. Names must not be longer than 100 characters, there is no user/group name information. Some archives have miscalculated header checksums in case of fields with non-ASCII characters.
- The SunOS tar extended format. This format is a variant of the POSIX.1-2001 pax format, but is not compatible.

Unicode issues

The tar format was originally conceived to make backups on tape drives with the main focus on preserving file system information. Nowadays tar archives are commonly used for file distribution and exchanging archives over networks. One problem of the original format (which is the basis of all other formats) is that there is no

concept of supporting different character encodings. For example, an ordinary tar archive created on a *UTF-8* system cannot be read correctly on a *Latin-1* system if it contains non-*ASCII* characters. Textual metadata (like filenames, linknames, user/group names) will appear damaged. Unfortunately, there is no way to autodetect the encoding of an archive. The pax format was designed to solve this problem. It stores non-ASCII metadata using the universal character encoding *UTF-8*.

The details of character conversion in **`tarfile`** are controlled by the *encoding* and *errors* keyword arguments of the **`TarFile`** class.

encoding defines the character encoding to use for the metadata in the archive. The default value is **`sys.getfilesystemencoding()`** or `'ascii'` as a fallback. Depending on whether the archive is read or written, the metadata must be either decoded or encoded. If *encoding* is not set appropriately, this conversion may fail.

The *errors* argument defines how characters are treated that cannot be converted. Possible values are listed in section Error Handlers. The default scheme is `'surrogateescape'` which Python also uses for its file system calls, see File Names, Command Line Arguments, and Environment Variables.

For **`PAX_FORMAT`** archives (the default), *encoding* is generally not needed because all the metadata is stored using *UTF-8*. *encoding* is only used in the rare cases when binary pax headers are decoded or when strings with surrogate characters are stored.

File Formats

The modules described in this chapter parse various miscellaneous file formats that aren't markup languages and are not related to e-mail.

- **csv** — CSV File Reading and Writing
  - Module Contents
  - Dialects and Formatting Parameters
  - Reader Objects
  - Writer Objects
  - Examples
- **configparser** — Configuration file parser
  - Quick Start
  - Supported Datatypes
  - Fallback Values
  - Supported INI File Structure
  - Interpolation of values
  - Mapping Protocol Access
  - Customizing Parser Behaviour
  - Legacy API Examples
  - ConfigParser Objects
  - RawConfigParser Objects
  - Exceptions
- **tomllib** — Parse TOML files
  - Examples
  - Conversion Table
- **netrc** — netrc file processing
  - netrc Objects

- **`plistlib`** — Generate and parse Apple **`.plist`** files
  - Examples

`csv` — CSV File Reading and Writing

Source code: Lib/csv.py [https://github.com/python/cpython/tree/3.11/Lib/csv.py]

The so-called CSV (Comma Separated Values) format is the most common import and export format for spreadsheets and databases. CSV format was used for many years prior to attempts to describe the format in a standardized way in **RFC 4180** [https://datatracker.ietf.org/doc/html/rfc4180.html]. The lack of a well-defined standard means that subtle differences often exist in the data produced and consumed by different applications. These differences can make it annoying to process CSV files from multiple sources. Still, while the delimiters and quoting characters vary, the overall format is similar enough that it is possible to write a single module which can efficiently manipulate such data, hiding the details of reading and writing the data from the programmer.

The `csv` module implements classes to read and write tabular data in CSV format. It allows programmers to say, “write this data in the format preferred by Excel,” or “read data from this file which was generated by Excel,” without knowing the precise details of the CSV format used by Excel. Programmers can also describe the CSV formats understood by other applications or define their own special-purpose CSV formats.

The `csv` module’s `reader` and `writer` objects read and write sequences. Programmers can also read and write data in dictionary form using the `DictReader` and `DictWriter` classes.

PEP 305 **[https://peps.python.org/pep-0305/]** **- CSV File API**

The Python Enhancement Proposal which proposed this addition to Python.

Module Contents

The **csv** module defines the following functions:

csv.reader(*csvfile*, *dialect='excel'*, ***fmtparams*)

Return a reader object which will iterate over lines in the given *csvfile*. *csvfile* can be any object which supports the iterator protocol and returns a string each time its **__next__()** method is called — file objects and list objects are both suitable. If *csvfile* is a file object, it should be opened with `newline=''`. 1 An optional *dialect* parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the **Dialect** class or one of the strings returned by the **list_dialects()** function. The other optional *fmtparams* keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about the dialect and formatting parameters, see section Dialects and Formatting Parameters.

Each row read from the csv file is returned as a list of strings. No automatic data type conversion is performed unless the `QUOTE_NONNUMERIC` format option is specified (in which case unquoted fields are transformed into floats).

A short usage example:

```
>>> import csv
>>> with open('eggs.csv', newline='') as csvfile:
...     spamreader = csv.reader(csvfile, delimiter=
...     for row in spamreader:
...         print(', '.join(row))
Spam, Spam, Spam, Spam, Spam, Baked Beans
Spam, Lovely Spam, Wonderful Spam
```

csv.writer(*csvfile*, *dialect*='excel', ***fmtparams*)

Return a writer object responsible for converting the user's data into delimited strings on the given file-like object. *csvfile* can be any object with a **write()** method. If *csvfile* is a file object, it should be opened with `newline=''` 1. An optional *dialect* parameter can be given which is used to define a set of parameters specific to a particular CSV dialect. It may be an instance of a subclass of the **Dialect** class or one of the strings returned by the **list_dialects()** function. The other optional *fmtparams* keyword arguments can be given to override individual formatting parameters in the current dialect. For full details about dialects and formatting parameters, see the Dialects and Formatting Parameters section. To make it as easy as possible to interface with modules which implement the DB API, the value **None** is written as the empty string. While this isn't a reversible transformation, it makes it easier to dump SQL NULL data values to CSV files without preprocessing the data returned from a `cursor.fetch*` call. All other non-string data are stringified with **str()** before being written.

A short usage example:

```
import csv
with open('eggs.csv', 'w', newline='') as csvfile:
    spamwriter = csv.writer(csvfile, delimiter=' ',
                            quotechar='|', quoting=
    spamwriter.writerow(['Spam'] * 5 + ['Baked Bean
    spamwriter.writerow(['Spam', 'Lovely Spam', 'Wo
```

csv.register_dialect(*name*[, *dialect*[, ***fmtparams*]])

Associate *dialect* with *name*. *name* must be a string. The dialect can be specified either by passing a sub-class of **Dialect**, or by *fmtparams* keyword arguments, or both, with keyword arguments overriding parameters of the dialect. For full details about dialects and formatting parameters, see section Dialects and Formatting Parameters.

csv.unregister_dialect(*name*)

Delete the dialect associated with *name* from the dialect registry. An **`Error`** is raised if *name* is not a registered dialect name.

csv.get_dialect(*name*)

Return the dialect associated with *name*. An **`Error`** is raised if *name* is not a registered dialect name. This function returns an immutable **`Dialect`**.

csv.list_dialects()

Return the names of all registered dialects.

csv.field_size_limit([*new_limit*])

Returns the current maximum field size allowed by the parser. If *new_limit* is given, this becomes the new limit.

The **`csv`** module defines the following classes:

class csv.DictReader(*f*, *fieldnames*=*None*, *restkey*=*None*, *restval*=*None*, *dialect*='*excel*', **args*, ***kwds*)

Create an object that operates like a regular reader but maps the information in each row to a **`dict`** whose keys are given by the optional *fieldnames* parameter.

The *fieldnames* parameter is a sequence. If *fieldnames* is omitted, the values in the first row of file *f* will be used as the fieldnames. Regardless of how the fieldnames are determined, the dictionary preserves their original ordering.

If a row has more fields than fieldnames, the remaining data is put in a list and stored with the fieldname specified by *restkey* (which defaults to `None`). If a non-blank row has fewer fields than fieldnames, the missing values are filled-in with the value of *restval* (which defaults to `None`).

All other optional or keyword arguments are passed to the underlying **`reader`** instance.

Changed in version 3.6: Returned rows are now of type **OrderedDict**.

Changed in version 3.8: Returned rows are now of type **dict**.

A short usage example:

```
>>> import csv
>>> with open('names.csv', newline='') as csvfile:
...     reader = csv.DictReader(csvfile)
...     for row in reader:
...         print(row['first_name'], row['last_name
...
Eric Idle
John Cleese

>>> print(row)
{'first_name': 'John', 'last_name': 'Cleese'}
```

class csv.DictWriter(*f*, *fieldnames*, *restval*='', *extrasaction*='raise', *dialect*='excel', **args*, ***kwds*)

Create an object which operates like a regular writer but maps dictionaries onto output rows. The *fieldnames* parameter is a **sequence** of keys that identify the order in which values in the dictionary passed to the **writerow()** method are written to file *f*. The optional *restval* parameter specifies the value to be written if the dictionary is missing a key in *fieldnames*. If the dictionary passed to the **writerow()** method contains a key not found in *fieldnames*, the optional *extrasaction* parameter indicates what action to take. If it is set to `'raise'`, the default value, a **ValueError** is raised. If it is set to `'ignore'`, extra values in the dictionary are ignored. Any other optional or keyword arguments are passed to the underlying **writer** instance.

Note that unlike the **DictReader** class, the *fieldnames* parameter of the **DictWriter** class is not optional.

A short usage example:

```
import csv

with open('names.csv', 'w', newline='') as csvfile:
    fieldnames = ['first_name', 'last_name']
    writer = csv.DictWriter(csvfile, fieldnames=fie

    writer.writeheader()
    writer.writerow({'first_name': 'Baked', 'last_n
    writer.writerow({'first_name': 'Lovely', 'last_
    writer.writerow({'first_name': 'Wonderful', 'la
```

class csv.Dialect

The **`Dialect`** class is a container class whose attributes contain information for how to handle doublequotes, whitespace, delimiters, etc. Due to the lack of a strict CSV specification, different applications produce subtly different CSV data. **`Dialect`** instances define how **`reader`** and **`writer`** instances behave.

All available **`Dialect`** names are returned by **`list_dialects()`**, and they can be registered with specific **`reader`** and **`writer`** classes through their initializer (`__init__`) functions like this:

```
import csv

with open('students.csv', 'w', newline='') as csvfi
    writer = csv.writer(csvfile, dialect='unix')
                                 ^^^^^^^^^^^^^^
```

class csv.excel

The **`excel`** class defines the usual properties of an Excel-generated CSV file. It is registered with the dialect name `'excel'`.

class csv.excel_tab

The **`excel_tab`** class defines the usual properties of an Excel-generated TAB-delimited file. It is registered with the dialect name `'excel-tab'`.

class csv.unix_dialect

The **unix_dialect** class defines the usual properties of a CSV file generated on UNIX systems, i.e. using `'\n'` as line terminator and quoting all fields. It is registered with the dialect name `'unix'`.

New in version 3.2.

class csv.Sniffer

The **Sniffer** class is used to deduce the format of a CSV file.

The **Sniffer** class provides two methods:

sniff(*sample*, *delimiters*=*None*)

Analyze the given *sample* and return a **Dialect** subclass reflecting the parameters found. If the optional *delimiters* parameter is given, it is interpreted as a string containing possible valid delimiter characters.

has_header(*sample*)

Analyze the sample text (presumed to be in CSV format) and return **True** if the first row appears to be a series of column headers. Inspecting each column, one of two key criteria will be considered to estimate if the sample contains a header:

- the second through n-th rows contain numeric values
- the second through n-th rows contain strings where at least one value's length differs from that of the putative header of that column.

Twenty rows after the first row are sampled; if more than half of columns + rows meet the criteria, **True** is returned.

Note

This method is a rough heuristic and may produce both false positives and negatives.

An example for **Sniffer** use:

```
with open('example.csv', newline='') as csvfile:
    dialect = csv.Sniffer().sniff(csvfile.read(1024))
    csvfile.seek(0)
    reader = csv.reader(csvfile, dialect)
    # ... process CSV file contents here ...
```

The **csv** module defines the following constants:

csv.QUOTE_ALL

Instructs **writer** objects to quote all fields.

csv.QUOTE_MINIMAL

Instructs **writer** objects to only quote those fields which contain special characters such as *delimiter*, *quotechar* or any of the characters in *lineterminator*.

csv.QUOTE_NONNUMERIC

Instructs **writer** objects to quote all non-numeric fields.

Instructs the reader to convert all non-quoted fields to type *float*.

csv.QUOTE_NONE

Instructs **writer** objects to never quote fields. When the current *delimiter* occurs in output data it is preceded by the current *escapechar* character. If *escapechar* is not set, the writer will raise **Error** if any characters that require escaping are encountered.

Instructs **reader** to perform no special processing of quote characters.

The **csv** module defines the following exception:

exception csv.Error

Raised by any of the functions when an error is detected.

Dialects and Formatting Parameters

To make it easier to specify the format of input and output records, specific formatting parameters are grouped together into dialects. A dialect is a subclass of the **Dialect** class having a set of specific methods and a single **validate()** method. When creating **reader** or **writer** objects, the programmer can specify a string or a subclass of the **Dialect** class as the dialect parameter. In addition to, or instead of, the *dialect* parameter, the programmer can also specify individual formatting parameters, which have the same names as the attributes defined below for the **Dialect** class.

Dialects support the following attributes:

Dialect.delimiter

A one-character string used to separate fields. It defaults to `','`.

Dialect.doublequote

Controls how instances of *quotechar* appearing inside a field should themselves be quoted. When **True**, the character is doubled. When **False**, the *escapechar* is used as a prefix to the *quotechar*. It defaults to **True**.

On output, if *doublequote* is **False** and no *escapechar* is set, **Error** is raised if a *quotechar* is found in a field.

Dialect.escapechar

A one-character string used by the writer to escape the *delimiter* if *quoting* is set to **QUOTE_NONE** and the *quotechar* if *doublequote* is **False**. On reading, the *escapechar* removes any special meaning from the following character. It defaults to **None**, which disables escaping.

Changed in version 3.11: An empty *escapechar* is not allowed.

Dialect.lineterminator

The string used to terminate lines produced by the **writer**. It defaults to `'\r\n'`.

Note

The **reader** is hard-coded to recognise either `'\r'` or `'\n'` as end-of-line, and ignores *lineterminator*. This behavior may change in the future.

Dialect.quotechar

A one-character string used to quote fields containing special characters, such as the *delimiter* or *quotechar*, or which contain new-line characters. It defaults to `'"'`.

Changed in version 3.11: An empty *quotechar* is not allowed.

Dialect.quoting

Controls when quotes should be generated by the writer and recognised by the reader. It can take on any of the **QUOTE_*** constants (see section Module Contents) and defaults to **QUOTE_MINIMAL**.

Dialect.skipinitialspace

When **True**, spaces immediately following the *delimiter* are ignored. The default is **False**.

Dialect.strict

When `True`, raise exception **Error** on bad CSV input. The default is `False`.

Reader Objects

Reader objects (**DictReader** instances and objects returned by the **reader()** function) have the following public methods:

csvreader._next_()

Return the next row of the reader's iterable object as a list (if the object was returned from **reader()**) or a dict (if it is a **DictReader** instance), parsed according to the current **Dialect**. Usually you should call this as `next(reader)`.

Reader objects have the following public attributes:

csvreader.dialect

A read-only description of the dialect in use by the parser.

csvreader.line_num

The number of lines read from the source iterator. This is not the same as the number of records returned, as records can span multiple lines.

DictReader objects have the following public attribute:

csvreader.fieldnames

If not passed as a parameter when creating the object, this attribute is initialized upon first access or when the first record is read from the file.

Writer Objects

Writer objects (**DictWriter** instances and objects returned by the **writer()** function) have the following public methods. A *row* must be an iterable of strings or numbers for **Writer** objects and a dictionary mapping fieldnames to strings or numbers (by passing them through **str()** first) for **DictWriter** objects. Note that complex numbers are written out surrounded by parens. This may cause some problems for other programs which read CSV files (assuming they support complex numbers at all).

csvwriter.writerow(*row*)

Write the *row* parameter to the writer's file object, formatted according to the current **Dialect**. Return the return value of the call to the *write* method of the underlying file object.

Changed in version 3.5: Added support of arbitrary iterables.

csvwriter.writerows(*rows*)

Write all elements in *rows* (an iterable of *row* objects as described above) to the writer's file object, formatted according to the current dialect.

Writer objects have the following public attribute:

csvwriter.dialect

A read-only description of the dialect in use by the writer.

DictWriter objects have the following public method:

DictWriter.writeheader()

Write a row with the field names (as specified in the constructor) to the writer's file object, formatted according to the current dialect. Return the return value of the **`csvwriter.writerow()`** call used internally.

New in version 3.2.

Changed in version 3.8: **`writeheader()`** now also returns the value returned by the **`csvwriter.writerow()`** method it uses internally.

Examples

The simplest example of reading a CSV file:

```
import csv
with open('some.csv', newline='') as f:
    reader = csv.reader(f)
    for row in reader:
        print(row)
```

Reading a file with an alternate format:

```
import csv
```

```
with open('passwd', newline='') as f:
    reader = csv.reader(f, delimiter=':', quoting=csv.QU
    for row in reader:
        print(row)
```

The corresponding simplest possible writing example is:

```
import csv
with open('some.csv', 'w', newline='') as f:
    writer = csv.writer(f)
    writer.writerows(someiterable)
```

Since **`open()`** is used to open a CSV file for reading, the file will by default be decoded into unicode using the system default encoding (see **`locale.getencoding()`**). To decode a file using a different encoding, use the `encoding` argument of open:

```
import csv
with open('some.csv', newline='', encoding='utf-8') as f
    reader = csv.reader(f)
    for row in reader:
        print(row)
```

The same applies to writing in something other than the system default encoding: specify the encoding argument when opening the output file.

Registering a new dialect:

```
import csv
csv.register_dialect('unixpwd', delimiter=':', quoting=c
with open('passwd', newline='') as f:
    reader = csv.reader(f, 'unixpwd')
```

A slightly more advanced use of the reader — catching and reporting errors:

```
import csv, sys
filename = 'some.csv'
with open(filename, newline='') as f:
    reader = csv.reader(f)
```

```
    try:
        for row in reader:
            print(row)
    except csv.Error as e:
        sys.exit('file {}, line {}: {}'.format(filename,
```

And while the module doesn't directly support parsing strings, it can easily be done:

```
import csv
for row in csv.reader(['one,two,three']):
    print(row)
```

Footnotes

1(*1*,*2*)

If `newline=''` is not specified, newlines embedded inside quoted fields will not be interpreted correctly, and on platforms that use `\r\n` linendings on write an extra `\r` will be added. It should always be safe to specify `newline=''`, since the csv module does its own (universal) newline handling.

`configparser` — Configuration file parser

Source code: Lib/configparser.py [https://github.com/python/cpython/tree/3.11/Lib/configparser.py]

This module provides the `ConfigParser` class which implements a basic configuration language which provides a structure similar to what's found in Microsoft Windows INI files. You can use this to write Python programs which can be customized by end users easily.

Note

This library does *not* interpret or write the value-type prefixes used in the Windows Registry extended version of INI syntax.

See also

Module `tomllib`
: TOML is a well-specified format for application configuration files. It is specifically designed to be an improved version of INI.

Module `shlex`
: Support for creating Unix shell-like mini-languages which can also be used for application configuration files.

Module `json`
: The `json` module implements a subset of JavaScript syntax which is sometimes used for configuration, but does not support comments.

Quick Start

Let's take a very basic configuration file that looks like this:

```
[DEFAULT]
ServerAliveInterval = 45
Compression = yes
CompressionLevel = 9
ForwardX11 = yes

[bitbucket.org]
User = hg

[topsecret.server.com]
Port = 50022
ForwardX11 = no
```

The structure of INI files is described in the following section. Essentially, the file consists of sections, each of which contains keys with values. **`configparser`** classes can read and write such files. Let's start by creating the above configuration file programmatically.

```
>>> import configparser
>>> config = configparser.ConfigParser()
>>> config['DEFAULT'] = {'ServerAliveInterval': '45',
...                      'Compression': 'yes',
...                      'CompressionLevel': '9'}
>>> config['bitbucket.org'] = {}
>>> config['bitbucket.org']['User'] = 'hg'
>>> config['topsecret.server.com'] = {}
>>> topsecret = config['topsecret.server.com']
>>> topsecret['Port'] = '50022'     # mutates the parser
>>> topsecret['ForwardX11'] = 'no'  # same here
>>> config['DEFAULT']['ForwardX11'] = 'yes'
>>> with open('example.ini', 'w') as configfile:
...   config.write(configfile)
...
```

As you can see, we can treat a config parser much like a dictionary. There are differences, outlined later, but the behavior is very close to what you would expect from a dictionary.

Now that we have created and saved a configuration file, let's read it back and explore the data it holds.

```
>>> config = configparser.ConfigParser()
>>> config.sections()
[]
>>> config.read('example.ini')
['example.ini']
>>> config.sections()
['bitbucket.org', 'topsecret.server.com']
>>> 'bitbucket.org' in config
True
>>> 'bytebong.com' in config
False
>>> config['bitbucket.org']['User']
'hg'
>>> config['DEFAULT']['Compression']
'yes'
>>> topsecret = config['topsecret.server.com']
>>> topsecret['ForwardX11']
'no'
>>> topsecret['Port']
'50022'
>>> for key in config['bitbucket.org']:
...     print(key)
user
compressionlevel
serveraliveinterval
compression
forwardx11
>>> config['bitbucket.org']['ForwardX11']
'yes'
```

As we can see above, the API is pretty straightforward. The only bit of magic involves the `DEFAULT` section which provides default

values for all other sections 1. Note also that keys in sections are case-insensitive and stored in lowercase 1.

It is possible to read several configurations into a single **ConfigParser**, where the most recently added configuration has the highest priority. Any conflicting keys are taken from the more recent configuration while the previously existing keys are retained.

```
>>> another_config = configparser.ConfigParser()
>>> another_config.read('example.ini')
['example.ini']
>>> another_config['topsecret.server.com']['Port']
'50022'
>>> another_config.read_string("[topsecret.server.com]\r
>>> another_config['topsecret.server.com']['Port']
'48484'
>>> another_config.read_dict({"topsecret.server.com": {"
>>> another_config['topsecret.server.com']['Port']
'21212'
>>> another_config['topsecret.server.com']['ForwardX11']
'no'
```

This behaviour is equivalent to a **ConfigParser.read()** call with several files passed to the *filenames* parameter.

Supported Datatypes

Config parsers do not guess datatypes of values in configuration files, always storing them internally as strings. This means that if you need other datatypes, you should convert on your own:

```
>>> int(topsecret['Port'])
50022
>>> float(topsecret['CompressionLevel'])
9.0
```

Since this task is so common, config parsers provide a range of handy getter methods to handle integers, floats and booleans. The last one is the most interesting because simply passing the value to `bool()` would do no good since `bool('False')` is still `True`.

This is why config parsers also provide `getboolean()`. This method is case-insensitive and recognizes Boolean values from `'yes'`/`'no'`, `'on'`/`'off'`, `'true'`/`'false'` and `'1'`/`'0'` 1. For example:

```
>>> topsecret.getboolean('ForwardX11')
False
>>> config['bitbucket.org'].getboolean('ForwardX11')
True
>>> config.getboolean('bitbucket.org', 'Compression')
True
```

Apart from `getboolean()`, config parsers also provide equivalent `getint()` and `getfloat()` methods. You can register your own converters and customize the provided ones. 1

Fallback Values

As with a dictionary, you can use a section's `get()` method to provide fallback values:

```
>>> topsecret.get('Port')
'50022'
>>> topsecret.get('CompressionLevel')
'9'
>>> topsecret.get('Cipher')
>>> topsecret.get('Cipher', '3des-cbc')
'3des-cbc'
```

Please note that default values have precedence over fallback values. For instance, in our example the `'CompressionLevel'` key was specified only in the `'DEFAULT'` section. If we try to get it from the section `'topsecret.server.com'`, we will always get the default, even if we specify a fallback:

```
>>> topsecret.get('CompressionLevel', '3')
'9'
```

One more thing to be aware of is that the parser-level `get()` method provides a custom, more complex interface, maintained for

backwards compatibility. When using this method, a fallback value can be provided via the `fallback` keyword-only argument:

```
>>> config.get('bitbucket.org', 'monster',
...             fallback='No such things as monsters')
'No such things as monsters'
```

The same `fallback` argument can be used with the **`getint()`**, **`getfloat()`** and **`getboolean()`** methods, for example:

```
>>> 'BatchMode' in topsecret
False
>>> topsecret.getboolean('BatchMode', fallback=True)
True
>>> config['DEFAULT']['BatchMode'] = 'no'
>>> topsecret.getboolean('BatchMode', fallback=True)
False
```

Supported INI File Structure

A configuration file consists of sections, each led by a `[section]` header, followed by key/value entries separated by a specific string (= or `:` by default 1). By default, section names are case sensitive but keys are not 1. Leading and trailing whitespace is removed from keys and values. Values can be omitted if the parser is configured to allow it 1, in which case the key/value delimiter may also be left out. Values can also span multiple lines, as long as they are indented deeper than the first line of the value. Depending on the parser's mode, blank lines may be treated as parts of multiline values or ignored.

By default, a valid section name can be any string that does not contain '\n' or ']'. To change this, see **`ConfigParser.SECTCRE`**.

Configuration files may include comments, prefixed by specific characters (`#` and `;` by default 1). Comments may appear on their own on an otherwise empty line, possibly indented. 1

For example:

```
[Simple Values]
key=value
spaces in keys=allowed
spaces in values=allowed as well
spaces around the delimiter = obviously
you can also use : to delimit keys from values

[All Values Are Strings]
values like this: 1000000
or this: 3.14159265359
are they treated as numbers? : no
integers, floats and booleans are held as: strings
can use the API to get converted values directly: true

[Multiline Values]
chorus: I'm a lumberjack, and I'm okay
    I sleep all night and I work all day

[No Values]
key_without_value
empty string value here =

[You can use comments]
# like this
; or this

# By default only in an empty line.
# Inline comments can be harmful because they prevent us
# from using the delimiting characters as parts of value
# That being said, this can be customized.

    [Sections Can Be Indented]
        can_values_be_as_well = True
        does_that_mean_anything_special = False
        purpose = formatting for readability
        multiline_values = are
            handled just fine as
            long as they are indented
```

```
        deeper than the first line
        of a value
    # Did I mention we can indent comments, too?
```

Interpolation of values

On top of the core functionality, **ConfigParser** supports interpolation. This means values can be preprocessed before returning them from `get()` calls.

class configparser.BasicInterpolation

The default implementation used by **ConfigParser**. It enables values to contain format strings which refer to other values in the same section, or values in the special default section [1]. Additional default values can be provided on initialization.

For example:

```
[Paths]
home_dir: /Users
my_dir: %(home_dir)s/lumberjack
my_pictures: %(my_dir)s/Pictures

[Escape]
# use a %% to escape the % sign (% is the only char
gain: 80%%
```

In the example above, **ConfigParser** with *interpolation* set to `BasicInterpolation()` would resolve `%(home_dir)s` to the value of `home_dir` (`/Users` in this case). `%(my_dir)s` in effect would resolve to `/Users/lumberjack`. All interpolations are done on demand so keys used in the chain of references do not have to be specified in any specific order in the configuration file.

With `interpolation` set to `None`, the parser would simply return `%(my_dir)s/Pictures` as the value of `my_pictures` and `%(home_dir)s/lumberjack` as the value of `my_dir`.

class configparser.ExtendedInterpolation

An alternative handler for interpolation which implements a more advanced syntax, used for instance in `zc.buildout`. Extended interpolation is using `${section:option}` to denote a value from a foreign section. Interpolation can span multiple levels. For convenience, if the `section:` part is omitted, interpolation defaults to the current section (and possibly the default values from the special section).

For example, the configuration specified above with basic interpolation, would look like this with extended interpolation:

```
[Paths]
home_dir: /Users
my_dir: ${home_dir}/lumberjack
my_pictures: ${my_dir}/Pictures

[Escape]
# use a $$ to escape the $ sign ($ is the only char
cost: $$80
```

Values from other sections can be fetched as well:

```
[Common]
home_dir: /Users
library_dir: /Library
system_dir: /System
macports_dir: /opt/local

[Frameworks]
Python: 3.2
path: ${Common:system_dir}/Library/Frameworks/

[Arthur]
nickname: Two Sheds
last_name: Jackson
my_dir: ${Common:home_dir}/twosheds
my_pictures: ${my_dir}/Pictures
```

```
python_dir: ${Frameworks:path}/Python/Versions/${Fr
```

Mapping Protocol Access

New in version 3.2.

Mapping protocol access is a generic name for functionality that enables using custom objects as if they were dictionaries. In case of **configparser**, the mapping interface implementation is using the `parser['section']['option']` notation.

`parser['section']` in particular returns a proxy for the section's data in the parser. This means that the values are not copied but they are taken from the original parser on demand. What's even more important is that when values are changed on a section proxy, they are actually mutated in the original parser.

configparser objects behave as close to actual dictionaries as possible. The mapping interface is complete and adheres to the **MutableMapping** ABC. However, there are a few differences that should be taken into account:

- By default, all keys in sections are accessible in a case-insensitive manner [1]. E.g. `for option in parser["section"]` yields only `optionxform`'ed option key names. This means lowercased keys by default. At the same time, for a section that holds the key `'a'`, both expressions return `True`:

  ```
  "a" in parser["section"]
  "A" in parser["section"]
  ```

- All sections include `DEFAULTSECT` values as well which means that `.clear()` on a section may not leave the section visibly empty. This is because default values cannot be deleted from the section (because technically they are not there). If they are overridden in the section, deleting causes the default value to be visible again. Trying to delete a default value causes a **KeyError**.

- `DEFAULTSECT` cannot be removed from the parser:
  - trying to delete it raises **`ValueError`**,
  - `parser.clear()` leaves it intact,
  - `parser.popitem()` never returns it.
- `parser.get(section, option, **kwargs)` - the second argument is **not** a fallback value. Note however that the section-level `get()` methods are compatible both with the mapping protocol and the classic configparser API.
- `parser.items()` is compatible with the mapping protocol (returns a list of *section_name*, *section_proxy* pairs including the DEFAULTSECT). However, this method can also be invoked with arguments: `parser.items(section, raw, vars)`. The latter call returns a list of *option*, *value* pairs for a specified `section`, with all interpolations expanded (unless `raw=True` is provided).

The mapping protocol is implemented on top of the existing legacy API so that subclasses overriding the original interface still should have mappings working as expected.

Customizing Parser Behaviour

There are nearly as many INI format variants as there are applications using it. **`configparser`** goes a long way to provide support for the largest sensible set of INI styles available. The default functionality is mainly dictated by historical background and it's very likely that you will want to customize some of the features.

The most common way to change the way a specific config parser works is to use the **`__init__()`** options:

- *defaults*, default value: `None`

  This option accepts a dictionary of key-value pairs which will be initially put in the `DEFAULT` section. This makes for an elegant way to support concise configuration files that don't specify values which are the same as the documented default.

Hint: if you want to specify default values for a specific section, use **`read_dict()`** before you read the actual file.

- *dict_type*, default value: **`dict`**

  This option has a major impact on how the mapping protocol will behave and how the written configuration files look. With the standard dictionary, every section is stored in the order they were added to the parser. Same goes for options within sections.

  An alternative dictionary type can be used for example to sort sections and options on write-back.

  Please note: there are ways to add a set of key-value pairs in a single operation. When you use a regular dictionary in those operations, the order of the keys will be ordered. For example:

```
>>> parser = configparser.ConfigParser()
>>> parser.read_dict({'section1': {'key1': 'value1'
...                                'key2': 'value2'
...                                'key3': 'value3'
...                    'section2': {'keyA': 'valueA'
...                                'keyB': 'valueB'
...                                'keyC': 'valueC'
...                    'section3': {'foo': 'x',
...                                'bar': 'y',
...                                'baz': 'z'}
... })
>>> parser.sections()
['section1', 'section2', 'section3']
>>> [option for option in parser['section3']]
['foo', 'bar', 'baz']
```

- *allow_no_value*, default value: `False`

  Some configuration files are known to include settings without values, but which otherwise conform to the syntax supported by **`configparser`**. The *allow_no_value* parameter

to the constructor can be used to indicate that such values should be accepted:

```
>>> import configparser

>>> sample_config = """
... [mysqld]
...   user = mysql
...   pid-file = /var/run/mysqld/mysqld.pid
...   skip-external-locking
...   old_passwords = 1
...   skip-bdb
...   # we don't need ACID today
...   skip-innodb
... """
>>> config = configparser.ConfigParser(allow_no_val
>>> config.read_string(sample_config)

>>> # Settings with values are treated as before:
>>> config["mysqld"]["user"]
'mysql'

>>> # Settings without values provide None:
>>> config["mysqld"]["skip-bdb"]

>>> # Settings which aren't specified still raise a
>>> config["mysqld"]["does-not-exist"]
Traceback (most recent call last):
  ...
KeyError: 'does-not-exist'
```

- *delimiters*, default value: `('=', ':')`

  Delimiters are substrings that delimit keys from values within a section. The first occurrence of a delimiting substring on a line is considered a delimiter. This means values (but not keys) can contain the delimiters.

  See also the *space_around_delimiters* argument to

ConfigParser.write().

- *comment_prefixes*, default value: `('#', ';')`
- *inline_comment_prefixes*, default value: `None`

  Comment prefixes are strings that indicate the start of a valid comment within a config file. *comment_prefixes* are used only on otherwise empty lines (optionally indented) whereas *inline_comment_prefixes* can be used after every valid value (e.g. section names, options and empty lines as well). By default inline comments are disabled and `'#'` and `';'` are used as prefixes for whole line comments.

  Changed in version 3.2: In previous versions of **configparser** behaviour matched `comment_prefixes=('#',';')` and `inline_comment_prefixes=(';',)`.

  Please note that config parsers don't support escaping of comment prefixes so using *inline_comment_prefixes* may prevent users from specifying option values with characters used as comment prefixes. When in doubt, avoid setting *inline_comment_prefixes*. In any circumstances, the only way of storing comment prefix characters at the beginning of a line in multiline values is to interpolate the prefix, for example:

```
>>> from configparser import ConfigParser, Extended
>>> parser = ConfigParser(interpolation=ExtendedInt
>>> # the default BasicInterpolation could be used
>>> parser.read_string("""
... [DEFAULT]
... hash = #
...
... [hashes]
... shebang =
...   ${hash}!/usr/bin/env python
...   ${hash} -*- coding: utf-8 -*-
...
... extensions =
```

```
...   enabled_extension
...   another_extension
...   #disabled_by_comment
...   yet_another_extension
...
... interpolation not necessary = if # is not at li
... even in multiline values = line #1
...   line #2
...   line #3
... """)
>>> print(parser['hashes']['shebang'])

#!/usr/bin/env python
# -*- coding: utf-8 -*-
>>> print(parser['hashes']['extensions'])

enabled_extension
another_extension
yet_another_extension
>>> print(parser['hashes']['interpolation not neces
if # is not at line start
>>> print(parser['hashes']['even in multiline value
line #1
line #2
line #3
```

- *strict*, default value: `True`

  When set to `True`, the parser will not allow for any section or option duplicates while reading from a single source (using **`read_file()`**, **`read_string()`** or **`read_dict()`**). It is recommended to use strict parsers in new applications.

  Changed in version 3.2: In previous versions of **`configparser`** behaviour matched `strict=False`.

- *empty_lines_in_values*, default value: `True`

  In config parsers, values can span multiple lines as long as they are indented more than the key that holds them. By

default parsers also let empty lines to be parts of values. At the same time, keys can be arbitrarily indented themselves to improve readability. In consequence, when configuration files get big and complex, it is easy for the user to lose track of the file structure. Take for instance:

```
[Section]
key = multiline
  value with a gotcha

 this = is still a part of the multiline value of '
```

This can be especially problematic for the user to see if she's using a proportional font to edit the file. That is why when your application does not need values with empty lines, you should consider disallowing them. This will make empty lines split keys every time. In the example above, it would produce two keys, `key` and `this`.

- *default_section*, default value: `configparser.DEFAULTSECT` (that is: `"DEFAULT"`)

  The convention of allowing a special section of default values for other sections or interpolation purposes is a powerful concept of this library, letting users create complex declarative configurations. This section is normally called `"DEFAULT"` but this can be customized to point to any other valid section name. Some typical values include: `"general"` or `"common"`. The name provided is used for recognizing default sections when reading from any source and is used when writing configuration back to a file. Its current value can be retrieved using the `parser_instance.default_section` attribute and may be modified at runtime (i.e. to convert files from one format to another).

- *interpolation*, default value: `configparser.BasicInterpolation`

  Interpolation behaviour may be customized by providing a custom handler through the *interpolation* argument. `None` can

be used to turn off interpolation completely, `ExtendedInterpolation()` provides a more advanced variant inspired by `zc.buildout`. More on the subject in the dedicated documentation section. **`RawConfigParser`** has a default value of `None`.

- *converters*, default value: not set

  Config parsers provide option value getters that perform type conversion. By default **`getint()`**, **`getfloat()`**, and **`getboolean()`** are implemented. Should other getters be desirable, users may define them in a subclass or pass a dictionary where each key is a name of the converter and each value is a callable implementing said conversion. For instance, passing `{'decimal': decimal.Decimal}` would add **`getdecimal()`** on both the parser object and all section proxies. In other words, it will be possible to write both `parser_instance.getdecimal('section', 'key', fallback=0)` and `parser_instance['section'].getdecimal('key', 0)`.

  If the converter needs to access the state of the parser, it can be implemented as a method on a config parser subclass. If the name of this method starts with `get`, it will be available on all section proxies, in the dict-compatible form (see the `getdecimal()` example above).

More advanced customization may be achieved by overriding default values of these parser attributes. The defaults are defined on the classes, so they may be overridden by subclasses or by attribute assignment.

ConfigParser.BOOLEAN_STATES

By default when using **`getboolean()`**, config parsers consider the following values `True`: `'1'`, `'yes'`, `'true'`, `'on'` and the following values `False`: `'0'`, `'no'`, `'false'`, `'off'`. You can override this by specifying a custom dictionary of strings and their Boolean outcomes. For example:

```
>>> custom = configparser.ConfigParser()
>>> custom['section1'] = {'funky': 'nope'}
>>> custom['section1'].getboolean('funky')
Traceback (most recent call last):
...
ValueError: Not a boolean: nope
>>> custom.BOOLEAN_STATES = {'sure': True, 'nope':
>>> custom['section1'].getboolean('funky')
False
```

Other typical Boolean pairs include `accept/reject` or `enabled/disabled`.

ConfigParser.optionxform(*option*)

This method transforms option names on every read, get, or set operation. The default converts the name to lowercase. This also means that when a configuration file gets written, all keys will be lowercase. Override this method if that's unsuitable. For example:

```
>>> config = """
... [Section1]
... Key = Value
...
... [Section2]
... AnotherKey = Value
... """
>>> typical = configparser.ConfigParser()
>>> typical.read_string(config)
>>> list(typical['Section1'].keys())
['key']
>>> list(typical['Section2'].keys())
['anotherkey']
>>> custom = configparser.RawConfigParser()
>>> custom.optionxform = lambda option: option
>>> custom.read_string(config)
>>> list(custom['Section1'].keys())
['Key']
>>> list(custom['Section2'].keys())
```

```
['AnotherKey']
```

Note

The optionxform function transforms option names to a canonical form. This should be an idempotent function: if the name is already in canonical form, it should be returned unchanged.

ConfigParser.SECTCRE

A compiled regular expression used to parse section headers. The default matches `[section]` to the name `"section"`. Whitespace is considered part of the section name, thus `[ larch ]` will be read as a section of name `" larch "`. Override this attribute if that's unsuitable. For example:

```
>>> import re
>>> config = """
... [Section 1]
... option = value
...
... [  Section 2  ]
... another = val
... """
>>> typical = configparser.ConfigParser()
>>> typical.read_string(config)
>>> typical.sections()
['Section 1', '  Section 2  ']
>>> custom = configparser.ConfigParser()
>>> custom.SECTCRE = re.compile(r"\[ *(?P<header>[^
>>> custom.read_string(config)
>>> custom.sections()
['Section 1', 'Section 2']
```

Note

While ConfigParser objects also use an `OPTCRE` attribute for recognizing option lines, it's not recommended to

override it because that would interfere with constructor options *allow_no_value* and *delimiters*.

Legacy API Examples

Mainly because of backwards compatibility concerns, **`configparser`** provides also a legacy API with explicit `get/set` methods. While there are valid use cases for the methods outlined below, mapping protocol access is preferred for new projects. The legacy API is at times more advanced, low-level and downright counterintuitive.

An example of writing to a configuration file:

```
import configparser

config = configparser.RawConfigParser()

# Please note that using RawConfigParser's set functions
# non-string values to keys internally, but will receive
# attempting to write to a file or when you get it in no
# values using the mapping protocol or ConfigParser's se
# such assignments to take place.
config.add_section('Section1')
config.set('Section1', 'an_int', '15')
config.set('Section1', 'a_bool', 'true')
config.set('Section1', 'a_float', '3.1415')
config.set('Section1', 'baz', 'fun')
config.set('Section1', 'bar', 'Python')
config.set('Section1', 'foo', '%(bar)s is %(baz)s!')

# Writing our configuration file to 'example.cfg'
with open('example.cfg', 'w') as configfile:
    config.write(configfile)
```

An example of reading the configuration file again:

```
import configparser
```

```
config = configparser.RawConfigParser()
config.read('example.cfg')

# getfloat() raises an exception if the value is not a f
# getint() and getboolean() also do this for their respe
a_float = config.getfloat('Section1', 'a_float')
an_int = config.getint('Section1', 'an_int')
print(a_float + an_int)

# Notice that the next output does not interpolate '%(ba
# This is because we are using a RawConfigParser().
if config.getboolean('Section1', 'a_bool'):
    print(config.get('Section1', 'foo'))
```

To get interpolation, use **ConfigParser**:

```
import configparser

cfg = configparser.ConfigParser()
cfg.read('example.cfg')

# Set the optional *raw* argument of get() to True if yo
# interpolation in a single get operation.
print(cfg.get('Section1', 'foo', raw=False))  # -> "Pyth
print(cfg.get('Section1', 'foo', raw=True))   # -> "%(ba

# The optional *vars* argument is a dict with members th
# precedence in interpolation.
print(cfg.get('Section1', 'foo', vars={'bar': 'Documenta
                                       'baz': 'evil'}))

# The optional *fallback* argument can be used to provid
print(cfg.get('Section1', 'foo'))
      # -> "Python is fun!"

print(cfg.get('Section1', 'foo', fallback='Monty is not.
      # -> "Python is fun!"
```

```
print(cfg.get('Section1', 'monster', fallback='No such t
      # -> "No such things as monsters."

# A bare print(cfg.get('Section1', 'monster')) would rai
# but we can also use:

print(cfg.get('Section1', 'monster', fallback=None))
      # -> None
```

Default values are available in both types of ConfigParsers. They are used in interpolation if an option used is not defined elsewhere.

```
import configparser

# New instance with 'bar' and 'baz' defaulting to 'Life'
config = configparser.ConfigParser({'bar': 'Life', 'baz'
config.read('example.cfg')

print(config.get('Section1', 'foo'))     # -> "Python is
config.remove_option('Section1', 'bar')
config.remove_option('Section1', 'baz')
print(config.get('Section1', 'foo'))     # -> "Life is h
```

ConfigParser Objects

class configparser.ConfigParser(*defaults=None*, *dict_type=dict*, *allow_no_value=False*, *delimiters=('=', ':')*, *comment_prefixes=('#', ';')*, *inline_comment_prefixes=None*, *strict=True*, *empty_lines_in_values=True*, *default_section=configparser.DEFAULTSECT*, *interpolation=BasicInterpolation()*, *converters={}*)

The main configuration parser. When *defaults* is given, it is initialized into the dictionary of intrinsic defaults. When *dict_type* is given, it will be used to create the dictionary objects for the list of sections, for the options within a section, and for the default values.

When *delimiters* is given, it is used as the set of substrings that divide keys from values. When *comment_prefixes* is given, it

will be used as the set of substrings that prefix comments in otherwise empty lines. Comments can be indented. When *inline_comment_prefixes* is given, it will be used as the set of substrings that prefix comments in non-empty lines.

When *strict* is `True` (the default), the parser won't allow for any section or option duplicates while reading from a single source (file, string or dictionary), raising **`DuplicateSectionError`** or **`DuplicateOptionError`**. When *empty_lines_in_values* is `False` (default: `True`), each empty line marks the end of an option. Otherwise, internal empty lines of a multiline option are kept as part of the value. When *allow_no_value* is `True` (default: `False`), options without values are accepted; the value held for these is `None` and they are serialized without the trailing delimiter.

When *default_section* is given, it specifies the name for the special section holding default values for other sections and interpolation purposes (normally named `"DEFAULT"`). This value can be retrieved and changed on runtime using the `default_section` instance attribute.

Interpolation behaviour may be customized by providing a custom handler through the *interpolation* argument. `None` can be used to turn off interpolation completely, `ExtendedInterpolation()` provides a more advanced variant inspired by `zc.buildout`. More on the subject in the dedicated documentation section.

All option names used in interpolation will be passed through the **`optionxform()`** method just like any other option name reference. For example, using the default implementation of **`optionxform()`** (which converts option names to lower case), the values `foo %(bar)s` and `foo %(BAR)s` are equivalent.

When *converters* is given, it should be a dictionary where each key represents the name of a type converter and each value is a callable implementing the conversion from string to the desired datatype. Every converter gets its own corresponding **`get*()`** method on the parser object and section proxies.

Changed in version 3.1: The default *dict_type* is `collections.OrderedDict`.

Changed in version 3.2: *allow_no_value*, *delimiters*, *comment_prefixes*, *strict*, *empty_lines_in_values*, *default_section* and *interpolation* were added.

Changed in version 3.5: The *converters* argument was added.

Changed in version 3.7: The *defaults* argument is read with `read_dict()`, providing consistent behavior across the parser: non-string keys and values are implicitly converted to strings.

Changed in version 3.8: The default *dict_type* is `dict`, since it now preserves insertion order.

defaults()

Return a dictionary containing the instance-wide defaults.

sections()

Return a list of the sections available; the *default section* is not included in the list.

add_section(*section*)

Add a section named *section* to the instance. If a section by the given name already exists, `DuplicateSectionError` is raised. If the *default section* name is passed, `ValueError` is raised. The name of the section must be a string; if not, `TypeError` is raised.

Changed in version 3.2: Non-string section names raise `TypeError`.

has_section(*section*)

Indicates whether the named *section* is present in the configuration. The *default section* is not acknowledged.

options(*section*)

Return a list of options available in the specified *section*.

has_option(*section*, *option*)

If the given *section* exists, and contains the given *option*, return **True**; otherwise return **False**. If the specified *section* is **None** or an empty string, DEFAULT is assumed.

read(*filenames*, *encoding*=*None*)

Attempt to read and parse an iterable of filenames, returning a list of filenames which were successfully parsed.

If *filenames* is a string, a **bytes** object or a path-like object, it is treated as a single filename. If a file named in *filenames* cannot be opened, that file will be ignored. This is designed so that you can specify an iterable of potential configuration file locations (for example, the current directory, the user's home directory, and some system-wide directory), and all existing configuration files in the iterable will be read.

If none of the named files exist, the **ConfigParser** instance will contain an empty dataset. An application which requires initial values to be loaded from a file should load the required file or files using **read_file()** before calling **read()** for any optional files:

```
import configparser, os

config = configparser.ConfigParser()
config.read_file(open('defaults.cfg'))
config.read(['site.cfg', os.path.expanduser('~/
            encoding='cp1250')
```

New in version 3.2: The *encoding* parameter. Previously, all files were read using the default encoding for

open().

New in version 3.6.1: The *filenames* parameter accepts a path-like object.

New in version 3.7: The *filenames* parameter accepts a **bytes** object.

read_file(*f*, *source*=*None*)

Read and parse configuration data from *f* which must be an iterable yielding Unicode strings (for example files opened in text mode).

Optional argument *source* specifies the name of the file being read. If not given and *f* has a **name** attribute, that is used for *source*; the default is `'<???>'`.

New in version 3.2: Replaces **readfp()**.

read_string(*string*, *source*='<*string*>')

Parse configuration data from a string.

Optional argument *source* specifies a context-specific name of the string passed. If not given, `'<string>'` is used. This should commonly be a filesystem path or a URL.

New in version 3.2.

read_dict(*dictionary*, *source*='<*dict*>')

Load configuration from any object that provides a dict-like `items()` method. Keys are section names, values are dictionaries with keys and values that should be present in the section. If the used dictionary type preserves order, sections and their keys will be added in order. Values are automatically converted to strings.

Optional argument *source* specifies a context-specific name of the dictionary passed. If not given, `<dict>` is

used.

This method can be used to copy state between parsers.

New in version 3.2.

get(*section*, *option*, *, *raw*=*False*, *vars*=*None*[, *fallback*])

Get an *option* value for the named *section*. If *vars* is provided, it must be a dictionary. The *option* is looked up in *vars* (if provided), *section*, and in *DEFAULTSECT* in that order. If the key is not found and *fallback* is provided, it is used as a fallback value. `None` can be provided as a *fallback* value.

All the `'%'` interpolations are expanded in the return values, unless the *raw* argument is true. Values for interpolation keys are looked up in the same manner as the option.

Changed in version 3.2: Arguments *raw*, *vars* and *fallback* are keyword only to protect users from trying to use the third argument as the *fallback* fallback (especially when using the mapping protocol).

getint(*section*, *option*, *, *raw*=*False*, *vars*=*None*[, *fallback*])

A convenience method which coerces the *option* in the specified *section* to an integer. See **`get()`** for explanation of *raw*, *vars* and *fallback*.

getfloat(*section*, *option*, *, *raw*=*False*, *vars*=*None*[, *fallback*])

A convenience method which coerces the *option* in the specified *section* to a floating point number. See **`get()`** for explanation of *raw*, *vars* and *fallback*.

getboolean(*section*, *option*, *, *raw*=*False*, *vars*=*None*[, *fallback*])

A convenience method which coerces the *option* in the specified *section* to a Boolean value. Note that the

accepted values for the option are `'1'`, `'yes'`, `'true'`, and `'on'`, which cause this method to return `True`, and `'0'`, `'no'`, `'false'`, and `'off'`, which cause it to return `False`. These string values are checked in a case-insensitive manner. Any other value will cause it to raise **`ValueError`**. See **`get()`** for explanation of *raw*, *vars* and *fallback*.

items(*raw=False*, *vars=None*)
items(*section*, *raw=False*, *vars=None*)

When *section* is not given, return a list of *section_name*, *section_proxy* pairs, including DEFAULTSECT.

Otherwise, return a list of *name*, *value* pairs for the options in the given *section*. Optional arguments have the same meaning as for the **`get()`** method.

Changed in version 3.8: Items present in *vars* no longer appear in the result. The previous behaviour mixed actual parser options with variables provided for interpolation.

set(*section*, *option*, *value*)

If the given section exists, set the given option to the specified value; otherwise raise **`NoSectionError`**. *option* and *value* must be strings; if not, **`TypeError`** is raised.

write(*fileobject*, *space_around_delimiters=True*)

Write a representation of the configuration to the specified file object, which must be opened in text mode (accepting strings). This representation can be parsed by a future **`read()`** call. If *space_around_delimiters* is true, delimiters between keys and values are surrounded by spaces.

Note

Comments in the original configuration file are not preserved when writing the configuration back. What is considered a comment, depends on the given values for *comment_prefix* and *inline_comment_prefix*.

remove_option(*section*, *option*)

Remove the specified *option* from the specified *section*. If the section does not exist, raise **NoSectionError**. If the option existed to be removed, return **True**; otherwise return **False**.

remove_section(*section*)

Remove the specified *section* from the configuration. If the section in fact existed, return `True`. Otherwise return `False`.

optionxform(*option*)

Transforms the option name *option* as found in an input file or as passed in by client code to the form that should be used in the internal structures. The default implementation returns a lower-case version of *option*; subclasses may override this or client code can set an attribute of this name on instances to affect this behavior.

You don't need to subclass the parser to use this method, you can also set it on an instance, to a function that takes a string argument and returns a string. Setting it to `str`, for example, would make option names case sensitive:

```
cfgparser = ConfigParser()
cfgparser.optionxform = str
```

Note that when reading configuration files, whitespace around the option names is stripped before **optionxform()** is called.

readfp(*fp*, *filename=None*)

Deprecated since version 3.2: Use **read_file()** instead.

Changed in version 3.2: **readfp()** now iterates on *fp* instead of calling `fp.readline()`.

For existing code calling **readfp()** with arguments which don't support iteration, the following generator may be used as a wrapper around the file-like object:

```
def readline_generator(fp):
    line = fp.readline()
    while line:
        yield line
        line = fp.readline()
```

Instead of `parser.readfp(fp)` use `parser.read_file(readline_generator(fp))`.

configparser.MAX_INTERPOLATION_DEPTH

The maximum depth for recursive interpolation for **get()** when the *raw* parameter is false. This is relevant only when the default *interpolation* is used.

RawConfigParser Objects

class configparser.RawConfigParser(*defaults=None*, *dict_type=dict*, *allow_no_value=False*, ***, *delimiters=('=', ':')*, *comment_prefixes=('#', ';')*, *inline_comment_prefixes=None*, *strict=True*, *empty_lines_in_values=True*, *default_section=configparser.DEFAULTSECT*[, *interpolation*])

Legacy variant of the **ConfigParser**. It has interpolation disabled by default and allows for non-string section names, option names, and values via its unsafe `add_section` and `set` methods, as well as the legacy `defaults=` keyword argument handling.

Changed in version 3.8: The default *dict_type* is `dict`, since it now preserves insertion order.

Note

Consider using `ConfigParser` instead which checks types of the values to be stored internally. If you don't want interpolation, you can use `ConfigParser(interpolation=None)`.

add_section(*section*)

Add a section named *section* to the instance. If a section by the given name already exists, `DuplicateSectionError` is raised. If the *default section* name is passed, `ValueError` is raised.

Type of *section* is not checked which lets users create non-string named sections. This behaviour is unsupported and may cause internal errors.

set(*section*, *option*, *value*)

If the given section exists, set the given option to the specified value; otherwise raise `NoSectionError`. While it is possible to use `RawConfigParser` (or `ConfigParser` with *raw* parameters set to true) for *internal* storage of non-string values, full functionality (including interpolation and output to files) can only be achieved using string values.

This method lets users assign non-string values to keys internally. This behaviour is unsupported and will cause errors when attempting to write to a file or get it in non-raw mode. **Use the mapping protocol API** which does not allow such assignments to take place.

Exceptions

exception configparser.Error

Base class for all other **configparser** exceptions.

exception configparser.NoSectionError

Exception raised when a specified section is not found.

exception configparser.DuplicateSectionError

Exception raised if **add_section()** is called with the name of a section that is already present or in strict parsers when a section if found more than once in a single input file, string or dictionary.

New in version 3.2: Optional `source` and `lineno` attributes and arguments to **__init__()** were added.

exception configparser.DuplicateOptionError

Exception raised by strict parsers if a single option appears twice during reading from a single file, string or dictionary. This catches misspellings and case sensitivity-related errors, e.g. a dictionary may have two keys representing the same case-insensitive configuration key.

exception configparser.NoOptionError

Exception raised when a specified option is not found in the specified section.

exception configparser.InterpolationError

Base class for exceptions raised when problems occur performing string interpolation.

exception configparser.InterpolationDepthError

Exception raised when string interpolation cannot be completed because the number of iterations exceeds **MAX_INTERPOLATION_DEPTH**. Subclass of **InterpolationError**.

exception configparser.InterpolationMissingOptionError

Exception raised when an option referenced from a value does not exist. Subclass of **InterpolationError**.

exception configparser.InterpolationSyntaxError

Exception raised when the source text into which substitutions are made does not conform to the required syntax. Subclass of **`InterpolationError`**.

exception configparser.MissingSectionHeaderError

Exception raised when attempting to parse a file which has no section headers.

exception configparser.ParsingError

Exception raised when errors occur attempting to parse a file.

Changed in version 3.2: The `filename` attribute and **`__init__()`** argument were renamed to `source` for consistency.

Footnotes

1(*1*,*2*,*3*,*4*,*5*,*6*,*7*,*8*,*9*,*10*,*11*)

Config parsers allow for heavy customization. If you are interested in changing the behaviour outlined by the footnote reference, consult the Customizing Parser Behaviour section.

`tomllib` — Parse TOML files

New in version 3.11.

Source code: Lib/tomllib [https://github.com/python/cpython/tree/3.11/Lib/tomllib]

This module provides an interface for parsing TOML (Tom's Obvious Minimal Language, https://toml.io [https://toml.io/en/]). This module does not support writing TOML.

See also

The Tomli-W package [https://pypi.org/project/tomli-w/] is a TOML writer that can be used in conjunction with this module, providing a write API familiar to users of the standard library `marshal` and `pickle` modules.

See also

The TOML Kit package [https://pypi.org/project/tomlkit/] is a style-preserving TOML library with both read and write capability. It is a recommended replacement for this module for editing already existing TOML files.

This module defines the following functions:

tomllib.load(*fp*, */*, ***, *parse_float=float*)

Read a TOML file. The first argument should be a readable and binary file object. Return a `dict`. Convert TOML types to Python using this conversion table.

parse_float will be called with the string of every TOML float to be decoded. By default, this is equivalent to

`float(num_str)`. This can be used to use another datatype or parser for TOML floats (e.g. **`decimal.Decimal`**). The callable must not return a **`dict`** or a **`list`**, else a **`ValueError`** is raised.

A **`TOMLDecodeError`** will be raised on an invalid TOML document.

tomllib.loads(*s*, /, *, *parse_float*=*float*)

Load TOML from a **`str`** object. Return a **`dict`**. Convert TOML types to Python using this conversion table. The *parse_float* argument has the same meaning as in **`load()`**.

A **`TOMLDecodeError`** will be raised on an invalid TOML document.

The following exceptions are available:

exception tomllib.TOMLDecodeError

Subclass of **`ValueError`**.

Examples

Parsing a TOML file:

```
import tomllib

with open("pyproject.toml", "rb") as f:
    data = tomllib.load(f)
```

Parsing a TOML string:

```
import tomllib

toml_str = """
python-version = "3.11.0"
python-implementation = "CPython"
"""
```

```
data = tomllib.loads(toml_str)
```

Conversion Table

TOML	Python
table	dict
string	str
integer	int
float	float (configurable with *parse_float*)
boolean	bool
offset datetime	datetime (`tzinfo` attribute set to an instance of `datetime.timezone`)
local datetime	datetime (`tzinfo` attribute set to `None`)
local date	date
local time	time
array	list

`netrc` — netrc file processing

Source code: Lib/netrc.py [https://github.com/python/cpython/tree/3.11/Lib/netrc.py]

The `netrc` class parses and encapsulates the netrc file format used by the Unix **ftp** program and other FTP clients.

class netrc.netrc([*file*])

A `netrc` instance or subclass instance encapsulates data from a netrc file. The initialization argument, if present, specifies the file to parse. If no argument is given, the file `.netrc` in the user's home directory – as determined by `os.path.expanduser()` – will be read. Otherwise, a `FileNotFoundError` exception will be raised. Parse errors will raise `NetrcParseError` with diagnostic information including the file name, line number, and terminating token. If no argument is specified on a POSIX system, the presence of passwords in the `.netrc` file will raise a `NetrcParseError` if the file ownership or permissions are insecure (owned by a user other than the user running the process, or accessible for read or write by any other user). This implements security behavior equivalent to that of ftp and other programs that use `.netrc`.

Changed in version 3.4: Added the POSIX permission check.

Changed in version 3.7: `os.path.expanduser()` is used to find the location of the `.netrc` file when *file* is not passed as argument.

Changed in version 3.10: `netrc` try UTF-8 encoding before using locale specific encoding. The entry in the netrc file no longer needs to contain all tokens. The missing tokens' value default to an empty string. All the tokens and their values

now can contain arbitrary characters, like whitespace and non-ASCII characters. If the login name is anonymous, it won't trigger the security check.

exception netrc.NetrcParseError

Exception raised by the **netrc** class when syntactical errors are encountered in source text. Instances of this exception provide three interesting attributes: **msg** is a textual explanation of the error, **filename** is the name of the source file, and **lineno** gives the line number on which the error was found.

netrc Objects

A **netrc** instance has the following methods:

netrc.authenticators(*host*)

Return a 3-tuple `(login, account, password)` of authenticators for *host*. If the netrc file did not contain an entry for the given host, return the tuple associated with the 'default' entry. If neither matching host nor default entry is available, return `None`.

netrc._repr_()

Dump the class data as a string in the format of a netrc file. (This discards comments and may reorder the entries.)

Instances of **netrc** have public instance variables:

netrc.hosts

Dictionary mapping host names to `(login, account, password)` tuples. The 'default' entry, if any, is represented as a pseudo-host by that name.

netrc.macros

Dictionary mapping macro names to string lists.

`plistlib` — Generate and parse Apple `.plist` files

Source code: Lib/plistlib.py [https://github.com/python/cpython/tree/3.11/Lib/plistlib.py]

This module provides an interface for reading and writing the "property list" files used by Apple, primarily on macOS and iOS. This module supports both binary and XML plist files.

The property list (`.plist`) file format is a simple serialization supporting basic object types, like dictionaries, lists, numbers and strings. Usually the top level object is a dictionary.

To write out and to parse a plist file, use the `dump()` and `load()` functions.

To work with plist data in bytes objects, use `dumps()` and `loads()`.

Values can be strings, integers, floats, booleans, tuples, lists, dictionaries (but only with string keys), `bytes`, `bytearray` or `datetime.datetime` objects.

Changed in version 3.4: New API, old API deprecated. Support for binary format plists added.

Changed in version 3.8: Support added for reading and writing `UID` tokens in binary plists as used by NSKeyedArchiver and NSKeyedUnarchiver.

Changed in version 3.9: Old API removed.

See also

PList manual page **[https://developer.apple.com/library/content/documentation/Cocoa/Conceptual/PropertyLists/]**
Apple's documentation of the file format.

This module defines the following functions:

plistlib.load(*fp*, *, *fmt=None*, *dict_type=dict*)

Read a plist file. *fp* should be a readable and binary file object. Return the unpacked root object (which usually is a dictionary).

The *fmt* is the format of the file and the following values are valid:

- **`None`**: Autodetect the file format
- **`FMT_XML`**: XML file format
- **`FMT_BINARY`**: Binary plist format

The *dict_type* is the type used for dictionaries that are read from the plist file.

XML data for the **`FMT_XML`** format is parsed using the Expat parser from **`xml.parsers.expat`** – see its documentation for possible exceptions on ill-formed XML. Unknown elements will simply be ignored by the plist parser.

The parser for the binary format raises **`InvalidFileException`** when the file cannot be parsed.

New in version 3.4.

plistlib.loads(*data*, *, *fmt=None*, *dict_type=dict*)

Load a plist from a bytes object. See **`load()`** for an explanation of the keyword arguments.

New in version 3.4.

plistlib.dump(*value*, *fp*, *, *fmt=FMT_XML*, *sort_keys=True*, *skipkeys=False*)

Write *value* to a plist file. *Fp* should be a writable, binary file object.

The *fmt* argument specifies the format of the plist file and can be one of the following values:

- **`FMT_XML`**: XML formatted plist file
- **`FMT_BINARY`**: Binary formatted plist file

When *sort_keys* is true (the default) the keys for dictionaries will be written to the plist in sorted order, otherwise they will be written in the iteration order of the dictionary.

When *skipkeys* is false (the default) the function raises **`TypeError`** when a key of a dictionary is not a string, otherwise such keys are skipped.

A **`TypeError`** will be raised if the object is of an unsupported type or a container that contains objects of unsupported types.

An **`OverflowError`** will be raised for integer values that cannot be represented in (binary) plist files.

New in version 3.4.

plistlib.dumps(*value*, *, *fmt=FMT_XML*, *sort_keys=True*, *skipkeys=False*)

Return *value* as a plist-formatted bytes object. See the documentation for **`dump()`** for an explanation of the keyword arguments of this function.

New in version 3.4.

The following classes are available:

class plistlib.UID(*data*)

Wraps an **`int`**. This is used when reading or writing NSKeyedArchiver encoded data, which contains UID (see PList manual).

It has one attribute, **data**, which can be used to retrieve the int value of the UID. **data** must be in the range `0 <= data < 2**64`.

New in version 3.8.

The following constants are available:

plistlib.FMT_XML
: The XML format for plist files.

  New in version 3.4.

plistlib.FMT_BINARY
: The binary format for plist files

  New in version 3.4.

Examples

Generating a plist:

```
pl = dict(
    aString = "Doodah",
    aList = ["A", "B", 12, 32.1, [1, 2, 3]],
    aFloat = 0.1,
    anInt = 728,
    aDict = dict(
        anotherString = "<hello & hi there!>",
        aThirdString = "M\xe4ssig, Ma\xdf",
        aTrueValue = True,
        aFalseValue = False,
    ),
    someData = b"<binary gunk>",
    someMoreData = b"<lots of binary gunk>" * 10,
    aDate = datetime.datetime.fromtimestamp(time.mktime(
)
with open(fileName, 'wb') as fp:
    dump(pl, fp)
```

Parsing a plist:

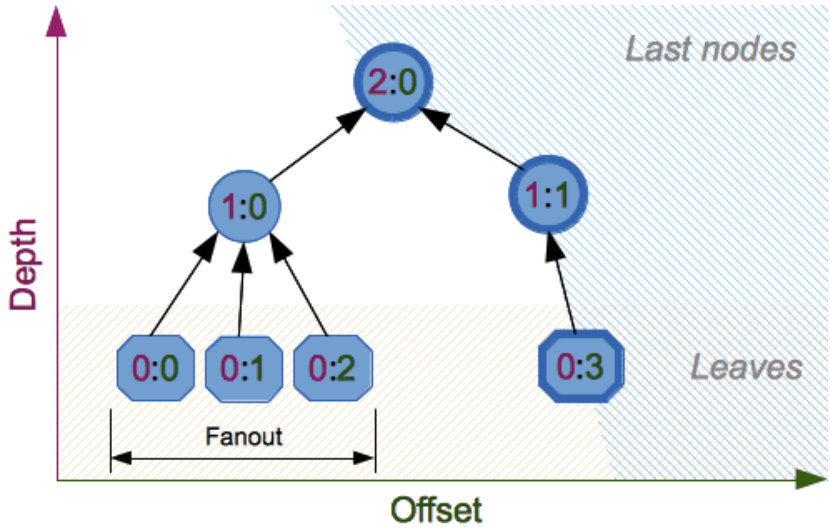
```
with open(fileName, 'rb') as fp:
    pl = load(fp)
print(pl["aKey"])
```

Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. On Unix systems, the **crypt** module may also be available. Here's an overview:

- **hashlib** — Secure hashes and message digests
  - Hash algorithms
  - SHAKE variable length digests
  - File hashing
  - Key derivation
  - BLAKE2
    - Creating hash objects
    - Constants
    - Examples
      - Simple hashing
      - Using different digest sizes
      - Keyed hashing
      - Randomized hashing
      - Personalization
      - Tree mode
    - Credits
- **hmac** — Keyed-Hashing for Message Authentication
- **secrets** — Generate secure random numbers for managing secrets
  - Random numbers
  - Generating tokens
    - How many bytes should tokens use?

○ Other functions
○ Recipes and best practices



`hashlib` — Secure hashes and message digests

Source code: Lib/hashlib.py [https://github.com/python/cpython/tree/3.11/Lib/hashlib.py]

This module implements a common interface to many different secure hash and message digest algorithms. Included are the FIPS secure hash algorithms SHA1, SHA224, SHA256, SHA384, and SHA512 (defined in FIPS 180-2) as well as RSA's MD5 algorithm (defined in internet **RFC 1321** [https://datatracker.ietf.org/doc/html/rfc1321.html]). The terms "secure hash" and "message digest" are interchangeable. Older algorithms were called message digests. The modern term is secure hash.

Note

If you want the adler32 or crc32 hash functions, they are available in the `zlib` module.

Warning

Some algorithms have known hash collision weaknesses, refer to the “See also” section at the end.

Hash algorithms

There is one constructor method named for each type of *hash*. All return a hash object with the same simple interface. For example: use **`sha256()`** to create a SHA-256 hash object. You can now feed this object with bytes-like objects (normally **`bytes`**) using the **`update()`** method. At any point you can ask it for the *digest* of the concatenation of the data fed to it so far using the **`digest()`** or **`hexdigest()`** methods.

Note

For better multithreading performance, the Python GIL is released for data larger than 2047 bytes at object creation or on update.

Note

Feeding string objects into **`update()`** is not supported, as hashes work on bytes, not on characters.

Constructors for hash algorithms that are always present in this module are **`sha1()`**, **`sha224()`**, **`sha256()`**, **`sha384()`**, **`sha512()`**, **`blake2b()`**, and **`blake2s()`**. **`md5()`** is normally available as well, though it may be missing or blocked if you are using a rare “FIPS compliant” build of Python. Additional algorithms may also be available depending upon the OpenSSL library that Python uses on your platform. On most platforms the **`sha3_224()`**, **`sha3_256()`**, **`sha3_384()`**, **`sha3_512()`**, **`shake_128()`**, **`shake_256()`** are also available.

New in version 3.6: SHA3 (Keccak) and SHAKE constructors **`sha3_224()`**, **`sha3_256()`**, **`sha3_384()`**, **`sha3_512()`**,

shake_128(), **shake_256()**.

New in version 3.6: **blake2b()** and **blake2s()** were added.

Changed in version 3.9: All hashlib constructors take a keyword-only argument *usedforsecurity* with default value `True`. A false value allows the use of insecure and blocked hashing algorithms in restricted environments. `False` indicates that the hashing algorithm is not used in a security context, e.g. as a non-cryptographic one-way compression function.

Hashlib now uses SHA3 and SHAKE from OpenSSL 1.1.1 and newer.

For example, to obtain the digest of the byte string `b"Nobody inspects the spammish repetition"`:

```
>>> import hashlib
>>> m = hashlib.sha256()
>>> m.update(b"Nobody inspects")
>>> m.update(b" the spammish repetition")
>>> m.digest()
b'\x03\x1e\xdd}Ae\x15\x93\xc5\xfe\\\x00o\xa5u+7\xfd\xdf\
>>> m.hexdigest()
'031edd7d41651593c5fe5c006fa5752b37fddff7bc4e843aa6af0c9
```

More condensed:

```
>>> hashlib.sha256(b"Nobody inspects the spammish repeti
'031edd7d41651593c5fe5c006fa5752b37fddff7bc4e843aa6af0c9
```

hashlib.new(*name*, [*data*,]*, *usedforsecurity*=*True*)

Is a generic constructor that takes the string *name* of the desired algorithm as its first parameter. It also exists to allow access to the above listed hashes as well as any other algorithms that your OpenSSL library may offer. The named constructors are much faster than **new()** and should be preferred.

Using **new()** with an algorithm provided by OpenSSL:

```
>>> h = hashlib.new('sha256')
>>> h.update(b"Nobody inspects the spammish repetition")
>>> h.hexdigest()
'031edd7d41651593c5fe5c006fa5752b37fddff7bc4e843aa6af0c9
```

Hashlib provides the following constant attributes:

hashlib.algorithms_guaranteed

A set containing the names of the hash algorithms guaranteed to be supported by this module on all platforms. Note that 'md5' is in this list despite some upstream vendors offering an odd "FIPS compliant" Python build that excludes it.

New in version 3.2.

hashlib.algorithms_available

A set containing the names of the hash algorithms that are available in the running Python interpreter. These names will be recognized when passed to **new()**. **algorithms_guaranteed** will always be a subset. The same algorithm may appear multiple times in this set under different names (thanks to OpenSSL).

New in version 3.2.

The following values are provided as constant attributes of the hash objects returned by the constructors:

hash.digest_size

The size of the resulting hash in bytes.

hash.block_size

The internal block size of the hash algorithm in bytes.

A hash object has the following attributes:

hash.name

The canonical name of this hash, always lowercase and always suitable as a parameter to **new()** to create another

hash of this type.

Changed in version 3.4: The name attribute has been present in CPython since its inception, but until Python 3.4 was not formally specified, so may not exist on some platforms.

A hash object has the following methods:

hash.update(*data*)

Update the hash object with the bytes-like object. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to `m.update(a+b)`.

Changed in version 3.1: The Python GIL is released to allow other threads to run while hash updates on data larger than 2047 bytes is taking place when using hash algorithms supplied by OpenSSL.

hash.digest()

Return the digest of the data passed to the **`update()`** method so far. This is a bytes object of size **`digest_size`** which may contain bytes in the whole range from 0 to 255.

hash.hexdigest()

Like **`digest()`** except the digest is returned as a string object of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

hash.copy()

Return a copy ("clone") of the hash object. This can be used to efficiently compute the digests of data sharing a common initial substring.

SHAKE variable length digests

The **`shake_128()`** and **`shake_256()`** algorithms provide

variable length digests with length_in_bits//2 up to 128 or 256 bits of security. As such, their digest methods require a length. Maximum length is not limited by the SHAKE algorithm.

shake.digest(*length*)

> Return the digest of the data passed to the **`update()`** method so far. This is a bytes object of size *length* which may contain bytes in the whole range from 0 to 255.

shake.hexdigest(*length*)

> Like **`digest()`** except the digest is returned as a string object of double length, containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

File hashing

The hashlib module provides a helper function for efficient hashing of a file or file-like object.

hashlib.file_digest(*fileobj*, *digest*, */*)

> Return a digest object that has been updated with contents of file object.
>
> *fileobj* must be a file-like object opened for reading in binary mode. It accepts file objects from builtin **`open()`**, **`BytesIO`** instances, SocketIO objects from **`socket.socket.makefile()`**, and similar. The function may bypass Python's I/O and use the file descriptor from **`fileno()`** directly. *fileobj* must be assumed to be in an unknown state after this function returns or raises. It is up to the caller to close *fileobj*.
>
> *digest* must either be a hash algorithm name as a *str*, a hash constructor, or a callable that returns a hash object.
>
> Example:
>
> ```
> >>> import io, hashlib, hmac
> ```

```
>>> with open(hashlib.__file__, "rb") as f:
...     digest = hashlib.file_digest(f, "sha256")
...
>>> digest.hexdigest()
'...'

>>> buf = io.BytesIO(b"somedata")
>>> mac1 = hmac.HMAC(b"key", digestmod=hashlib.sha5
>>> digest = hashlib.file_digest(buf, lambda: mac1)

>>> digest is mac1
True
>>> mac2 = hmac.HMAC(b"key", b"somedata", digestmod
>>> mac1.digest() == mac2.digest()
True
```

New in version 3.11.

Key derivation

Key derivation and key stretching algorithms are designed for secure password hashing. Naive algorithms such as `sha1(password)` are not resistant against brute-force attacks. A good password hashing function must be tunable, slow, and include a salt [https://en.wikipedia.org/wiki/Salt_%28cryptography%29].

hashlib.pbkdf2_hmac(*hash_name*, *password*, *salt*, *iterations*, *dklen=None*)

The function provides PKCS#5 password-based key derivation function 2. It uses HMAC as pseudorandom function.

The string *hash_name* is the desired name of the hash digest algorithm for HMAC, e.g. 'sha1' or 'sha256'. *password* and *salt* are interpreted as buffers of bytes. Applications and libraries should limit *password* to a sensible length (e.g. 1024). *salt* should be about 16 or more bytes from a proper source, e.g. **`os.urandom()`**.

The number of *iterations* should be chosen based on the hash

algorithm and computing power. As of 2022, hundreds of thousands of iterations of SHA-256 are suggested. For rationale as to why and how to choose what is best for your application, read *Appendix A.2.2* of NIST-SP-800-132 [https://nvlpubs.nist.gov/nistpubs/Legacy/SP/nistspecialpublication800-132.pdf]. The answers on the stackexchange pbkdf2 iterations question [https://security.stackexchange.com/questions/3959/recommended-of-iterations-when-using-pbkdf2-sha256/] explain in detail.

dklen is the length of the derived key. If *dklen* is `None` then the digest size of the hash algorithm *hash_name* is used, e.g. 64 for SHA-512.

```
>>> from hashlib import pbkdf2_hmac
>>> our_app_iters = 500_000  # Application specific
>>> dk = pbkdf2_hmac('sha256', b'password', b'bad s
>>> dk.hex()
'15530bba69924174860db778f2c6f8104d3aaf9d26241840c8
```

New in version 3.4.

Note

A fast implementation of *pbkdf2_hmac* is available with OpenSSL. The Python implementation uses an inline version of `hmac`. It is about three times slower and doesn't release the GIL.

Deprecated since version 3.10: Slow Python implementation of *pbkdf2_hmac* is deprecated. In the future the function will only be available when Python is compiled with OpenSSL.

hashlib.scrypt(*password*, ***, *salt*, *n*, *r*, *p*, *maxmem=0*, *dklen=64*)

The function provides scrypt password-based key derivation function as defined in **RFC 7914** [https://datatracker.ietf.org/doc/html/rfc7914.html].

password and *salt* must be bytes-like objects. Applications and libraries should limit *password* to a sensible length (e.g. 1024). *salt* should be about 16 or more bytes from a proper

source, e.g. `os.urandom()`.

n is the CPU/Memory cost factor, *r* the block size, *p* parallelization factor and *maxmem* limits memory (OpenSSL 1.1.0 defaults to 32 MiB). *dklen* is the length of the derived key.

New in version 3.6.

BLAKE2

BLAKE2 [https://blake2.net] is a cryptographic hash function defined in **RFC 7693** [https://datatracker.ietf.org/doc/html/rfc7693.html] that comes in two flavors:

- **BLAKE2b**, optimized for 64-bit platforms and produces digests of any size between 1 and 64 bytes,
- **BLAKE2s**, optimized for 8- to 32-bit platforms and produces digests of any size between 1 and 32 bytes.

BLAKE2 supports **keyed mode** (a faster and simpler replacement for HMAC [https://en.wikipedia.org/wiki/Hash-based_message_authentication_code]), **salted hashing**, **personalization**, and **tree hashing**.

Hash objects from this module follow the API of standard library's `hashlib` objects.

Creating hash objects

New hash objects are created by calling constructor functions:

hashlib.blake2b(*data=b''*, ***, *digest_size=64*, *key=b''*, *salt=b''*, *person=b''*, *fanout=1*, *depth=1*, *leaf_size=0*, *node_offset=0*, *node_depth=0*, *inner_size=0*, *last_node=False*, *usedforsecurity=True*)

hashlib.blake2s(*data=b''*, ***, *digest_size=32*, *key=b''*, *salt=b''*, *person=b''*, *fanout=1*, *depth=1*, *leaf_size=0*, *node_offset=0*, *node_depth=0*, *inner_size=0*, *last_node=False*, *usedforsecurity=True*)

These functions return the corresponding hash objects for calculating BLAKE2b or BLAKE2s. They optionally take these general parameters:

- *data*: initial chunk of data to hash, which must be bytes-like object. It can be passed only as positional argument.
- *digest_size*: size of output digest in bytes.
- *key*: key for keyed hashing (up to 64 bytes for BLAKE2b, up to 32 bytes for BLAKE2s).
- *salt*: salt for randomized hashing (up to 16 bytes for BLAKE2b, up to 8 bytes for BLAKE2s).
- *person*: personalization string (up to 16 bytes for BLAKE2b, up to 8 bytes for BLAKE2s).

The following table shows limits for general parameters (in bytes):

BLAKE2b				
BLAKE2s				

Note

BLAKE2 specification defines constant lengths for salt and personalization parameters, however, for convenience, this implementation accepts byte strings of any size up to the specified length. If the length of the parameter is less than specified, it is padded with zeros, thus, for example, `b'salt'` and `b'salt\x00'` is the same value. (This is not the case for *key*.)

These sizes are available as module constants described below.

Constructor functions also accept the following tree hashing parameters:

- *fanout*: fanout (0 to 255, 0 if unlimited, 1 in sequential mode).
- *depth*: maximal depth of tree (1 to 255, 255 if unlimited, 1 in sequential mode).
- *leaf_size*: maximal byte length of leaf (0 to `2**32-1`, 0 if

unlimited or in sequential mode).
- *node_offset*: node offset (0 to `2**64-1` for BLAKE2b, 0 to `2**48-1` for BLAKE2s, 0 for the first, leftmost, leaf, or in sequential mode).
- *node_depth*: node depth (0 to 255, 0 for leaves, or in sequential mode).
- *inner_size*: inner digest size (0 to 64 for BLAKE2b, 0 to 32 for BLAKE2s, 0 in sequential mode).
- *last_node*: boolean indicating whether the processed node is the last one (`False` for sequential mode).

See section 2.10 in BLAKE2 specification [https://blake2.net/blake2_20130129.pdf] for comprehensive review of tree hashing.

Constants

blake2b.SALT_SIZE

blake2s.SALT_SIZE

Salt length (maximum length accepted by constructors).

blake2b.PERSON_SIZE

blake2s.PERSON_SIZE

Personalization string length (maximum length accepted by constructors).

blake2b.MAX_KEY_SIZE

blake2s.MAX_KEY_SIZE

Maximum key size.

blake2b.MAX_DIGEST_SIZE

blake2s.MAX_DIGEST_SIZE

Maximum digest size that the hash function can output.

Examples

Simple hashing

To calculate hash of some data, you should first construct a hash object by calling the appropriate constructor function (**`blake2b()`** or **`blake2s()`**), then update it with the data by calling **`update()`** on the object, and, finally, get the digest out of the object by calling **`digest()`** (or **`hexdigest()`** for hex-encoded string).

```
>>> from hashlib import blake2b
>>> h = blake2b()
>>> h.update(b'Hello world')
>>> h.hexdigest()
'6ff843ba685842aa82031d3f53c48b66326df7639a63d128974c5c1
```

As a shortcut, you can pass the first chunk of data to update directly to the constructor as the positional argument:

```
>>> from hashlib import blake2b
>>> blake2b(b'Hello world').hexdigest()
'6ff843ba685842aa82031d3f53c48b66326df7639a63d128974c5c1
```

You can call **`hash.update()`** as many times as you need to iteratively update the hash:

```
>>> from hashlib import blake2b
>>> items = [b'Hello', b' ', b'world']
>>> h = blake2b()
>>> for item in items:
...     h.update(item)
>>> h.hexdigest()
'6ff843ba685842aa82031d3f53c48b66326df7639a63d128974c5c1
```

Using different digest sizes

BLAKE2 has configurable size of digests up to 64 bytes for BLAKE2b and up to 32 bytes for BLAKE2s. For example, to replace SHA-1

with BLAKE2b without changing the size of output, we can tell BLAKE2b to produce 20-byte digests:

```
>>> from hashlib import blake2b
>>> h = blake2b(digest_size=20)
>>> h.update(b'Replacing SHA1 with the more secure funct
>>> h.hexdigest()
'd24f26cf8de66472d58d4e1b1774b4c9158b1f4c'
>>> h.digest_size
20
>>> len(h.digest())
20
```

Hash objects with different digest sizes have completely different outputs (shorter hashes are *not* prefixes of longer hashes); BLAKE2b and BLAKE2s produce different outputs even if the output length is the same:

```
>>> from hashlib import blake2b, blake2s
>>> blake2b(digest_size=10).hexdigest()
'6fa1d8fcfd719046d762'
>>> blake2b(digest_size=11).hexdigest()
'eb6ec15daf9546254f0809'
>>> blake2s(digest_size=10).hexdigest()
'1bf21a98c78a1c376ae9'
>>> blake2s(digest_size=11).hexdigest()
'567004bf96e4a25773ebf4'
```

Keyed hashing

Keyed hashing can be used for authentication as a faster and simpler replacement for Hash-based message authentication code [https://en.wikipedia.org/wiki/HMAC] (HMAC). BLAKE2 can be securely used in prefix-MAC mode thanks to the indifferentiability property inherited from BLAKE.

This example shows how to get a (hex-encoded) 128-bit authentication code for message `b'message data'` with key `b'pseudorandom key'`:

```
>>> from hashlib import blake2b
>>> h = blake2b(key=b'pseudorandom key', digest_size=16)
>>> h.update(b'message data')
>>> h.hexdigest()
'3d363ff7401e02026f4a4687d4863ced'
```

As a practical example, a web application can symmetrically sign cookies sent to users and later verify them to make sure they weren't tampered with:

```
>>> from hashlib import blake2b
>>> from hmac import compare_digest
>>>
>>> SECRET_KEY = b'pseudorandomly generated server secre
>>> AUTH_SIZE = 16
>>>
>>> def sign(cookie):
...     h = blake2b(digest_size=AUTH_SIZE, key=SECRET_KE
...     h.update(cookie)
...     return h.hexdigest().encode('utf-8')
>>>
>>> def verify(cookie, sig):
...     good_sig = sign(cookie)
...     return compare_digest(good_sig, sig)
>>>
>>> cookie = b'user-alice'
>>> sig = sign(cookie)
>>> print("{0},{1}".format(cookie.decode('utf-8'), sig))
user-alice,b'43b3c982cf697e0c5ab22172d1ca7421'
>>> verify(cookie, sig)
True
>>> verify(b'user-bob', sig)
False
>>> verify(cookie, b'0102030405060708090a0b0c0d0e0f00')
False
```

Even though there's a native keyed hashing mode, BLAKE2 can, of course, be used in HMAC construction with **`hmac`** module:

```
>>> import hmac, hashlib
>>> m = hmac.new(b'secret key', digestmod=hashlib.blake2
>>> m.update(b'message')
>>> m.hexdigest()
'e3c8102868d28b5ff85fc35dda07329970d1a01e273c37481326fe0
```

Randomized hashing

By setting *salt* parameter users can introduce randomization to the hash function. Randomized hashing is useful for protecting against collision attacks on the hash function used in digital signatures.

> Randomized hashing is designed for situations where one party, the message preparer, generates all or part of a message to be signed by a second party, the message signer. If the message preparer is able to find cryptographic hash function collisions (i.e., two messages producing the same hash value), then they might prepare meaningful versions of the message that would produce the same hash value and digital signature, but with different results (e.g., transferring $1,000,000 to an account, rather than $10). Cryptographic hash functions have been designed with collision resistance as a major goal, but the current concentration on attacking cryptographic hash functions may result in a given cryptographic hash function providing less collision resistance than expected. Randomized hashing offers the signer additional protection by reducing the likelihood that a preparer can generate two or more messages that ultimately yield the same hash value during the digital signature generation process — even if it is practical to find collisions for the hash function. However, the use of randomized hashing may reduce the amount of security provided by a digital signature when all portions of the message are prepared by the signer.
>
> (NIST SP-800-106 “Randomized Hashing for Digital

Signatures" [https://csrc.nist.gov/publications/detail/sp/800-106/final])

In BLAKE2 the salt is processed as a one-time input to the hash function during initialization, rather than as an input to each compression function.

Warning

Salted hashing (or just hashing) with BLAKE2 or any other general-purpose cryptographic hash function, such as SHA-256, is not suitable for hashing passwords. See BLAKE2 FAQ [https://blake2.net/#qa] for more information.

```
>>> import os
>>> from hashlib import blake2b
>>> msg = b'some message'
>>> # Calculate the first hash with a random salt.
>>> salt1 = os.urandom(blake2b.SALT_SIZE)
>>> h1 = blake2b(salt=salt1)
>>> h1.update(msg)
>>> # Calculate the second hash with a different random
>>> salt2 = os.urandom(blake2b.SALT_SIZE)
>>> h2 = blake2b(salt=salt2)
>>> h2.update(msg)
>>> # The digests are different.
>>> h1.digest() != h2.digest()
True
```

Personalization

Sometimes it is useful to force hash function to produce different digests for the same input for different purposes. Quoting the authors of the Skein hash function:

> We recommend that all application designers seriously consider doing this; we have seen many protocols where a hash that is computed in one part of the protocol can be used in an entirely

> different part because two hash computations were done on similar or related data, and the attacker can force the application to make the hash inputs the same. Personalizing each hash function used in the protocol summarily stops this type of attack.
>
> (The Skein Hash Function Family [https://www.schneier.com/wp-content/uploads/2016/02/skein.pdf], p. 21)

BLAKE2 can be personalized by passing bytes to the *person* argument:

```
>>> from hashlib import blake2b
>>> FILES_HASH_PERSON = b'MyApp Files Hash'
>>> BLOCK_HASH_PERSON = b'MyApp Block Hash'
>>> h = blake2b(digest_size=32, person=FILES_HASH_PERSON
>>> h.update(b'the same content')
>>> h.hexdigest()
'20d9cd024d4fb086aae819a1432dd2466de12947831b75c5a30cf26
>>> h = blake2b(digest_size=32, person=BLOCK_HASH_PERSON
>>> h.update(b'the same content')
>>> h.hexdigest()
'cf68fb5761b9c44e7878bfb2c4c9aea52264a80b75005e65619778c
```

Personalization together with the keyed mode can also be used to derive different keys from a single one.

```
>>> from hashlib import blake2s
>>> from base64 import b64decode, b64encode
>>> orig_key = b64decode(b'Rm5EPJai72qcK3RGBpW3vPNfZy5OZ
>>> enc_key = blake2s(key=orig_key, person=b'kEncrypt').
>>> mac_key = blake2s(key=orig_key, person=b'kMAC').dige
>>> print(b64encode(enc_key).decode('utf-8'))
rbPb15S/Z9t+agffno5wuhB77VbRi6F9Iv2qIxU7WHw=
>>> print(b64encode(mac_key).decode('utf-8'))
G9GtHFE1YluXY1zWPlYk1e/nWfu0WSEb0KRcjhDeP/o=
```

Tree mode

Here's an example of hashing a minimal tree with two leaf nodes:

```
  10
 /  \
00  01
```

This example uses 64-byte internal digests, and returns the 32-byte final digest:

```
>>> from hashlib import blake2b
>>>
>>> FANOUT = 2
>>> DEPTH = 2
>>> LEAF_SIZE = 4096
>>> INNER_SIZE = 64
>>>
>>> buf = bytearray(6000)
>>>
>>> # Left leaf
... h00 = blake2b(buf[0:LEAF_SIZE], fanout=FANOUT, depth
...               leaf_size=LEAF_SIZE, inner_size=INNER_
...               node_offset=0, node_depth=0, last_node
>>> # Right leaf
... h01 = blake2b(buf[LEAF_SIZE:], fanout=FANOUT, depth=
...               leaf_size=LEAF_SIZE, inner_size=INNER_
...               node_offset=1, node_depth=0, last_node
>>> # Root node
... h10 = blake2b(digest_size=32, fanout=FANOUT, depth=D
...               leaf_size=LEAF_SIZE, inner_size=INNER_
...               node_offset=0, node_depth=1, last_node
>>> h10.update(h00.digest())
>>> h10.update(h01.digest())
>>> h10.hexdigest()
'3ad2a9b37c6070e374c7a8c508fe20ca86b6ed54e286e93a0318e95
```

`hmac` — Keyed-Hashing for Message Authentication

Source code: Lib/hmac.py [https://github.com/python/cpython/tree/3.11/Lib/hmac.py]

This module implements the HMAC algorithm as described by **RFC 2104** [https://datatracker.ietf.org/doc/html/rfc2104.html].

hmac.new(*key*, *msg=None*, *digestmod=''*)

Return a new hmac object. *key* is a bytes or bytearray object giving the secret key. If *msg* is present, the method call `update(msg)` is made. *digestmod* is the digest name, digest constructor or module for the HMAC object to use. It may be any name suitable to **`hashlib.new()`**. Despite its argument position, it is required.

Changed in version 3.4: Parameter *key* can be a bytes or bytearray object. Parameter *msg* can be of any type supported by **`hashlib`**. Parameter *digestmod* can be the name of a hash algorithm.

Deprecated since version 3.4, removed in version 3.8: MD5 as implicit default digest for *digestmod* is deprecated. The digestmod parameter is now required. Pass it as a keyword argument to avoid awkwardness when you do not have an initial msg.

hmac.digest(*key*, *msg*, *digest*)

Return digest of *msg* for given secret *key* and *digest*. The function is equivalent to `HMAC(key, msg, digest).digest()`, but uses an optimized C or inline implementation, which is faster for messages that fit into memory. The parameters *key*, *msg*, and *digest* have the same

meaning as in **new()**.

CPython implementation detail, the optimized C implementation is only used when *digest* is a string and name of a digest algorithm, which is supported by OpenSSL.

New in version 3.7.

An HMAC object has the following methods:

HMAC.update(*msg*)

Update the hmac object with *msg*. Repeated calls are equivalent to a single call with the concatenation of all the arguments: `m.update(a); m.update(b)` is equivalent to `m.update(a + b)`.

Changed in version 3.4: Parameter *msg* can be of any type supported by **hashlib**.

HMAC.digest()

Return the digest of the bytes passed to the **update()** method so far. This bytes object will be the same length as the *digest_size* of the digest given to the constructor. It may contain non-ASCII bytes, including NUL bytes.

Warning

When comparing the output of **digest()** to an externally supplied digest during a verification routine, it is recommended to use the **compare_digest()** function instead of the == operator to reduce the vulnerability to timing attacks.

HMAC.hexdigest()

Like **digest()** except the digest is returned as a string twice the length containing only hexadecimal digits. This may be used to exchange the value safely in email or other non-binary environments.

Warning

When comparing the output of `hexdigest()` to an externally supplied digest during a verification routine, it is recommended to use the `compare_digest()` function instead of the == operator to reduce the vulnerability to timing attacks.

HMAC.copy()

Return a copy ("clone") of the hmac object. This can be used to efficiently compute the digests of strings that share a common initial substring.

A hash object has the following attributes:

HMAC.digest_size

The size of the resulting HMAC digest in bytes.

HMAC.block_size

The internal block size of the hash algorithm in bytes.

New in version 3.4.

HMAC.name

The canonical name of this HMAC, always lowercase, e.g. `hmac-md5`.

New in version 3.4.

Deprecated since version 3.9: The undocumented attributes `HMAC.digest_cons`, `HMAC.inner`, and `HMAC.outer` are internal implementation details and will be removed in Python 3.10.

This module also provides the following helper function:

hmac.compare_digest(*a*, *b*)

Return `a == b`. This function uses an approach designed to prevent timing analysis by avoiding content-based short circuiting behaviour, making it appropriate for cryptography. *a* and *b* must both be of the same type: either **`str`** (ASCII only, as e.g. returned by **`HMAC.hexdigest()`**), or a bytes-like object.

Note

If *a* and *b* are of different lengths, or if an error occurs, a timing attack could theoretically reveal information about the types and lengths of *a* and *b*—but not their values.

New in version 3.3.

Changed in version 3.10: The function uses OpenSSL's `CRYPTO_memcmp()` internally when available.

Module `hashlib`
The Python module providing secure hash functions.

`secrets` — Generate secure random numbers for managing secrets

New in version 3.6.

Source code: Lib/secrets.py [https://github.com/python/cpython/tree/3.11/Lib/secrets.py]

The `secrets` module is used for generating cryptographically strong random numbers suitable for managing data such as passwords, account authentication, security tokens, and related secrets.

In particular, `secrets` should be used in preference to the default pseudo-random number generator in the `random` module, which is designed for modelling and simulation, not security or cryptography.

Random numbers

The `secrets` module provides access to the most secure source of randomness that your operating system provides.

class secrets.SystemRandom

A class for generating random numbers using the highest-quality sources provided by the operating system. See `random.SystemRandom` for additional details.

secrets.choice(*sequence*)

Return a randomly chosen element from a non-empty sequence.

secrets.randbelow(*n*)

Return a random int in the range [0, *n*).

secrets.randbits(*k*)

Return an int with *k* random bits.

Generating tokens

The **secrets** module provides functions for generating secure tokens, suitable for applications such as password resets, hard-to-guess URLs, and similar.

secrets.token_bytes([*nbytes=None*])

Return a random byte string containing *nbytes* number of bytes. If *nbytes* is `None` or not supplied, a reasonable default is used.

```
>>> token_bytes(16)
b'\xebr\x17D*t\xae\xd4\xe3S\xb6\xe2\xebP1\x8b'
```

secrets.token_hex([*nbytes=None*])

Return a random text string, in hexadecimal. The string has *nbytes* random bytes, each byte converted to two hex digits. If *nbytes* is `None` or not supplied, a reasonable default is used.

```
>>> token_hex(16)
'f9bf78b9a18ce6d46a0cd2b0b86df9da'
```

secrets.token_urlsafe([*nbytes=None*])

Return a random URL-safe text string, containing *nbytes* random bytes. The text is Base64 encoded, so on average each byte results in approximately 1.3 characters. If *nbytes* is `None`

or not supplied, a reasonable default is used.

```
>>> token_urlsafe(16)
'Drmhze6EPcv0fN_81Bj-nA'
```

How many bytes should tokens use?

To be secure against brute-force attacks [https://en.wikipedia.org/wiki/Brute-force_attack], tokens need to have sufficient randomness. Unfortunately, what is considered sufficient will necessarily increase as computers get more powerful and able to make more guesses in a shorter period. As of 2015, it is believed that 32 bytes (256 bits) of randomness is sufficient for the typical use-case expected for the **`secrets`** module.

For those who want to manage their own token length, you can explicitly specify how much randomness is used for tokens by giving an **`int`** argument to the various `token_*` functions. That argument is taken as the number of bytes of randomness to use.

Otherwise, if no argument is provided, or if the argument is `None`, the `token_*` functions will use a reasonable default instead.

Note

That default is subject to change at any time, including during maintenance releases.

Other functions

secrets.compare_digest(*a*, *b*)

Return `True` if strings or bytes-like objects *a* and *b* are equal, otherwise `False`, using a "constant-time compare" to reduce the risk of timing attacks [https://codahale.com/a-lesson-in-timing-attacks/]. See **`hmac.compare_digest()`** for additional details.

Recipes and best practices

This section shows recipes and best practices for using **`secrets`** to manage a basic level of security.

Generate an eight-character alphanumeric password:

```
import string
import secrets
alphabet = string.ascii_letters + string.digits
password = ''.join(secrets.choice(alphabet) for i in ran
```

Note

Applications should not store passwords in a recoverable format [https://cwe.mitre.org/data/definitions/257.html], whether plain text or encrypted. They should be salted and hashed using a cryptographically strong one-way (irreversible) hash function.

Generate a ten-character alphanumeric password with at least one lowercase character, at least one uppercase character, and at least three digits:

```
import string
import secrets
alphabet = string.ascii_letters + string.digits
while True:
    password = ''.join(secrets.choice(alphabet) for i in
    if (any(c.islower() for c in password)
            and any(c.isupper() for c in password)
            and sum(c.isdigit() for c in password) >= 3)
        break
```

Generate an XKCD-style passphrase [https://xkcd.com/936/]:

```
import secrets
# On standard Linux systems, use a convenient dictionary
# Other platforms may need to provide their own word-lis
with open('/usr/share/dict/words') as f:
    words = [word.strip() for word in f]
    password = ' '.join(secrets.choice(words) for i in r
```

Generate a hard-to-guess temporary URL containing a security token suitable for password recovery applications:

```
import secrets
url = 'https://example.com/reset=' + secrets.token_urlsa
```

Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modeled after the Unix or C interfaces, but they are available on most other systems as well. Here's an overview:

- `os` — Miscellaneous operating system interfaces
  - File Names, Command Line Arguments, and Environment Variables
  - Python UTF-8 Mode
  - Process Parameters
  - File Object Creation
  - File Descriptor Operations
    - Querying the size of a terminal
    - Inheritance of File Descriptors
  - Files and Directories
    - Linux extended attributes
  - Process Management
  - Interface to the scheduler
  - Miscellaneous System Information
  - Random numbers
- `io` — Core tools for working with streams
  - Overview
    - Text I/O
    - Binary I/O

        - Raw I/O
    - Text Encoding
        - Opt-in EncodingWarning
    - High-level Module Interface
    - Class hierarchy
        - I/O Base Classes
        - Raw File I/O
        - Buffered Streams
        - Text I/O
    - Performance
        - Binary I/O
        - Text I/O
        - Multi-threading
        - Reentrancy
- **`time`** — Time access and conversions
    - Functions
    - Clock ID Constants
    - Timezone Constants
- **`argparse`** — Parser for command-line options, arguments and sub-commands
    - Core Functionality
    - Quick Links for add_argument()
    - Example
        - Creating a parser
        - Adding arguments
        - Parsing arguments
    - ArgumentParser objects
        - prog
        - usage

- description
- epilog
- parents
- formatter_class
- prefix_chars
- fromfile_prefix_chars
- argument_default
- allow_abbrev
- conflict_handler
- add_help
- exit_on_error

- The add_argument() method
  - name or flags
  - action
  - nargs
  - const
  - default
  - type
  - choices
  - required
  - help
  - metavar
  - dest
  - Action classes
- The parse_args() method
  - Option value syntax
  - Invalid arguments
  - Arguments containing `-`
  - Argument abbreviations (prefix matching)
  - Beyond `sys.argv`
  - The Namespace object
- Other utilities
  - Sub-commands
  - FileType objects
  - Argument groups

        - Mutual exclusion
        - Parser defaults
        - Printing help
        - Partial parsing
        - Customizing file parsing
        - Exiting methods
        - Intermixed parsing

    - Upgrading optparse code

- **getopt** — C-style parser for command line options
- **logging** — Logging facility for Python

    - Logger Objects
    - Logging Levels
    - Handler Objects
    - Formatter Objects
    - Filter Objects
    - LogRecord Objects
    - LogRecord attributes
    - LoggerAdapter Objects
    - Thread Safety
    - Module-Level Functions
    - Module-Level Attributes
    - Integration with the warnings module

- **logging.config** — Logging configuration

    - Configuration functions
    - Security considerations
    - Configuration dictionary schema

        - Dictionary Schema Details
        - Incremental Configuration
        - Object connections
        - User-defined objects
        - Access to external objects
        - Access to internal objects
        - Import resolution and custom importers

    - Configuration file format

- **logging.handlers** — Logging handlers
  - StreamHandler
  - FileHandler
  - NullHandler
  - WatchedFileHandler
  - BaseRotatingHandler
  - RotatingFileHandler
  - TimedRotatingFileHandler
  - SocketHandler
  - DatagramHandler
  - SysLogHandler
  - NTEventLogHandler
  - SMTPHandler
  - MemoryHandler
  - HTTPHandler
  - QueueHandler
  - QueueListener
- **getpass** — Portable password input
- **curses** — Terminal handling for character-cell displays
  - Functions
  - Window Objects
  - Constants
- **curses.textpad** — Text input widget for curses programs
  - Textbox objects
- **curses.ascii** — Utilities for ASCII characters
- **curses.panel** — A panel stack extension for curses
  - Functions
  - Panel Objects
- **platform** — Access to underlying platform's identifying data
  - Cross Platform
  - Java Platform
  - Windows Platform

    - macOS Platform
    - Unix Platforms
    - Linux Platforms

- **errno** — Standard errno system symbols
- **ctypes** — A foreign function library for Python

    - ctypes tutorial

`os` — Miscellaneous operating system interfaces

Source code: Lib/os.py [https://github.com/python/cpython/tree/3.11/Lib/os.py]

This module provides a portable way of using operating system dependent functionality. If you just want to read or write a file see `open()`, if you want to manipulate paths, see the `os.path` module, and if you want to read all the lines in all the files on the command line see the `fileinput` module. For creating temporary files and directories see the `tempfile` module, and for high-level file and directory handling see the `shutil` module.

Notes on the availability of these functions:

- The design of all built-in operating system dependent modules of Python is such that as long as the same functionality is available, it uses the same interface; for example, the function `os.stat(path)` returns stat information about *path* in the same format (which happens to have originated with the POSIX interface).
- Extensions peculiar to a particular operating system are also available through the `os` module, but using them is of course a threat to portability.
- All functions accepting path or file names accept both bytes and string objects, and result in an object of the same type, if a path or file name is returned.
- On VxWorks, os.popen, os.fork, os.execv and os.spawn*p* are not supported.
- On WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`, large parts of the `os` module are not available or behave differently. API related to processes (e.g. `fork()`, `execve()`), signals (e.g. `kill()`, `wait()`), and resources (e.g. `nice()`) are not available. Others like

getuid() and **getpid()** are emulated or stubs.

Note

All functions in this module raise **OSError** (or subclasses thereof) in the case of invalid or inaccessible file names and paths, or other arguments that have the correct type, but are not accepted by the operating system.

exception os.error

An alias for the built-in **OSError** exception.

os.name

The name of the operating system dependent module imported. The following names have currently been registered: `'posix'`, `'nt'`, `'java'`.

See also

sys.platform has a finer granularity. **os.uname()** gives system-dependent version information.

The **platform** module provides detailed checks for the system's identity.
